Except for the Broadway theater, the professional performing arts are collecting much less in admissions than they are paying out in operating costs. The "income gap" ranges from an average of 15 per cent of expenditures of regional theaters to 46 per cent for 25 major orchestras. The total gap in 1963-64 is estimated at \$20 million to \$23 million, not including outlays for new buildings. Baumol and Bowen expect the gap to widen as costs continue to rise faster than ticket prices.

Up to now the income gap has been filled mainly by private contributions with only minor direct assistance from government. The question arises whether philanthropy will be adequate in the future or whether local, state, and federal governments should substantially increase support of the performing arts. Baumol and Bowen are formally neutral on government support but appear to be sympathetic.

Four general or external benefits which may justify government support of the performing arts are mentioned: (1) national prestige; (2) indirect benefits to other business such as restaurants, hotels, and shops; (3) maintenance of the arts for the enjoyment of future generations; and (4) educational contribution. National prestige may seem a nebulous or unworthy consid-

eration, but as the authors remind us it has figured in many government decisions, including the expenditure of billions for space exploration. The educational argument is basically that exposure to live performances is necessary to develop taste and a high quality of civilization. The second argument mentioned above—the indirect benefits to other businesses—seems to me fallacious, since there is no indication that these benefits are peculiar to the arts or that they should be paid for by taxpayers rather than the business beneficiaries. Nor can I see that the future-generations argument is an independent one.

Granted that there are general benefits, it seems clear that the major benefits accrue to the audience. The government is already providing substantial indirect assistance to the noncommercial performing arts organizations in the form of tax exemptions and tax deductions for contributions. To the extent that government contributions exceed general benefits, an elite will be subsidized by taxpayers who are on the average poorer and less well educated. If subsidies follow the present distribution of artistic performances, they will be concentrated along the East and West Coasts, especially in New York City. In view of the speculative nature of all appraisals of general benefits, the lines appear to be drawn for a long and vigorous debate.

RICHARD GOODE

International Monetary Fund

The British Monopolies Commission. By CHARLES K. ROWLEY. London: George Allen & Unwin Ltd., 1966. Pp. 394. 50s.

An economist assigned the task of designing the "hereafter" would probably specify nothing but linear relationships as well as an identity relationship between *ex ante* and *ex post*. In "this best of all worlds" making and evaluating public policy would be more precise than it is in the "here and now," where relationships between variables, if known at all, are extremely complex. The *ex ante* concepts of the economist do not match the *ex post* data available to the administrative or judicial agency. Thus the concepts of the former yield limited insight into the problems of the latter. While there would be no need for such a book in the world which was so briefly described above, this book surveying the performance of the British Monopolies Commission is a needed and valuable addition to the literature.

The economist dealing with problems of industrial organization is seldom able to state, with precision, the relationship between structure, on one hand, and performance and/or behavior on the other; however, it is generally agreed that there is some relationship. The individuals or agencies charged with shaping and enforcing public policy in this area are neither able nor willing to wait for the day when the economist is able to establish the relationships to the satisfaction of all. Instead, policy must be determined and enforced on the basis of some rather vague assumptions as to the basis and nature of the relationship between industry structure and industry behavior and/or performance.

In the United States, the Antitrust Division, the FTC, the courts, and other

regulatory commissions all attempt to influence industry behavior and performance by using industry structure as the independent variable. In Great Britain, the Monopolies Commission and the Restrictive Practices Court function on the basis of the same premise. The work being reviewed is a rather detailed report on one such agency—the Monopolies Commission, and, as such, is a valuable companion to *The Restrictive Practices Court* by R. B. Stevens and B. S. Yamey (London, 1965). The two give the reader a rather exhaustive picture of the practices, problems, and results of these two agencies charged with the supervision of much of British industry.

In the present work, the author commences with the history of the government's attempts to deal with the dominant firm including its international trade policy and the contribution of the common law. He moves on, in the second part, to a detailed discussion of the structure of the Commission and its method of operation. The actual inquiries of the Commission are explored in the third and fourth parts of the book and are divided into trade association inquiries and dominant firm inquiries. The last three sections of the book discuss, in turn, statistical measures of economic performance, economic consequences of government action, and final conclusions and recommendations. This approach permits both the author and reader to examine the economic aspects of public policy. This is, to the reviewer, at least, a much more interesting and significant problem than is the investigation of the administrative problems of regulation.

Of the various issues raised relating economic analysis to the problems of public policy, the discussion of costs and prices was most interesting. The Commission has devoted considerable effort to the relationship between the two in its investigation, but the author still found significant shortcomings in their efforts. He may have been unduly critical of the Commission for there are several problems for which the Monopolies Commission is not responsible and about which it can do little.

First, there is the conceptual problem in economic analysis. In the *ex ante* world of economic theory, the relationship between cost and price at the time of the investment decision is well known and rather precisely defined. But there is no reason to believe that the same relationship should be found in contemporary company records. Second, there is the problem of accounting—particularly the accounting associated with joint products. Accountants generally assign joint or overhead costs on the basis of direct costs of one type or another. But a firm would be rational to assign such costs on the basis of what the products will bear. For example, a firm producing two products one of which is sold in a highly competitive market and the second in a market dominated by a price-fixing ring would be expected to assign a disproportionate share of the overhead and joint costs to the latter. Third, there is the difficulty inherent in the inaccuracy of the accounting process itself. The regulatory agency which examines cost and price data of the investigated firm may well find figures which were computed with the taxing agency in mind rather than an agency with the responsibility of determining the optimal degree of competition. Faced with these problems, then, one should not be surprised that the regulatory agencies have had considerable difficulty in determining the ap-

propriate cost-price relationship. In fact, one might be justified in expressing some amazement at that which has been accomplished.

The basic question raised in this book, along with other studies of regulatory commissions, is whether such a public agency can, with any confidence of success, act in such a way as to move the industrial structure toward some optimal state of social organization. Is it possible, furthermore, to define an objective function for society in such a way as to indicate what structural adjustments are needed in order to move that society to (not just toward) that optimal state? Further, given the current state of economics, is it possible for such an agency to compare the current and proposed industrial structure with all possible structures? The best that can probably be achieved is to compare the existing structure with one or two alternatives—that is, engage in only local search.

Because of the nature of the work of such agencies, economists can find a great deal to criticize. The author in his discussion of the analytical level of economic analysis criticizes the Commission for its analysis of resale price agreements, economies of scale, impact of advertising, and many other aspects of the Commission's investigatory activities. On a more practical or applied level, the Commission is criticized because there is no effective method of following up and assessing consequences of decision, enforcement is inadequate, and it has had varying degrees of support from the party in power. In sum, one gets the picture that the particular method of approaching the problem of industrial structure has considerable merit, but, in practice, the implementation of policy has been far from satisfactory. The recommendations of the author are directed, for the most part, toward making that implementation more effective. He seems to be convinced that this is possible.

JOHN M. KUHLMAN

University of Missouri

Atti della Commissione Parlamentare di Inchiesta sui Limiti Positi alla Concorrenza nel Campo Economico. Camera dei Deputati, Pols. 1-9. Roma: Servizio Studi Legislazione e Inchiesta Parlamentari, 1965. Pp. 3382. L 35.000.

This nine-volume Parliamentary Report on Competition is filled with interesting and valuable material on the structure of the Italian economy, its degree of concentration, and the principal forms of restriction on competition. The study was initiated in Parliament on April 19, 1961, and was designed to serve as a basis for antitrust legislation in Italy. Its completion had the active support of the Center-Left government (Christian Democrats and moderate wing Socialists).

The stated purposes of the inquiry were to ascertain the principal restrictions on competition; to examine the immediate causes of the restrictions; to evaluate the effects of the restrictions on economic development; and to suggest measures to eliminate the causes and effects of business restrictions. The Center-Left sponsors of the study, as well as of the proposed antitrust bill, have taken an interest in competition to improve the market mechanism and to bring business rules in Italy in harmony with those of the Common Market.

They do not support economic competition as a basis for economic and political freedom in accordance with American tradition and doctrine.

In the past, studies on cartels and business restraints in Italy have been made mostly by Communist groups to condemn the present system, not to provide a basis for public policy. With the present study, however, Parliamentary leadership for the first time declared that "antimonopoly law" is a proper instrument for the state to use in the economic field. This represents a significant change in public policy in Italy.

The Report emphasizes that the study is in an important way a *pioneer* investigation, for in Italy there has been no tradition of making industry studies, studies on business restrictions and cartels, either in the universities or by governmental bureaus. The Parliamentary inquiry was limited by the fact that many knowledgeable persons—in the universities and in business—were not willing to participate in the inquiry. Questionnaire returns from labor and business were very few, very poor, and of little use. A further limitation was the fact that in Italy there is no legislation or formal control over business agreements, so that evidence on the probable existence of restrictions was not available. Despite these limitations, the Parliamentary inquiry developed in the nine volumes a substantial amount of information on restraints in the Italian economy.

In its investigation, the Parliamentary committee arranged with experts for the making of some 30 monographic studies on the Italian economy. Eight of the monographs are included in the nine volume report. They cover (1) Industrial Concentration, (2) Patents, (3) Insurance, (4) Sugar, (5) Pulp and Paper, (6) Fertilizer and Insecticides, (7) Commercial Credit, and (8) Public Contracts with Private Firms.

The volume on Industrial Concentration will be of special interest to U.S. economists not only for the data presented but also for the statistical methods used. Industries covered include sugar, matches, cast iron, iron alloys, steel, aluminum, lead zinc, automobiles, typewriters, artificial fibers, bottled gas, and electricity. Industrial concentration has been an historical fact in Italy because of the small domestic market, long-existing financial concentration, and the policy of autarchy followed between the two wars. Industrial concentration, the report states, has not increased greatly during the past 25 years. Since World War II, the large companies have expanded mainly by entering other fields. The large companies, it is observed, have advantages in obtaining credit and in lower interest costs.

Concentration in Italy, as in the United States, has promoted unified selling. In a few areas, such as motorcycles, typewriters, and calculating machines, price competition does exist although sellers are few. In general, however, the report concludes that concentration has promoted unified selling, usually through the use of basing-point methods of pricing, managed and administered by gentlemen's agreements or cartel arrangements.

It is significant to note that the economies of the United States and of Italy are both characterized (1) by substantial firm concentration in the basic manufacturing industries; and (2) by unified selling with use of basing-point methods of pricing. Italy has no antitrust law and no antitrust action; the

United States has a complement of antitrust legislation and fairly active antitrust enforcement. Industrial concentration and geographical separation of firms and plants, however, have given rise to the common use of basing-point pricing and unified selling, regardless of antitrust.

Much material for the Parliamentary study was secured from questionnaires given to Italian professors of economics and law, as well as to various scholars abroad. In the main, the questionnaires asked for (1) copies of studies or research already done on markets and business restrictions; (2) suggestions on the main areas for study; (3) information on the most frequent forms of restrictions on competition; and (4) remedies for economic policy.

According to the Italian professors of economics, the principal sectors in Italy having restrictions on competition are the electrical industry, chemicals, cement, industrial machinery, sugar, and steel. The forms of restriction thought to be most frequently used are public regulation, particularly licenses and concessions (as in public transport), cartels or ententes, financial concentration, concerted practices (gentlemen's agreements, tacit understandings), integration, mergers, and abuse of economic power (price incursions). Although there is no formal law in Italy against *cartels* (written agreements on price and output enforceable by the civil law), such agreements are not generally openly practiced, because the Communist-dominated CGIL union members are likely to detect such agreements and use them "to make scandal" in Parliament. Thus, evidence in the report on specific cartels, as well as on gentlemen's agreements, reflects only the opinions of those answering the questionnaires.

According to the questionnaire replies, the restrictions on competition manifest themselves in unified price policy (as illustrated by basing-point pricing in cement and sugar), restrictions on entry, distortions on the use of resources, limitations on production, and limitations on investment. To secure further evidence on restrictions, the economists recommended studies on price and costs, the composition of boards of directors of corporations, corporation financial records, stock exchange transactions and prices, bookkeeping methods, a study of ownership concentration in the largest companies, mergers, and interties of foreign investments.

As remedies for restrictions on competition, the professors of economics recommended the further creation and use of public enterprise in competition. At the present time, state-owned enterprises exist in numerous, traditionally private sectors. Such enterprises account, for example, for 55 per cent of steel production, 13.5 per cent of cement, and 25 percent of petroleum distribution activities. The economists also suggested further nationalization programs. In 1962 the entire electric power and light industry—some 462 companies—was nationalized, except for a few municipal systems and industrial self-suppliers. Nationalization has also been proposed for the cement industry. It is estimated that approximately 40 per cent of all industrial output in Italy comes from state-owned firms and the nationalized sectors.

In Italy, public enterprises (government firms) have been used mainly to assist in developing an industry (airlines and shipping), to increase capacity as in steel, or to provide essential services as telephone and electricity at low

prices and rates, rather than to fight monopoly. In the case of cement, public investment reportedly did "disturb the equilibrium." However, presently, the general rule is that government firms "meet" the prices of other firms.

Further remedial measures suggested by the Italian economists are the enactment of antimonopoly legislation, the reform of corporate statutes creating and regulating share companies, an improved fiscal and monetary policy, and the continued and further use of direct price control.

At the present time, maximum price control is exercised by the Comitato Interministeriale dei Prezzi (CIP) for such products as cement, coal, lime, glass and various chemicals, grain, rice, sugar beets, sugar and molasses, electric energy, gas telephone service, hotels and pensions. Direct price control was adopted as a wartime measure. It has been continued to date, however, despite efforts of the controlled industries to repeal the legislation. With the strong influence of the Italian labor unions on government, repeal does not seem likely. In the price control program, prices are fixed on the basis of the high cost producers; and the efficient producers do not find "control" too burdensome.

The study on competition led to the introduction in Parliament, on September 2, 1964, of a bill Safeguarding Freedom of Competition. The bill provides for the condemnation of all agreements which fix prices, limit or control production, or allocate markets. This prohibition, however, the bill provides, may be declared inapplicable with respect to agreements which are found to improve production or distribution, promote scientific research, technical or economic progress, or which increase the level of employment. Dominant enterprises are forbidden to control the market in such a way as to impose unwarranted burdens or restrictions on consumers, customers, or suppliers. A dominant firm is considered to be one not subjected "to an efficient domestic-market competition." In essence, the bill parallels the antitrust provisions of Articles 85 and 86 of the Treaty of Rome (1958) applicable to interstate commerce in the Common Market. Sponsors of the bill believe that the Center-Left government will adopt an antitrust measure during 1967.

The planned antitrust law for Italy will undoubtedly serve to eliminate or modify traditional cartel agreements and provide a legal basis for regulating the conduct of dominant firms. The established pattern of concentration, however, will continue; and business firms will increasingly turn to mergers in place of cartels, business leaders report. Some cartel agreements will undoubtedly be authorized—as in the Common Market. There will still remain, moreover, the underlying problems of gentlemen's agreements and unified selling when firms are few. Indeed, the Parliamentary study points out that in numerous Italian industries today unified selling is being practiced through price leadership (*prezzi guida*) and price following, as well as by tacit pacts to match or align prices. Dominant firms are able to impose their price leadership by the menace or threat of "price incursions."

Despite the antitrust provisions of the Treaties of Paris and Rome, the cartel practices of basing-point pricing and unified selling still prevail in the Common Market countries. There is every reason to believe that they will also be continued in Italy. The general approach of antitrust in Western Europe is

to modify somewhat the formal traditional cartel behavior of established firms. It is not designed to regulate competition, to provide for fair competition, or to curb predatory and discriminatory acts. The purpose of antitrust in Europe falls short of seeking to promote competitive, independent enterprise as a basis for economic and political freedom. A further significant weakness of antitrust in Western Europe is the absence of any provision providing for private enforcement by means of treble damage proceedings. Enforcement rests entirely with government.

A problem faced by the Italian government, indeed by all Western governments—including the United States—in their efforts to improve the market mechanism, is a determination of the kind of competition called for by public policy. At present, it appears that public policy is willing to accept as a norm the concept of sales-effort competition, with prices aligned by the basing-point formula and managed by price leadership. The alternative, long advocated by economists since John Bates Clark, of competition as open, aboveboard, non-discriminatory, independent price competition (never perfect) is yet to be accepted. Basic, too, is the need to determine that, if business structure cannot be, or is not to be, modified, regulation of conduct must be exercised to provide behavior analogous to that provided by market-type competition. Antitrust in Italy, Western Europe, Canada, and the United States faces a common need to meet common problems.

VERNON A. MUND

University of Washington

The New Economics of National Defense. By JOHN J. CLARK. New York: Random House, 1966. Pp. 242. \$4.95.

This book contains virtually no new material but is a summary of existing literature. Some of this literature is summarized quite well, but the discussion of more theoretical and analytical topics is rather unsatisfactory. For instance, it is asserted that price theory . . . "in its orthodox presentation has tended to assume that all relationships are *simultaneously* satisfied" (p. 9, my italics. What about Marshall's distinction between short run and long run? What about dynamic models?). Again, it is said that the use of the opportunity cost concept "carries inherently a degree of circular reasoning" (pp. 52-53)—a rather surprising statement. The section dealing with game theory is particularly confused.

United States Merchant Shipping Policies and Politics. By SAMUEL A. LAWRENCE. Washington: The Brookings Institution, 1966. Pp. xiii, 405. \$8.75.

This book is a worthy addition to the long list of publications of the Brookings Institution. It bears the usual characteristics of the published products of that venerable organization. It is carefully written. The research is meticulous. There is much evidence of the access to governmental sources of information enjoyed by scholars at Brookings. This was especially so for the author of this volume since, for at least three years during his career as an examiner in the Bureau of the Budget, he was assigned to "maritime problems."

Though some readers may be disappointed that Lawrence decided to direct his study "solely to consideration of U.S. government programs dealing with dry cargo shipping in foreign trade," most will agree that his decision was wise. A much longer book, filled with the kind of interesting, detailed data he assembled for this narrower report, would have been both exhausting and tedious for the reader.

Lawrence begins with a brief description of the merchant shipping industry, providing the usual kinds of information about its operations, structure, and regulation. This is followed by an account of the pre-World War II development of maritime policy into which he weaves observations on the political forces which helped to shape it.

After noting the all-too-familiar changes in the shipping industry—e.g., the growth of bulk cargo trade as compared with liner cargoes, the declining percentage of the total foreign trade of the United States lifted by vessels flying its flag, and the rising cost of replacing obsolete ships—Lawrence cites the military, commercial, and foreign economic policy developments which today affect the shipping industry.

Lawrence next turns to the administration of the Merchant Marine Act of 1936 since World War II. Not surprisingly, he states that considerations of national defense have provided the basic political support for the continued and increasing subsidies for shipping as provided in the Act. He also examines other types of support such as the variety of cargo preference schemes which set aside cargoes for American-flag vessels, and the registration of American-owned ships under "flags of convenience" (e.g., Panama, Honduras, Liberia) which enable shipowners to escape from certain costly requirements entailed in registering under the American flag while reserving these vessels for use by the United States during national emergencies.

In common with other students of maritime affairs, Lawrence concludes that the government program to support and develop a strong merchant fleet has not succeeded. He believes that the shortcomings of the program are the result of the government's yielding "too often to the industry's importunings for additional aid. In some instances, expediency has been substituted for prudent judgment in determining ways to meet alleged defense needs. In other cases, administrators of the maritime program have appeared to lose sight of its ultimate public purposes in their effort to be reasonably responsive to what the industry conceived to be its immediate need."

Strong words; and what does Lawrence propose? Three fact-filled chapters describing the complex machinery of government, the intricate web of interests involved in shipping, and the complicated relations between the government and the industry intervene before we are told. He then proposes, as the best of three choices, a program based upon "[a] subsidy program aimed at increasing the competitiveness of U.S. merchant shipping." It would be a "single comprehensive subsidy system covering all U.S. registered vessels in foreign trade" and would "be geared initially to supporting the current U.S. flag fleet."

The total subsidy to be distributed to all eligible shipowners would be a fixed sum. It would be allocated either through bidding by shipowners in ex-

change for performance of certain services or awarded "in proportion to net revenues earned during the year in foreign trade." Lawrence recognizes that there would be administrative difficulties under either method of distribution but believes these would be offset by the advantages of the competitive nature of both.

There are many other parts to Lawrence's proposal. Among them are relaxation of "buy American" provisions to allow U.S. ship operators to buy at least one-half their "supplies, maintenance, repairs, and other services . . . from foreign sources," and greater freedom to register vessels under foreign flags. He makes some very thoughtful recommendations for administering his proposed program—placing primary responsibility in the Department of Commerce "(or, if approved, the new Department of Transportation)" and assigning clear-cut roles to the Federal Maritime Administration, the Federal Maritime Board, the Department of Defense, and the Department of State.

To this admittedly jaundiced reviewer, much of what appears in Lawrence's fine book is not novel; nor is it probably meant to be. However, a substantial part of the book contains much that only an "insider" such as Lawrence could write about with such élan. The reader vividly senses the frustrating complexity of the federal government as Lawrence describes the forces and institutions at work. We can hope that his having made so clear the complicated political and administrative arrangements created in part by our maritime policies will provide additional stimulation to encourage serious consideration of his proposals.

Land Economics; Agricultural Economics; Economic Geography; Housing

Spatial Dispersion of Economic Activity. By H. C. Bos. Rotterdam: Rotterdam University Press, 1965. Pp. ix, 99. f 21.50.

This book—originally a doctoral dissertation but in fact the seasoned work of a mature scholar—addresses itself to the following problem, first proposed by Christaller and Lösch, and formulated more rigorously by Tinbergen: Since "production, consumption, capital goods, and population are not spread evenly" in space but are concentrated in agglomerations of various size, can a "purely economic explanation" be given for the "systematic differences in the industrial structure of centers of different size?" The key to this question is seen in an associated planning problem: What is the most efficient assignment of activities to clusters of various size and distance, i.e., the optimum dispersion of economic activity?

After a brief exposition of some well-known empirical facts concerning spatial dispersion and after a (somewhat skimpy) summary of the theories of central places as developed by Christaller and Lösch and continued by Böven-ter, the author gives a careful presentation of the "Tinbergen hypothesis" which casts the general idea of central places in a more rigorous form:

- "1. In each center with an industry of a given rank all industries of lower rank are also located.
2. There is only one production unit of each highest-ranking industry in a center. This industry is the only one in the center exporting to other centers and to the agricultural area. The production of all other industries in the center is consumed within this center" (p. 21).

The first question to be answered is, under what conditions this represents the most efficient, i.e., least cost pattern of production in space? The author looks first at the optimum dispersion of a single industry both in a one- and a two-dimensional setting. The assumptions are the standard one of linear cost functions and the unorthodox one of a given demand per area independent of price. Explicit formulae can be given for the optimum market radius. These results are extended to the case where the number of centers is so large and the centers are spaced so closely that at each level demand may be assumed to be distributed continuously at an even density. At this level of abstraction "combination of plants of different industries in one center" produces no cost saving, and so a first ranking of industries can be found according to the optimum size of market areas regardless of mutual interaction.

Next savings in transportation cost resulting from combination of several industries in one center (vertical integration) are examined for several types of transportation cost functions: depending on total value of goods shipments, on the dominant flow, and finally (and conventionally) on distance. Certain combinations can be ruled out, and Tinbergen's hypothesis comes out rather strong in the case of a small number of industries, the only case examined in view of the size of the combinatorial problem.

Next the whole problem is recast as an integer program by restricting locations to a given hexagonal grid. A general analysis proves impossible, but an example produces a solution very close to Tinbergen's hypothesis.

Finally, intermediate commodities are introduced and the Tinbergen hypothesis is generalized accordingly. In this case the results of the analysis are less clear cut. Actually a review of relevant empirical facts would show that the Tinbergen hypothesis does violence to an important sector of the economy, viz., the processing of agricultural raw materials. Dairies, sugar factories, paper mills, cotton gins, tanneries, fruit canneries, etc., are all located in centers of low or sometimes lowest order and export their output to centers of higher order. The principle involved seems to be this: all processes that reduce weight and/or bulk and have modest scale requirements occur near the agricultural base. This principle is in line with broader locational analysis of transport economies and is consistent with the Tinbergen hypotheses in the case of industrial production when raw materials are imported through the metropolis or are ubiquitous: The main stream of industrial products does in fact move down the hierarchical ladder from higher to lower distribution centers as the Tinbergen hypothesis states.

While this book does not succeed in proving the Tinbergen hypothesis, it marks a great step forward in the formulation and the analysis of one of the most intricate problems in location theory: agglomeration. Many insights are

provided and numerous suggestions emerge for further research, both theoretical and empirical. For the student of location theory and spatial economics this book is a must; for the general economist it affords fascinating glimpses into an area of economic research that deserves to be wider known.

MARTIN J. BECKMANN

Brown University

The Conditions of Agricultural Growth: The Economics of Agrarian Change Under Population Pressure. By ESTER BOSERUP. Chicago: Aldine Publishing Company, 1965. Pp. 124. \$5.00.

Mrs. Boserup has observed, as have many others, that explanation of the rapid increase in world population since World War II "is to be sought, not in improved conditions of food production, but in medical invention and . . . other factors . . ." If the line of causation is not from increased agricultural productivity to increased population, perhaps it is in the reverse direction. Mrs. Boserup's book is based on that assumption, and most of its 111 text pages are devoted to attempting to prove that the assumption is true.

The proof rests essentially on a theory or a set of axioms about the way in which agriculture has evolved. There are: (1) Agriculture began (begins) in forested areas; (2) Where it is not necessary to remove weeds from among growing crops; (3) Grasslands are the result of farming with short periods of fallow; (4) Crops grown in the forest yield more food calories per acre than do crops grown in the grasslands; (5) Fertility of the soil is determined (exclusively?) by population density and by the system of agriculture; (6) At any time in the history of a community, all land belonging to the community is used in some way; (7) The system of land tenure is determined by population density and by the system of agriculture.

These assumptions about the development of agriculture and about the direction of causation lead to an evolutionary scheme for classifying agricultural systems according to the period of time that elapses between harvesting and planting on a particular plot. Mrs. Boserup finds five steps—forest fallow, bush fallow, short fallow, annual cropping, and multicropping—but recognizes that not all agriculture passes through all steps. Each step or stage is characterized by lower output per man-hour than the preceding one, with the consequence that a farming community does not willingly enter into the next stage until forced to do so by rising population. But total output in each stage is higher than in the preceding one because leisure time is reduced and more hours are devoted to farming, i.e., cultivators "get accustomed . . . to regular, hard work instead of a more leisurely life with long periods of seasonal idleness" (p. 64). In the long run, productivity of the total economy is raised as increasing population density facilitates the division of labor, the spread of communications and education, and public investment. The happy outcome of all this is that ". . . population growth often seems to be the cause of prosperity, in sharp contrast to the causation from prosperity to population growth and poverty, which was suggested by Malthus" (p. 98).

The argument is attractive, and there is much in it that seems to correspond

with history; if it were advanced as one of the possible lines of causation in agricultural change it would probably meet little serious opposition. But Mrs. Boserup means it to be *the* line of causation, and supports that thesis by a mass of assertions, mostly undocumented, about the nature of agriculture around the world and through history. Many of her assertions of fact are open to question—that irrigation is adopted because the shortening of fallow makes additional operations necessary (p. 26); that under short fallow there is virtually no agricultural work outside the plough season and the harvest season (she assumes that only small grains are grown) (p. 48); that short fallow systems are particularly susceptible to famine (p. 49); that members of primitive rural communities lack foresight and shun hard agricultural work (p. 54); that early systems of agriculture are characterized by large amounts of free time not required, or used, for economically productive activities (*passim*); that high food prices in Japan in the late 1940s resulted from increasing population density (p. 110); and that expanded production of export crops in the tropics was always at the expense of food crop production (p. 119).

More troublesome is the validity of her basic assumptions about how agriculture has evolved; some of these seem to be contrary to the evidence and none of them can be taken as proven. The analysis is also handicapped throughout by failure to recognize important differences between agriculture under temperate and tropical, particularly equatorial, conditions, and between the impact of population growth at 0.3 to 0.5 per cent per annum and recent rates of 2.5 to 3.0 per cent.

Mrs. Boserup's book suffers from two major defects, and they are likely to weaken the influence of many of her perceptive comments: it is argued too single-mindedly in support of one, exclusive proposition; and it is too short! The problem is too complex to be summed up in another counter-Malthusian type of hypothesis, and 111 pages are too few to explore the implications of many of the relationships referred to, or to examine carefully the evidence for their validity.

W. O. JONES

Stanford University

The Economics of Agricultural Development. By JOHN W. MELLOR. Ithaca, N.Y.: Cornell University Press, 1966. Pp. xiv, 403. \$10.00.

This book fills an important gap in the economic development literature. For the first time a monograph is available that is suitable as a text for courses dealing with the economics of agricultural development taught at the undergraduate level.

The book is organized under three major headings: I—The Role of Agriculture in Economic Development; II—The Nature of Traditional Agriculture; and III—The Modernization of Agriculture. I covers both those changes that are internal to the agricultural sector and the changing relationships between agriculture and the rest of the economy, particularly those relationships expressed through the factor and product markets, during the development process.

Mellor has consistently devoted his research and writing to problems of agricultural development for over a decade. The authority which he brings to the subject is a major strength of the book. It also is responsible for the somewhat uneven treatment given to the several topics. On topics which Mellor has emphasized in his own research the treatment tends to be both authoritative and as sophisticated as treatment designed for an undergraduate text will allow. The chapters on "Income and Growth and the Effective Demand for Food" (Ch. 4); "The Farm in Traditional Agriculture" (Ch. 8); and "Labor Use and Productivity" (Ch. 9) are particularly good. In many other areas the treatment is less adequate. The chapter on "Planning Agricultural Development" (Ch. 21) is particularly weak.

It should be emphasized that this unevenness should not be taken as a criticism of Mellor's work but rather of the limited contribution by the profession as a whole to the analysis of the economics of agricultural development. The scholarly work resulting from the rather intensive involvement of agricultural economists in international work during the last decade and a half is pitifully weak. One response to this criticism might be that, working as applied economists, major attention was placed on getting agriculture moving rather than writing monographs. My own reaction is that the particular form of involvement, typically AID (and predecessor agencies) contracts for institutional development, failed to provide an environment that has permitted or encouraged effective research efforts.

A second major strength of the book is that Mellor is not blinded to the complexities of the agricultural development problem by single minded adherence to one of the several models which are currently competing for recognition in the effort to establish a "new development economics." He does not employ either the Rostow growth stage approach of the Lewis-Ranis-Fei two-sector approach as an exclusive organizing principle.

An elaboration of the Rostow stage approach is utilized as an organizing principle in Chapter 13, "The Economic Framework of Agricultural Modernization."¹ A Lewis two-sector scheme clearly is implicit in Chapter 14, "Labor Use and Productivity." At no point does Mellor attempt to present either (a) a careful criticism of the limitations of existing development models, or (b) a general analytical framework of his own. As a result the information which he presents, though generally interesting, frequently degenerates into a pattern of "conventional development wisdom" through a lack of any set of integrating principles.

In conclusion: (a) this is an important and useful book, (b) its weaknesses stem largely from the unsatisfactory nature of current development literature, (c) its strengths are largely a product of Mellor's own impressive research performance, and (d) it would be twice as good if it were half as long.

VERNON W. RUTTAN

¹I have commented more extensively on this part of Mellor's work in V. W. Ruttan, "Growth Stage Theories and Agricultural Development Policy," *Australian Jour. Agric. Econ.*, 1965, 9, 17-32.

The Economics of Air Pollution. EDITED BY HAROLD WOLOZIN. New York: W. W. Norton and Co., 1966. Pp. 318. \$5.00; paper \$2.95.

The book is primarily a collection of essays, most of which were delivered at a seminar at The American University. In addition, it contains a staff report to the Senate Committee on Public Works and a copy of the Federal Clean Air Act with amendments. Three of the essays (those by Allen V. Kneese, Edwin Mills, and Thomas Crocker) pertain primarily to the nature of the "social problem" of air pollution and the alternative means by which it can be solved. Two essays (those by Edward Crowder and Helen Lamale) provide generalizations about the sources and uses of federal statistics with specific comments about data used in air pollution studies. A paper by Ronald Ridker is a good summary of many problems encountered in measuring the cost of air pollution. An essay by Lester Goldner is a case study of the proposals, political pressures, and legislative acts which contributed to the development of the Boston pollution control program. The remaining two articles are hard to categorize. Leslie Chambers sets as a goal not to "engage in a philosophical polemic on the nature of man, the cosmos, or even the biosphere." Toward this goal, however, he takes no more than one or two steps. Harold Wolozin indicates, in broad terms, positions taken by various people on such topics as the purpose of welfare economics, welfare functions, value judgments, cost-benefit analysis, public goods, etc. The report to the Senate Committee (80 pages) could have been omitted without great loss. The only things of interest in this document are lists (without documentation) of major incidents, damages and illnesses which someone has claimed are connected to various items on a list of possible pollutants.

The essays contain many interesting observations and generalizations about the nature of air pollution, externalities and the problems involved in the associated cost-benefit studies. In this respect the book will be of considerable value to anyone interested in these problems. It begins with Allen Kneese drawing from his experience in dealing with water pollution to indicate the parallel and divergent aspects of air pollution. He finds that similarities arise in the many problems of identifying relationships among pollutants, their sources and their effects. When it comes to problems of control, air pollution is considerably more difficult. All authors repeatedly contribute good examples of the problems.

On the other hand, the book contains little of general theoretical interest even though most of the essays are of a theoretical nature. Furthermore, in my opinion, these authors are guilty of a drastic oversimplification of the "social problem" they wish to solve. The contributors who deal with the problem (Kneese, Mills, Crocker, Wolozin and in some respects, Chambers and Ridker) present in essence, the same analysis and similar conclusions. Crocker provides an extension or two. The central thesis is most clearly stated by Edwin Mills. Consequently, I shall discuss his paper in detail.

Mills's argument runs something like the following: There is a "market failure" because costs "are inadequately imputed to the sources of the pollution." Aside from income distribution considerations, the problem is to find a way to "internalize" these costs. The alternatives are to tax (according to the

social cost) or bribe (foregone bribes are an opportunity cost to the firm). The tax alternative is preferable to the bribe (payment) for two reasons. (1) "There is no natural origin for payments. In principle, the payment should be for a reduction in the discharge of pollutants below what it would have been without the payment. Estimation of this magnitude would be difficult and the recipient would have obvious incentive to exaggerate the amount of pollutant he would have discharged without the subsidy." (2) "Payments violate feelings of equity many people have on this subject. People feel that if polluting the air is a cost of producing certain products, then the consumers who benefit ought to pay this cost just as they ought to pay the costs of labor and other inputs needed in production." Thus we choose the tax alternative and create an authority which undertakes cost-benefit analysis to determine the proper tax.

Now to me this analysis is incomplete at every step. The first step is a statement of the problem and the alternative solutions. Presumably there is a "market failure" in that at an "equilibrium" there exist gains from trade (the equilibrium is not a Pareto Optimum). Either some resources used (individual's freedom from the effects of pollutants) remain uncompensated or individuals would like to pay the producer for not exercising some of his rights (the right to produce the effects). The possible exchanges do not take place because of the free rider, hold out, or prisoner's dilemma phenomena typical of externality and public goods problems. Aside from distribution, the problem is to devise a means by which these gains from exchange can be realized. Mills argues that a tax on the producer will correct this "failure." Here he fails to explain that unless the tax revenues go to the damaged party some odd results can occur. The fact that "marginal social cost equals marginal social benefit" is of little consolation to an individual who remains uncompensated for choking on the "optimal" amount of smoke. It is easy to construct an example where, unless payment is made for the factors used (for lack of a better name call them "suffering from effects"), everyone is hurt by such a tax scheme. Even the names of the alternatives are really misnomers. Without additional rather elaborate arguments, the alternatives are either tax the people and bribe the producer (the bribe) or tax the producer and bribe the people (the tax). In either case, where the money comes from and where it goes must be an integral part of the analysis. It cannot be neglected as these authors suppose.

The second step of Mills's analysis is the choice between possible "solutions." Here I have two points to make. Mills does not indicate that the choice between taxes and bribes is actually a choice about property rights, or ownership. Furthermore, unless some type of income redistributing mechanism is specified, the choice between a tax or bribe involves a decision about the income distribution alone. I suggest that the "feelings of equity" which Mills observes are actually "feelings about dollars." While some people claim they own the right to be free of such effects unless compensated, others may claim the right to produce them unless compensated. I see no reason, since there is a distribution question at stake, for the "natural origin" of rights to be "zero effects" as a choice of the tax alternative presupposes. Secondly, the "exagger-

ation problem" Mills recognizes is not unique to the bribe alternative. It is symmetrical. If the tax alternative is chosen, the damaged individuals have the obvious incentive to exaggerate the amount of damage.

The final step in Mills's analysis is his "tentative" policy recommendation. The possible relative merits of this line of attack are not obvious since Mills does not address himself to some fundamental aspects of the problem which, explicitly or implicitly, any "solution" must involve. Several important considerations can be listed under the heading of property rights. In what terms should property rights be defined? Crocker argues that, with allowance for certain meteorological variables, property rights should be defined in terms of the right to take certain actions, e.g., the rate of pollution emission and the time interval of emission. This is an interesting proposal but it is not the only one worth examining. Rights can also be defined in terms of the effects of actions. Producers may or may not have the right to cause certain effects. That is, individuals may or may not have the right to be free from certain effects. There are also problems of specifying what will suffice as "proof" of the violation of a right. Finally, and perhaps most difficult, "who owns what" must be determined.

Aside from the important area of property rights there is the complex problem of determining the exchange mechanism. It should be one through which the gains from exchange are exhausted. The literature does contain some suggestions.¹ Even the courts can be viewed as such a mechanism. Although the cost of this system is great it is not clear that an equally accurate cost-benefit study is less expensive—in both cases the information to be found is the value of the damage. The essays in this book contain some observations in this respect. Crocker touches upon the possibilities of a model where groups bid for certain rights. The group size and cost sharing arrangement would be determined by an air pollution authority. Goldner's whole paper is devoted to the thesis that political action in the Boston case was due to a single major incident. He concludes that the object to be investigated should be the community decision framework. Ridker suggests that simply trying out controls and observing the electorate's reaction is worth considering. In any case, the relationship between the proposed "solution" and the initial "problem" should be made explicit.

The Economy of the Israeli Kibbutz. By ELIJAHU KANOVSKY. Harvard Middle Eastern Monograph No. 13, Cambridge, Mass.: Harvard University Press, 1966. Pp. ix, 169.

Eliyahu Kanovsky's book offers a concise account of the fundamentals of the Israeli collective settlement—the Kibbutz. The first chapter of this book consists of a brief and accurate review of the nature and institutional structure of the Israeli agriculture. An attempt is made to familiarize the reader

with the noncooperative Jewish settlement, the Arab village, and the cooperative family farm—the moshav—which together with the kibbutz constitute the diversified framework of rural living in Israel.

The second chapter deals briefly with the historical and ideological background of the kibbutz movement. A review of the role of the kibbutz as a tool in the Zionist attempt to reestablish the Jewish community in Palestine in the past precedes an appraisal of the role played by the kibbutz movement in the state of Israel today. The author then proceeds to describe the internal organization of the individual kibbutz and the network of kibbutz federations.

The third chapter is devoted to a more detailed description of the operation of the kibbutz economy. The author is concerned with the determination of resource allocation, and the investment and financial operations with special reference to the internal mechanisms of the collective unit and the policy of the settlement and governmental agencies at the national level. The fourth chapter concentrates on recent developments in the kibbutz economy. Special attention is paid to the process of industrialization on the one hand and changes in the consumption patterns of the kibbutz household on the other.

Whereas the first four chapters are mainly descriptive, Chapters 5 and 6 attempt to analyze and appraise the kibbutz economic performance or in the words of the author, the kibbutz productivity and profitability. To show the kibbutz's relatively high productivity, the author quotes input and output indices for the average kibbutz in the 1950s. In terms of yield per man years the kibbutz is reported to be superior to the other forms of agricultural settlements in Israel. Chapter 6 deals with kibbutz profits. These are defined as the difference between gross returns and costs. Costs in the case of the kibbutz—which constitute a firm and a household at the same time—include its consumption expenditures. Thus profitability in this case is the result either of the firm's efficiency or the household's thriftiness or both. Profitability may be envisaged as a criterion of the firm's efficiency if, and only if, consumption expenditures are considered to be predetermined. On the other hand, profitability as a yardstick of thriftiness alone necessarily assumes a given efficiency of the firm unit. This of course is a major weakness if the attempt is to employ profitability as a major criterion of the economic behavior and performance of the kibbutz.

The author presents some evidence—all second hand—according to which the "average" kibbutz profitability is shown to be rather low. In an attempt to explain this phenomenon the author offers an array of propositions, which he summarizes in Chapter 7. As external factors affecting the kibbutz profitability the author mentions (a) inferior location, (b) weak financial structure, (c) inability of the kibbutz to attract new settlers, (d) adverse parity of agriculture prices, and (e) expensive educational policy of the kibbutzim. Among the internal factors the author mentions: (a) the structure of the kibbutz farm, traditionally and ideologically geared towards mixed farming, (b) a ban on the "exploitation" of (nonmembers) wage labor; (c) inefficient and costly consumption patterns, (d) a misleading bookkeeping system and (e) extensive and expensive political activity. This classification of the various factors listed above is arguable. For instance, neither the financial structure

nor the educational policy is really "external" to the individual kibbutz unit. Yet, the more serious shortcoming is the lack of a consistent attempt to identify the underlying relationships and to weigh the relative importance of the various factors.

Presenting the case of the kibbutz's "low profitability" the author compares the economic performance of the kibbutz with that of the family farm in the moshav. In this attempt—which relies upon rather limited information regarding the moshav—the author overlooks the important distinction between the individual member-farm unit in a moshav and the moshav village as a whole, an unnecessary distinction in the case of the kibbutz. For instance, the author emphasizes "defection" as a major kibbutz shortcoming but fails to recognize the inability of the moshav as a whole to cope with a similar phenomenon of outmigration. The author is correct in emphasizing the ideological impediments involved in the case of the kibbutz. However, similar elements affect the moshav as whole though not necessarily the individual family farm.

Considering ideology the author's approach is somewhat naive. The third chapter, for instance, opens with the proposition that the abolition of private property and the socialist tenet "from each according to his ability and to each according to his needs" are antithetical to the concept of profit maximization. While it is true that individual kibbutzim adhere to the "socialist" yardsticks in remunerating their own membership there is no adherence to "socialism" in the way they handle their affairs with the "outside world." This includes—contrary to Kanovsky's impression—inter-kibbutz relationships. In other words the rich kibbutzim—and some of them are quite well to do, despite the reported low profitability of the "average" kibbutz—do not share their property or net returns with the poor collectives. The kibbutz may be and generally is looked upon as a "profit-maximizing" economic unit, subject to some limitations which may have a lesser effect than some union regulations such as the seniority rule in a typical "capitalistic" enterprise.

Labor Economics

Wage Determination in an Integrating Europe. By MALCOLM R. FISHER.

Study No. 6 relating to European integration published under the auspices of the Council of Europe. Leyden: A. W. Sijthoff, 1966. Pp. 104. f. 10.

This theoretical monograph is difficult to understand, partly because the author ventures into the field of psychology and partly because he fails to integrate his contribution into the existing body of economic doctrine. It has very little to do with wage determination in an integrating Europe.

I shall first present the most interesting new idea I was able to synthesize from the text and then I will sketch the particular framework in which the author clothed his idea.

The pure theory of the gains from international trade permits us to make the analytical distinction between production and consumption effects. Thus, if a closed economy is opened up to trade it is possible to identify the gains in

utility which are due to the more efficient production and increased world output, even if excise taxes or subsidies force consumers to continue paying the pre-trade prices for commodities. The increased utility stemming from the removal of these commodity-price distorting taxes and subsidies in turn is considered to be the consumption effect. Now when international trade is opened like this, the relative prices of factors are likely to change, as are the compensations for different labor skills. The welfare gains (or losses) accruing to labor of different skills can be considered as consisting of two parts, analytically similar to production and consumption effects. First, the change in welfare caused by the new money wages which accrue when workers are not allowed to switch occupations. Second, there is an additional change in welfare associated with the switching of occupations which, given the workers' preferences, normally have differing amounts of disutility attached to them for a given amount and intensity of work. This basic idea of differing disutility of work for alternative occupations has some interesting implications for the traditional theorems from the economics of integration, migration, and the pure theory of international trade. The author ventures into these areas, giving an adequate but not particularly lucid exposition of the standard literature, and attempts an analysis of these implications. In my view he has not been very successful.

The reason for this lack of success is that the author tries to set out a new theory of the supply of labor, which he admits is a "mere sketch" (p. 95), and which on closer examination turns out to be not a theory of the supply of labor, but an attempt to use psychology to explain the formation of preferences. After deploring that economists have considered all work as having negative and goods as having positive utility he suggests that as a result of his theory "job satisfaction then acquires an importance hitherto accorded to goods satisfaction alone" (p. 13).

Fisher does know that job satisfaction is incorporated in the traditional theory in the sense that jobs are chosen by individuals maximizing utility within the constraints of the wages paid and personal satisfaction obtained in alternative occupations, quite analogously to the theory of consumer choice where relative prices and personal tastes determine the purchase of commodities. Without saying so explicitly, the author has tried to develop a theory of preference formation as can be seen from the terms he uses to describe an individual's "capacity": "mental and manual ability; ability to assimilate and develop; versatility and adaptability; dependence on externals" (p. 16), which through training and experience become what he calls his "activity frontier."

The formation of tastes and preferences may well be a significant area for future economic analysis and lead to fruitful cooperation between sociologists, psychologists, and economists. Fisher's little book might be hailed as a path-breaking work, if future generations can understand sentences like this: "Work experience stresses the advantages, *ceteris paribus*, of a labor force of higher average age than would be justified in its absence if production possibilities in the nearer future are to be maximized" (p. 66).

The University of Pennsylvania

Critical Issues in Employment Policy. Edited by FREDERICK H. HARBISON AND JOSEPH D. MOONEY. New Jersey: Princeton University, 1966. Pp. viii, 163. \$3.00.

Dimensions of Manpower Policy: Programs & Research. Edited by SAR A. LEVITAN AND IRVING H. SIEGEL. Baltimore: The Johns Hopkins Press, 1966. Pp. 299. \$6.95.

"Hydraulics is to plumbing, as ——— is to manpower." The absence of an acceptable answer to the above question underlies the intellectual ferment in these two books. Until a clear, thoughtful response is forthcoming, much of the material in these works and the surfeit of writing on manpower will continue to be intellectual lint on the blue serge of policy (by government, foundations and other diverse sources).

Critical Issues in Employment Policy (referred to as I) is the compilation of papers and commentaries at a conference in Princeton in May, 1966. It is a relatively homogeneous work. The seven papers center on policy needs and cover both economic issues, such as the needs of local markets, and governmental issues of leadership and intergovernmental cooperation.

Dimensions of Manpower Policy: Programs & Research (referred to as II), seventeen papers, is a "do it yourself" *festschrift* by and for the twentieth anniversary of the W.E. Upjohn Institute for Employment Research. There is an absence of focus in this book which is uneven in subject matter as well as writing style. All the authors are totally or partially connected with the Upjohn Institute. It would be a rare group of scholars under one roof who could produce significant papers on demand for a deadline.

Author overlap is minimal with only Garth Mangum presenting papers in both I and II and Herbert Striner presenting a criticism in I and a paper in II. Subject overlap is considerable and shall be discussed under the headings of data needs, experience, and administration. A missing thread in both works serves as a unifying force.

Anyone who has worked in the field of manpower knows that policy and analysis suffer from data deficiency. Ross (I), Striner, Morton, Sheppard and Siegel (II) are strong advocates of increased research efforts. Nearly all the other writers overtly or by implication lament the deficiency in knowledge. Their emphasis is placed on expansion of what we are already doing. They lay great stress on micro-analytical data needs relevant to jobs, demand and other labor market data on a local market bases. The strong structuralist undercurrent in these works seeks to match worker to employer as found in space and time.

There are only vague hints of the great failings, the emptiness of the statistical categories. Thus, the continued accumulation of statistical data in computers by occupations (currently defined) for counties will not really help answer the problem of putting our labor force to more efficient employment.

Morton (II) stresses an electronic manpower data bank and implies that a sophisticated statistical methodology is the proper research approach to end the manpower problems. Unfortunately, the categories into which we shall organize the data are our first gap. The failure to take due cognizance of the

qualitative deficiencies will make us choke on a pile of not too useful "facts."

Our empirical work must be purposive and not comprehensive in some casual way. For example, until we have a theory of occupations integrated with capital theory and the corpus of modern economics, our acquisitive instincts may do us more harm than good.

Absence of an analytical schema means we lose the basis for experience. Joseph Mooney (I), in an interesting essay on the activities of a Neighborhood Youth Corp in Newark, alludes to one form of the real output of the N.Y.C. as a crime combatant. What is lacking and could be done is construction of a test for the programs' long-run effect on a variable such as recidivism based upon different groups propensity to offend. Without care and design in special projects, as well as gross statistical design, we know neither where we have been, or where we should go in a policy sense.

The absence of direction fostered by a casual notion of past events is not compensated for by strong direction in operational procedure or goals and policy. Robson-Mangum (I), Davidson (II), McKeen (II), Belitsky (II) and Cassel (I) are concerned, though not exclusively, with the independent impact of organization on the dependent variable defined as poverty, unemployment, etc. Whether the subject is intragovernmental organization, state, local and private activities as substitutes, or complements for one another in the production of manpower policy, we are left at sea over the absence of an objective function. Davidson (II), a political scientist, does a scholarly job on the New Federalism, but his economics are wanting. The rest playing amateur political scientists and worse organization theorists, lend little insight to an enormously complex field. A stern lesson is that economists should stick to their knitting.

How we are to organize, and the appropriate relation of decision units, is crucial to successful operation of manpower policy. While Harold Taylor (II) asserts "a sound consensus for acceptable policies can truly be developed" there is no apparent consensus. The pure issues of state-federal relationships obscure the more important problem of the most effective type of organization to increase employment, or the optimal program to satisfy a number of categories within boundaries.

One of the frontiers for this apparently bounded subject is the area of the poor; in fact a strong remedial tone permeates most of the essays. Joseph Kershaw (I) makes an interesting argument for the government as an employer of last resort for the poor; and Streiner, in commenting on this, points to the role of transportation in clearing the local labor market. On the other hand, Levitan (II) asks why a war on poverty? He, however, never does answer the question, but contributes to an understanding of the activities of OEO complementing the essay of Mooney (I). The role of the poor in the policy mix is asayed with some sympathy and would be useful reading for most.

Geographic areas of distress are also in the province of manpower. Thus, Belitsky (II) and Holmquist (II) interestingly view specific problems of activating local communities. Burt (II) leaves one with homilies on the desirability of cooperation while the other two have more insight if not analysis.

Neither book will whet the analytical palate, but this is not to imply that

there are no theoretical problems worthy of examination—a fact recognized by the authors. The works being uneven, it would be useful to take parts I, II and IV of “Critical” and the last two sections of “Dimensions” and splice them as a moderately valuable work.

As manpower policy approaches puberty, it is hoped a clear demarcation between scholar and administrator will form. We cannot have manpower be both a discipline and an operational set of activities; thus the answer to the opening question cannot be “Manpower.”

PAUL A. WEINSTEIN

University of Maryland

Soviet Trade Unions and Labor Relations. By EMILY CLARK BROWN. Cambridge: Harvard University Press, 1966. Pp. ix, 394. \$6.95.

Industry and Labour in the U.S.S.R. Edited by G. V. OSIPOV. London: Tavistock Publications, 1966. Pp. viii, 297. \$8.00.

Despite the congruity of the titles, these volumes deal with different ranges of subject matter. Dr. Brown is concerned rather narrowly with trade unionism, while the Osipov book contains a number of essays on what can best be described as industrial sociology. The only point of contact is a common focus on the Soviet labor market.

Soviet Trade Unions is the more interesting of the two books. It contains the best available account of the structure, government, and operation of labor institutions that have undergone many drastic changes in the half century of Soviet power. Starting out as quasisyndicalist bodies, they were reduced by Stalin to relatively unimportant appendages of the state and given the responsibility of spurring workers on to greater productive efforts. Their functions began to shift after the Twentieth Party Congress, and they have gradually taken on more of a “consumptionist” hue, particularly at the local level. However, they continue to operate as “productionist” organizations as well, and to exercise some governmental functions, including administration of the social security system. Dr. Brown has had as much access to Soviet enterprises as any American in recent years, but she was not able to arrange for more than a casual visit to any single plant. For this reason, much of what she has written describes how people say things work, rather than actual practice. She is careful to make this clear to the reader, but there are occasional lapses. Can one really say that “elections appeared to follow the democratic rules and local officers seemed to consider themselves responsible to the members who elected them” in the face of constant Soviet self-criticism in this regard? Or that “if management tries to get rid of a critic on the pretext of reducing the staff, this can be prevented”? Or that “workers do not in general resist technological change. Improvements typically are to the advantage of workers.”? Sweeping statements of this nature, which would be difficult to prove even in the best of circumstances, are impossible to justify in the Soviet context.

I would take issue with Dr. Brown on one important matter of interpretation. She points out quite correctly that strikes have no place in the Soviet

system, and suggests that an occasional strike might have a salutary effect on labor relations. But then she goes on to write of the "withering away" of the strike in the West, and implies that some convergence between East and West is taking place in this respect. Apart from the fact that the strike is still very much alive in the West, one must be clear that there is a fundamental difference between a system of industrial relations which allows strikes, and one which does not, that the line is a sharply drawn one and not just a matter of shading. It may be true that, in the West, "the trend in modern labor relations seems to be toward seeking other channels for the settlement of disputes," but the foundation stone on which Western industrial relations systems rest is the ultimate right to strike. Despite their workers' councils, the Yugoslavs have recently acknowledged that the strike may be a legitimate weapon in a socialist state, but the Russians have given no indication that they are prepared to move in this direction.

In general, Dr. Brown has done an admirable job of presenting a considerable amount of information difficult to come by. She has chapters on national, regional, and local trade union bodies; the settlement of plant grievances; and the specific functions of the unions in other spheres. (One subject that she does not treat, presumably because her field work was completed in 1962, is the attitude of the unions toward Libermanism. I suspect that the Soviet trade unions have been quite conservative on this issue.) *Soviet Trade Unions* is the standard work on the subject, and is likely to retain that status until the Russians permit outsiders to make studies in depth.

Industry and Labour in the U.S.S.R. is quite a different proposition. It is intended as a representative sample of recent work, some of it never before published. Some 60 papers were collected by a Soviet editorial board, and 18 of these were selected by Maurice Hookham of the University of Leicester on the basis of potential interest to Western readers. When reading recent Soviet writing in the social sciences, one constantly alternates between hope and despair: hope because there are many signs that Soviet scholars are at last emerging from the "cult of personality" era, despair because many of them are finding it so difficult to surmount the past. Of the 18 essays in the volume, two impress me as being of possible interest to psychologists, two more may have some value for specialists in vocational education. The rest, with two exceptions, can be of no earthly use to anyone, consisting as they do of commentaries on tables taken from Soviet statistical abstracts, or containing information such as that boiler-assemblyman A. Markin and his team at the Urals Heavy Engineering Plant managed to complete their course work in a technical education program, or passing on the following: "An analysis of the composition of rationalizers working in shops No. 4 and No. 5 of the Pervouralsk Pipe Plant has revealed that rationalization suggestions are made by 50.5 per cent of the setters working there, 42.5 per cent of the electricians, and only 23.2 per cent of the operators." And what is one to make of the numerous passages such as the following, which summarizes what purports to be an essay of a scientific character: "In the transition from socialism to communism, the intelligentsia is playing a greater role. It is helping to create the material and technical basis, to raise the standard of education, culture and technical

knowledge among the people, to promote sciences, technology, the arts, and public health, and to foster communist consciousness and morals."

On the hopeful side, there is an interesting article by V. N. Shubkin of the Novosibirsk Institute of Economics on the occupational preferences expressed by secondary school graduates in that city in 1962. He compares the stated preferences with actual paternal occupations, and finds that by far the greatest continuity prevailed among children of men in technical and physico-mathematical fields; that in the biological sciences, it was mainly the daughters who were maintaining continuity; and that in the humanities (it is not clear from the context whether this includes economics) it was *only* girls who wanted to follow in the footsteps of their fathers. Virtually no one wanted to enter into farm work or the public service (!); a fair number were interested in careers in industry; while "one hundred per cent of the children of intellectuals and of workers in industry and the public services, and eighty-seven per cent of the children of collective farmers want to enter an intellectual profession."

The second essay that is well worth a careful reading is by the late F. Yu. Aleshina of the Institute of Labor in Moscow. It consists of an analysis of budgets for 100 families in three cities for the months of March in 1951, 1956, 1959, and 1961. It is quite objective and almost entirely devoid of the propagandistic overtones that have characterized most Soviet writing on consumption in the past. For example, it is acknowledged that dependents of textile workers have a higher labor force participation rate than those of steel workers simply because the latter are higher paid, a statement that one would not have found a decade ago. We also learn that Engel's law operates in a socialist economy; that caloric intake is positively correlated with family income (indeed, in 1961, Soviet families in the highest income bracket were consuming 3,500 calories each day per person); and that television has adverse effects on theater attendance. The economics of consumption is a very popular area of study in the Soviet Union at the present time, perhaps reflecting Russia's attainment of a new stage of development, and this essay is a good example of the kind of work being done.

The papers were translated initially in Moscow, and then worked over by Mr. Hookham. He has done a magnificent job; they read as though they had been written in the original by good English stylists. Let us hope that the further volumes in the series which are promised, to be concerned with rural and urban studies and with problems of methodology, will be more worthy of his skill.

WALTER GALENSON

Cornell University

Unemployment Insurance in the American Economy. By WILLIAM HABER AND MERRILL G. MURRAY. Homewood, Ill.: Richard D. Irwin, 1966. Pp. xx, 538. \$8.50.

The description on the dust jacket is accurate: "Here is the first comprehensive book on unemployment insurance in the United States, providing in

one volume the principles of unemployment insurance, its history, and a detailed analysis and discussion of the live issues in the field."

Thirty years is a long time to wait for this "first," but the book is worth the wait. Out of what was once a tangled forest of state and federal laws, mountains of documents and reports, swamps of studies and debates—Dean Haber and Dr. Murray have made an ordered suburb with paved roads, street signs, even house numbers. Teachers of labor economics and of social welfare programs will sleep with it under their pillows and smile in their dreams over the added free time they will have, now that so much of their work has been done for them.

The two authors were ideal for the job. Intimately associated with unemployment insurance since its beginning, they brought to the task more than 60 years of combined experience. The book's comprehensive coverage and balanced treatment of all aspects of the subject reflect the authors' long preparation.

After 100 pages of background information on the nature (Part I) and history (Part II) of unemployment insurance, there follow nearly 400 pages of analytical description of unemployment insurance provisions, accompanied by a discussion of the major issues surrounding each provision. The final 100 pages discuss "problems in relationships" between federal and state governments, between unemployment insurance and the employment service, and between unemployment insurance and other related programs.

In discussing issues, the authors frequently indicate their own preferences, which in general are close to, though not identical with, the recommendations of the Johnson administration as reflected in the 1965-1966 bill, H.R. 8282. Despite their frequent expressions of personal preference, the authors manage to maintain an admirable objectivity in presenting both sides of controversial issues. They also supply numerous bibliographical references in which the reader can find further development of the chief debates.

As the only comprehensive treatment of unemployment insurance, this book is likely to do service for a long time and to go through many editions. If some modifications were made in the future editions, a very useful work could be made even more useful. The following critical observations are made with this constructive objective primarily in view.

In a work as comprehensive and detailed as this one, some errors are inevitable. But there are too many printing errors. All numbers, especially dates, need to be rechecked. The table of contents is detailed and clear. It is a good tool. However, it could be improved by a list of tables. The endless and annoying repetition of *op. cit.* makes one wish the book had used the *AER's* superior system of bibliographical reference.

In a program like unemployment insurance, where the largest ten states account for 60 per cent of all covered workers and the smallest ten states account for only 2 per cent, statements that X number of states have a certain provision, or have had a certain kind of experience, would be more meaningful if accompanied by parentheses indicating the percentage of covered workers in the states spoken of. At the very least, the book should include a table show-

ing the percentage of covered workers in each state. The absence of such a table is a major defect in a work that undertakes to describe a system consisting of 52 separate programs (the District of Columbia and Puerto Rico are included).

In a reference work, the index is unusually important and deserves professional handling. If one may judge by the elementary errors made in the construction of this index, it was done by an amateur. For example, the reader is told that "the largest unemployment benefit plan was that of the General Electric Co." (p. 74). One looks in vain for this important fact in the index under "G" or "E." Certain that it must be there somewhere, I finally found it under "V" (voluntary), which was a subdivision under "U" (unemployment insurance), an arrangement which was simply a repetition of the table of contents. This is a typical mistake of the amateur indexer.

In its treatment of some issues, the book repeats unthinkingly—so it seems to me—positions and data that for years have been a part of the official "line." (It would not be surprising if this happened, considering the multitude of problems covered by the book; not all of them could be rethought.) One example is the book's treatment of the problem of "abuse," whose solution is crucial, as the authors explain, to the development of unemployment insurance. In support of its statement that "the amount of willful misrepresentation is small" (p. 137), the book uses the kind of argument employed for years by the Bureau of Employment Security: "In fiscal year 1954 . . . of every \$100 paid out in benefits during the year, only 31 cents was an overpayment resulting from fraud."

These data reflect only *detected, provable* fraud perpetrated by working violators. Much misrepresentation by claimants is not detected; much that is detected cannot be proved to be deliberate; and, most important, the non-working violator is probably the source of more misrepresentation than the working violator. As a measure of the seriousness of misrepresentation in the program, "31 cents out of every \$100," is the kind of statement that produces a credibility gap. The gap is the more unfortunate because it is unnecessary. The full truth is something the program can easily live with.

For another example, in a statement of the adequacy of the maximum benefit the book's Table 11-1 (p. 125) repeats data which include Illinois and Michigan. These states, which use a variable maximum benefit, should never have been included. The unsuspecting reader is left with the impression that in Illinois, for example, only 40 per cent of the claimants receive a benefit that meets the norm of adequacy (a benefit equal to half of wages). But as a matter of fact, in fiscal 1966, 54 per cent of Illinois beneficiaries received a benefit equal to half their gross wages and 67 per cent received a benefit equal to half their take-home pay.

For a third example, in its otherwise excellent treatment of experience rating, the book repeats a common error in its description of the central argument of this kind of tax system; "The allocation of costs argument is based on the assumption that the costs of unemployment compensation will be passed on to the consumer in higher prices." To be correct, the sentence should have continued: . . . or be borne by the owner in the form of lower profits, or be borne

by the worker in the form of lower wages, or be divided among the three. It is an erroneous test of the social-cost argument to inquire into the effect of experience rating on only consumer prices. The source quoted by the authors (p. 343) does little to support their position, for the writer of the quoted Ph. D. dissertation is thoroughly confused on the issue of social cost. I would hope that in any future edition of the Haber-Murray book the social-cost argument would be rethought and rewritten.

A final example is the book's treatment of disqualification provisions. In view of the lack of information on the effects of existing disqualification provisions (this is one of the unexplored areas of the program); in view of the lack of information on nonworking violators, as mentioned above; in view of the industrial differences between states and the consequent differences in a given state's need for a certain type of disqualification; in view of the interrelationships between disqualification provisions and other unemployment insurance provisions, especially eligibility and duration provisions, and also in view of the different mix of these provisions that the various states have chosen; in view, finally, of the ineffectiveness of the job test as administered by the public employment service ("In practice, it has been found that the public employment service cannot adequately apply the 'work test' " [p. 268])—the authors are surprisingly certain about what the disqualification provisions ought to be. Although my own opinions in this area are fairly close to those of the authors, I believe that the reader, especially the student reader, would be better served by a text that made him see why, in the current state of our knowledge, positions on disqualifications provisions must be largely matters of personal opinion.

In conclusion, it is well to repeat that this is a beautiful book: clear, comprehensive, analytical, balanced. The critical observations above do not amount to more than a gloss on this overall evaluation. The authors and the W.E. Upjohn Institute for Employment Research, which financed the writing of the book, are to be praised for a work that is likely to stand for a long time as a unique, and uniquely valuable, contribution to the field of unemployment insurance.

NOTES

A nominating committee consisting of Edward S. Mason, chairman, Harold J. Barnett, Marvin Frankel, Ruth P. Mack, Clarence E. Philbrook, and Edward S. Shaw has submitted the following slate of nominees for 1968 officers of the American Economic Association.

President Elect:

William Fellner, Yale University

Vice-Presidents:

Edgar M. Hoover, University of Pittsburgh

Walter W. Heller, University of Minnesota

Robert Solow, Massachusetts Institute of Technology

Harry Johnson, University of Chicago and London School of Economics

Executive Committee:

Lyle C. Fitch, Princeton University

Ilse Mintz, Columbia University

A. D. Scott, University of British Vancouver

Otto Eckstein, Harvard University

The annual meeting of the Association will be held in Washington, D.C., December 28-30, 1967, with headquarters at the Sheraton Park Hotel.

AER MANUSCRIPTS

The following manuscripts, exclusive of comments and replies and in addition to those listed in previous issues, have been accepted for publication in subsequent issues of the *American Economic Review*:

H. J. Bruton, Productivity Growth in Latin America.

W. R. B-yan, Bank Adjustments to Monetary Policy: Alternative Estimates of the Lag.

G. C. Chow, Technological Change and the Demand for Computers.

W. J. Fellner, Measures of Technological Progress in the Light of Recent Growth Theories.

R. J. Gordon, The Incidence of the Corporation Income Tax in Manufacturing, 1925-62.

J. P. Gould, Market Value and the Theory of Investment of the Firm.

P. M. Gutmann, External Financing and the Rate of Economic Growth.

M. J. Hamburger, Interest Rates and the Demand for Consumer Durable Goods.

P. Helmberger and A. C. Johnson, Price Elasticity of Demand as an Element of Market Structure.

J. P. Houck, Price Elasticity and Linear Supply Curves.

E. H. Hunt, Railroad Social Saving in Nineteenth Century Central America.

N. M. Kaplan, Growth of Output and Inputs in Soviet Transport and Communications.

M. E. Kreinin, "Price" vs. "Tariff" Elasticities in International Trade—A Suggested Reconciliation.

 C. Wright, Some Evidence on the Interest Elasticity of Consumption.

REPORT ON PROPOSED NATIONAL SOCIAL SCIENCE FOUNDATION

On October 11, 1966, Senator Fred R. Harris, chairman of the Subcommittee on Government Research of the Senate Committee on Government Operations, introduced in the Senate S-836, "A Bill to Create a National Foundation for the Social Sciences." The bill was co-sponsored by twenty of Senator Harris' Senate colleagues. In June 1966, a corresponding bill had been introduced in the House by Representative Dante B. Fascell of Florida, chairman of a Foreign Affairs subcommittee, along with a bill to create an Office of Social Sciences in the Executive Office of the President (parallel to the Office of Science and Technology) and another to authorize the holding of a White House conference on the social and the behavioral sciences. An avowed purpose of this proposed legislation is to augment the support of social sciences which are drawing about \$21 million direct support and perhaps as much as \$29 million indirect support from the National Science Foundation, out of its budget of \$480 million (*Science*, 17 Feb. 1967, p. 814). In fiscal 1966 the total federal contribution to research in social science fields amounted to \$188 million (compared with \$35 million in 1960), together with \$87 million for social psychology (*Science*, 28 Oct. 1966, p. 488.)

Two types of dissatisfaction in the social science community and the university community seem to be generating some support for the proposed NSSF. It is felt that support for social science within the framework of the NSF has not grown fast enough. It is also believed that funds have been too unevenly distributed. The view that in principle heavy governmental support of science is questionable seems to have little support. There is complaint, of course, about the disorganizing impact of the governmental and foundation grants system upon the university structure, interuniversity distribution of personnel, and the conduct of education (*Time*, March 17, 1967, pp. 59-60). Interest is increasing in much greater emphasis upon block-grants to universities instead of grants to scientists and persons gifted in "the fine art of grantsmanship." Such funds are administerable within the structure of the recipient university, and, it is believed, in keeping with the sovereignty of the university. Grants to individuals or groups, on the contrary, tend to reduce university sovereignty, it is believed.

The Board of Trustees responsible for the supervision and direction of the proposed Foundation—24 in number—shall be appointed by the President, with the advice and consent of the Senate, from among Americans "widely recognized for their knowledge of, or experience in, the social sciences or related public affairs." A director and a deputy director will be similarly appointed.

Under Section 6 the Foundation is authorized to—

- (1) Develop and encourage the pursuit of a national policy for the promotion of programs of research and scholarship in the social sciences;
- (2) Initiate and support research and programs to strengthen the research potential of the United States in the social sciences, and to promote such research in foreign countries, by making arrangements (including grants, loans, or other forms of assistance) with individuals or groups, including other government or international agencies for such purposes;
- (3) In making grants or other arrangements for scientific research, to utilize appropri-

ations available therefor in such manner as will, in its discretion, best realize the objectives of (a) strengthening the research staff of such organization, particularly institutions of higher learning in the States, Territories, and Possessions and the District of Columbia; (b) aiding institutions of higher learning or non-profit research organization and foundations, which, if aided, will advance basic research; (c) encouraging social science research by individuals, university faculties, interdisciplinary teams of researchers, non-profit and foundation researchers, and (d) to avoid the concentration of research grants in any one state or geographic region; and

(4) foster the interchange of information in the social sciences by disseminating the results of research projects in such sciences not otherwise published, providing at least annually a listing and description of all projects which are receiving assistance from the Foundation, and maintaining a current register of social scientists."

A parenthetical comment. Clause (d) under (3) probably reflects a sentiment embedded also in President Johnson's directive (*Science*, 24 Sept 1965, pp. 1483-85) calling for a broader distribution of research funds. "We are witnessing," D. S. Greenberg reports (*Science*, 24 June 1966, p. 1726), "the slow but certain demolition of the unique enclave that a segment of the scientific enterprise carved out for itself in the period after World War II."

Under Section 7 the Foundation is instructed to correlate its programs with other ongoing programs and authorized to carry out research for other governmental agencies.

"(a) The Foundation shall correlate programs carried out pursuant to this Act, insofar as practicable, with existing Federal programs and with programs being carried out by other public agencies or private groups and shall develop the programs carried out pursuant to this Act, with due regard to the national interest and the contribution to the purposes of this Act, which can be made by other Federal agencies under existing programs.

(b) At the request of any department or agency of the Government, the Foundation may carry out any project within the purposes and authorization of this Act. Such projects shall be carried out on a reimbursable basis, but the total amount expended on such projects in any fiscal year shall not exceed an amount equal to twenty-five percent of the amount expended by the Foundation in such year for projects pursuant to this Act from funds appropriated to the Foundation.

(c) In the administration of this Act, no department, agency, officer, or employee of the United States shall exercise any direction, supervision, or control over the policy determination, personnel, making of loans and grants, or the administration or implementation of any research project funded by the Foundation, except as may be otherwise provided for herein."

Subsection (b) makes the NSSF an operating as well as a disbursing agency. Whether these two functions may economically coexist within an essentially disbursing agency is considered open to question by some.

Section (8) has to do with international cooperation and coordination with foreign policy. It reflects in part dissatisfaction with Camelot and other social science projects supported by the military. There is need, Senator Harris observed in his speech on February 6, 1967, "for the 'civilianizing' of U. S. social science research abroad." Section (8) reads as follows:

"(a) In carrying out projects pursuant to this Act the Foundation may support international activities, in the social sciences, consistent with the purposes of this act, and the national objectives of the United States.

(b) No project pursuant to this Act shall be carried out in any foreign country (1) until forty-five days after the government of such country has been given notice of such project, and (2) at any time if such government objects to such project.

(c) If, in carrying out the provisions of this Act, any negotiation, other than the notice provided for in subsection (b) of this section, with the government of a foreign country becomes necessary, such negotiations shall be carried out by the Secretary of State at the request of the Foundation."

Section 12 authorizes the use of Public Law 480 funds.

"Sec. 12. Section 104 of the Agricultural Trade Development and Assistance Act of 1954 as amended (7U.S.C. 1704), is amended (1) by striking out the period at the end of sub-

section (t) and inserting in lieu thereof a semicolon, and (2) by adding at the end of such section a new subsection as follows:

(u) for supporting projects and providing assistance, in such amounts as may be specified in appropriation Acts, in accordance with the provisions of the National Foundation for the Social Sciences Act of 1966."

Senator Harris's bill does not make provision for education or training, "areas in which NSF, by wide agreement, has filled an enormously valuable role," D. S. Greenberg reports. "The fact that NSF's money has really been secondary to the stimulation and leadership it has provided for educational activities—ranging from reforms in high school curricula to post-doctoral fellowships—seems to have had no impact on the Harris formulation" (*Science*, 17 Feb. 1967, p. 812).

Some social scientists favor the expansion of NSF support over a new NSSF because: (a) the NSF has made quite full use of the scientific community in administering its program; (b) it has strengthened the ties between the natural and the social sciences; and (c) it has in effect put the high prestige of some of the natural sciences back of the less prestigious social sciences.

Senator Harris's bill seems to attach weight to the practical applications of social science. It is thus spiritually in keeping with H.R. 6698 introduced March 7, 1967, by Representative Emilio Q. Daddario as an amendment to the Act creating the NSF in 1950. This bill is intended "to provide a method for identifying, assessing, publicizing and dealing with implications and effects of applied research and technology." Support for applied social science research is envisaged. Representative Henry S. Reuss, chairman of the House Subcommittee on Research and Technical Programs, is undertaking a study of applied social science research and its capability in coping with domestic problems.

PUBLICATIONS

Cambridge University Press announces the publication of a new quarterly journal, *Modern Asian Studies*. The new journal is devoted to the modern history, human geography, politics, economics, sociology, and literature of the countries lying in an area from West Pakistan to Japan, including China, South and Southeast Asia. In addition to original papers and major review articles, *Modern Asian Studies* publishes reviews of books, particularly those available only in Asian languages. The entire journal is published in English. Subscribers to *Modern Asian Studies* before January 1968 will receive a special charter annual rate of \$8.50 instead of the regular rate of \$9.50. For additional information, write to C. A. Fisher, editor, Cambridge University Press, 32 East 57th Street, New York, N.Y. 10022.

The publishers of the *East African Economic Review* call the attention of U.S. economists to its New Series continuing the publication of articles and book reviews related to the problems of East Africa. The journal is published twice a year, summer and winter, by the Oxford University Press, National and Grindlays Bank Building, Government Road, Nairobi, at a subscription price of E.A. Shs. 25/—.

The *Bentley Business and Economic Review* is now in its fourth year of publication. The editors would welcome a larger flow of manuscripts; they should be sent to Dr. Edward George, editor, Bentley College, Boston, Massachusetts 02115.

The book review editors of *Military Affairs* would like to expand their file of academic and professional reviewers of publications in the field of military, naval, and air history and national security. Write to: Mr. Jack Hilliard, American Military Institute, 1307 New Hampshire Ave., N.W., Washington, D.C. 20036.

The editors of *The Antitrust Bulletin* wish to encourage the submission of more original articles of merit on antitrust economics, foreign and domestic. Send manuscripts to Joseph Taubman, editor, Federal Legal Publications, Inc., 95 Morton St., New York, N.Y. 10014.

Announcements

The Office of Economic Research (OER), a staff organization of the Economic Development Administration, U.S. Department of Commerce, is responsible for research programs to increase the understanding of economic development and improve the implementation of federal development policies. It would welcome proposals in any of the following subject areas: (1) understanding area and regional growth; (2) marshaling and using resources for economic development; (3) forging strategies for economic development; (4) training and educating economic development specialists. Research inquiries and proposals in any of the above categories may be submitted at any time. Each proposal is given individual consideration in terms of current research needs, the adequacy of the research design, and the competence to carry it out successfully. Proposals and inquiries should be submitted to the Director, Office of Economic Research, Staff Office of Assistant Secretary of Commerce for Economic Development, U.S. Department of Commerce, Washington, D.C. 20007.

One of the objectives of the Operations Research Society is to stimulate research of high quality and articles suitable for publication. The Cost-Effectiveness Section is sponsoring its second annual essay contest. This year's topic is *Methodology for Measurement of Effectiveness*. Papers should include an illustration of proposed effectiveness (benefit, utility) measurement methods to a given field, for example, (a) research and development, (b) foreign affairs, or (c) education, urban development or transportation. A premium will be placed on the comprehensiveness, explicitness and potential operational feasibility of the techniques suggested. Applications to various governmental levels are welcome. First and second prizes of \$200 and \$100, respectively, will be awarded. Contest results will be announced in November and prizes presented at the national meeting of the Society.

Researchers, analysts, academicians and practitioners are invited to submit papers. Articles should be typed double-spaced and submitted in four copies to Cost-Effectiveness Essay Contest, c/o Frederick S. Pardee, The RAND Corporation, 1700 Main Street, Santa Monica, California 90406, and must arrive not later than 10 September 1967.

An Economics Society of Michigan was formed at the March 1967 meeting of the Michigan Academy of Arts and Sciences. The officers of the society are: honorary president, Lawrence H. Seltzer, Wayne State University; president, Charles C. Killingsworth, Michigan State University; president-elect, Kenneth E. Boulding, University of Michigan; treasurer, Jared Wend, Western Michigan University; and secretary, John W. Simpson, Eastern Michigan University.

The Econometric Society announces its annual North American summer meeting held jointly with The American Mathematics Society and The Mathematics Association of America at the University of Toronto, Toronto, Ontario, Canada, August 28-30, 1967. Accommodations for the meeting will be available at the University of Toronto and nearby hotels. Further information is given in current issues of the *Notices of the American Mathematics Society*.

The National Institute of Social and Behavioral Science will hold its regular sessions for contributed papers at the 134th annual meeting of the American Association for the Advancement of Science, December 26-31, 1967, in New York. Sessions are held with the collaboration of the Section on Social and Economic Sciences of the A.A.A.S.

Economists interested in presenting a paper at these sessions are invited to forward titles and abstracts of 300 words to Donald P. Ray, National Institute of Social and Behavioral Science, 863 Benjamin Franklin Station, Washington, D.C. 20044, not later than September 1st.

Papers should concern recently completed or well-advanced ongoing research in any of the fields of national or international economics. Of perhaps especial interest would be studies on, for example, European-American trade relations, trends in domestic wage-price levels and

the U.S. balance of payments, professional human resources and American foreign assistance programs, legislation and public economic policy, problems in labor economics, regional and foreign area economic development, and interdisciplinary studies.

Selected materials of the sessions will be published, and papers are eligible, upon nomination, for the \$1000 and bronze medal Newcomb Cleveland Prize of the A.A.A.S. The annual meeting invariably receives extensive coverage by science writers from all media. The American Economic Association is an affiliated member of the Section on Social and Economic Sciences of the A.A.A.S.

Edwin G. Nourse has a number of "remainder" copies of his book *Economics in the Public Service* which he will be glad to present to individuals or libraries that have particular interest in early developments under the Employment Act of 1946, the Council of Economic Advisers, and the Joint Economic Committee. Requests should be sent to the author, 1775 Massachusetts Ave., N.W., Washington, D.C.

Deaths

Amotz Morag, The Eliezer Kaplan School of Economic and Social Sciences, Jerusalem.
John G. Shott, economist, Department of Labor, September 1966.

Retirements

Ben W. Lewis, professor of economics, Oberlin College, June 1967.
Shorey Peterson, professor of economics, University of Michigan, retirement furlough 1967-68.

Visiting Foreign Scholars

Christopher Archibald, University of Essex: visiting professor of economics, Northwestern University, fall 1967.

Horace B. Davis, University of Guyana: visiting professor of economics, Hofstra University.

George France, University of York: visiting assistant professor of economics, University of Connecticut.

Robert G. Gregory, The London School of Economics: visiting assistant professor of economics, Northwestern University, fall 1967.

Alexander M. Kerr, University of Western Australia: visiting professor of economics, University of Texas, fall 1967.

G. D. McColl, University of New South Wales: visiting professor of economics, Duke University, spring 1967.

Omer Sarc, University of Istanbul: visiting professor of economics, Columbia University, 1967-68.

Eugene N. Savin, University of Essex: visiting assistant professor of economics, Northwestern University, fall 1967.

Klaus F. Stegemann: visiting assistant professor of economics, Queen's University, fall 1967.

Promotions

Louis P. Beleký: associate professor of economics, C. W. Post College, Long Island University.

Martin R. Blyn: assistant professor of banking, School of Commerce, New York University.

Barry Bressler: instructor in economics, City College of New York.

Henry J. Bruton: professor of economics, Williams College.

- John F. Chant: associate professor of economics, Queen's University.
 David G. Edens: associate professor of economics, University of Connecticut.
 Walter L. Eisenberg: professor of economics, Hunter College, City University of New York.
 Arnold M. Faden: assistant professor of economics, Iowa State University.
 John Firestone: professor of economics, City College of New York.
 Galvin G. Gall: associate professor of economics, University of Connecticut.
 Henry N. Goldstein: associate professor of economics, Washington State University.
 Michael A. Hall: assistant professor of economics, Beloit College.
 Erich Isaac: associate professor of economics, City College of New York.
 Edward B. Jakubauskas: professor of economics, Iowa State University.
 Clinton E. Jencks: associate professor of economics, San Diego State College.
 Richard Leighton: associate professor of economics, State University of New York, Binghamton.
 Albert M. Levenson: associate professor of economics, Queens College, City University of New York.
 Glenn L. Johnson: associate professor of business administration, University of Kansas.
 Hirschel Kasper: associate professor, Oberlin College.
 Allan V. Palmer: professor of business management, Old Dominion College.
 Robert Piron: assistant professor of economics, Oberlin College.
 Fredric Raines: assistant professor of economics, Washington University, St. Louis.
 Werner Sichel: associate professor of economics, Western Michigan University.
 Matthew Simon: associate professor of economics, Queens College, City University of New York.
 Morris Singer: professor of economics, University of Connecticut.
 Gerald Sirkin: associate professor of economics, City College of New York.
 Babette Solon: associate professor of economics, Queens College, City University of New York.
 Thomas M. Stanback: professor of economics, School of Commerce, New York University.
 Edward Sussna: professor of business administration, Graduate School of Business, University of Pittsburgh.
 H. John Thorkelson: professor of economics, University of Connecticut.
 Paul Weiner: associate professor of economics, University of Connecticut.
 Gordon Winston: associate professor of economics, Williams College.

Administrative Appointments

- Abraham C. Burstein: principal analyst, Human Resources Administration, New York City.
 Fred I. Courtney: chairman, department of business management, Guilford College.
 Paul E. Fenlon: head of department and professor of economics, University of Texas.
 William D. Geer: dean, School of Business, Samford University, Birmingham, Alabama.
 Donald Grunewald, Rutgers: professor and dean, College of Business Administration and Graduate School of Administration, Suffolk University.
 John Hein, Federal Reserve Bank of New York: senior economist, International Economics Department, National Industrial Conference Board.
 Peter B. Kenen: chairman, department of economics, Columbia University.
 Kenyon A. Knopf, Grinnell College: dean and professor of economics, Whitman College.
 Richard L. Kozelka, University of Minnesota: professor and director of graduate studies, College of Business Administration, University of South Florida.

Markos J. Mamalakis, Yale Growth Center: associate professor of economics and director of Latin American Center, University of Wisconsin, Milwaukee.

William J. McKinstry: chairman, department of economics, Miami University.

William M. Morgenroth: professor and head of the division of business and economics, California State College, Hayward.

George R. Morrison, State University of New York, Buffalo: senior economist, money markets section, First National City Bank, New York.

Abdul Hameed Naz: senior regional economist, Maryland-National Capital Park and Planning Commission.

Jack W. Nickson, Jr.: acting chairman, department of economics, Old Dominion College.

W. H. Patterson: acting chairman, department of accounting, Old Dominion College.

Donald K. Pemberton: chairman of department of economics, Hiram College.

Janus Poppe, Industrial College of the Armed Forces: dean, United States Merchant Marine Academy, Kings Point, New York.

Edward J. Powers: chairman, department of economics, Saint Anselm's College.

George Rosen: deputy director of economics and technical assistance division, Asia Development Bank, Manila.

Richard H. Rush: professor and director of finance program, School of Business Administration, American University, fall 1967.

Frank I. Stern, New York Central System: director of marketing information systems, Chicago and Northwestern Railway Company.

Paul P. Streeten: acting director, Institute of Development Studies, University of Sussex.

Eugene L. Swearingen, Oklahoma State University: president, Tulsa University.

Roger C. Van Tassel: chairman, department of economics, Clark University.

Joseph S. Wright, Zenith Radio Corporation: chairman, Council on the Graduate School of Business, University of Chicago.

Appointments

Robert F. Adams, University of Maryland: lecturer, University of California, Santa Cruz, 1967-68.

Charles F. Austin, Personnel Research Division, U.S. Army: associate professor of organizational behavior and business administration, School of Business Administration, American University, fall 1967.

Christopher Bach, Western Reserve University: appointment in economics, Lafayette College.

Bela Balassa: professor of political economy, Johns Hopkins University.

Arnold P. Ballantyne: associate professor of economics, University of Colorado, 1967-68.

Bhal J. Bhatt: assistant professor of industrial relations, State University of New York, Buffalo.

Sanjit Bose: assistant professor of economics, Brandeis University.

Anthony Bottomley, chair in economics, University of Bradford, Yorkshire.

Kenneth E. Boulding: visiting professor of economics, University of Colorado, 1967-68.

Dwight S. Brothers, Rice University: Graduate School of Business Administration, Harvard University.

Thomas Burney: assistant professor of economics, Denison University.

Robert C. Burton: associate professor of economics, Old Dominion College, fall 1967.

Marshall L. Casse, III: assistant professor of economics, School of Business Administration, Emory University, September 1967.

V. Karuppan Chetty, University of Wisconsin: associate professor of economics, Columbia University, fall 1967.

Laurits Christensen: assistant professor of economics, University of Wisconsin, fall 1967.

Peter Clark: assistant professor of economics, Duke University, 1967-68.

Norris C. Clement: visiting assistant professor of economics, University of Colorado, 1967-68.

William R. Cline, Yale University: assistant professor of economics, Princeton University, September 1967.

Raymond Coleman: professor of economics and management, College of Business Administration, University of Illinois, Chicago.

Andre Corbeau, Louisiana State University: assistant professor of economics, University of Oklahoma.

Richard R. Cornwall, University of California, Berkeley: assistant professor of economics, Princeton University, September 1967.

Ronald W. Crowley: assistant professor of economics, Queen's University, fall 1967.

Thomas D. Curtis, University of Arizona: associate professor of economics, University of Oklahoma, September 1967.

Herschel Cutler, Association of American Railroads: associate professor of transportation and business administration, School of Business Administration, The American University, fall 1967.

Ralph d'Arge: assistant professor of economics, University of New Mexico, September 1967.

James V. Davis: assistant professor of business administration, Vanderbilt University.

Joseph S. DeSalvo, Virginia Military Institute: research staff, logistics department, RAND Corporation.

Eugene J. Devine, University of California, Los Angeles: instructor in economics and commerce, Simon Fraser University, fall 1967.

Barend A. de Vries, International Bank for Reconstruction and Development: visiting professor of political economy, Johns Hopkins University.

Stephen Dresch, Yale University: instructor in economics, Miami University.

Jan W. Duggar, Florida State University: assistant professor of economics, Louisiana State University, fall 1967.

Robert Eagley, Wayne State University: associate professor of economics, University of Massachusetts, fall 1967.

Robert B. Ekelund, Jr., Louisiana State University: assistant professor of economics, Texas A and M College, fall 1967.

Frank W. Fetter, Northwestern University: visiting professor of economics, Dartmouth College.

Walter Fisher, professor of economics, Northwestern University, fall 1967.

Myron D. Fottler: assistant professor of industrial relations, State University of New York, Buffalo.

Kenneth D. Frederick: assistant professor of economics, California Institute of Technology.

Martin J. Gannon: assistant professor of industrial relations, State University of New York, Buffalo.

Marshall Geer, III: visiting assistant professor of economics, University of Colorado, 1967-68.

Malcolm Gillis: assistant professor of economics, Duke University, 1967-68.

Micha Gisser: associate professor of economics, University of New Mexico, September 1967.

Michael Gort, State University of New York, Buffalo: visiting professor of economics, Northwestern University, fall 1967.

Julian M. Greene: assistant professor of economics, Southern Methodist University, 1967-68.

Benton E. Gup, University of Cincinnati: economist, Federal Reserve Bank of Cleveland.

Jerry W. Gustafson: assistant professor of economics, Beloit College, fall 1967.

David Hahn: assistant professor of marketing, Ohio State University.

James Halstead: assistant professor of economics, Williams College.

Curtis C. Harris, Jr., Economic Development Administration, Department of Commerce: research associate in Bureau of Business and Economic Research and assistant professor of economics, University of Maryland.

Donald J. Harris, University of Illinois: visiting assistant professor of economics, Northwestern University, fall 1967.

John A. Haslem: assistant professor, School of Business, University of Wisconsin.

F. Gregory Hayden, University of Texas: assistant professor of economics, University of Nebraska, fall 1967.

Patric H. Hendershott: assistant professor of economics, Northwestern University, fall 1967.

Robert Hinckley: assistant professor of economics, University of Massachusetts, fall 1967.

Edward P. Holland: economist, Office of Program Coordination, Agency for International Development.

Robinson Hollister: assistant professor of economics, University of Wisconsin, fall 1967.

Sheng-tieh (Frank) Hsiao: assistant professor of economics, University of Colorado, 1967-68.

David S. Huang, Southern Methodist University: visiting professor of business economics, Graduate School of Business, University of Chicago, 1967-68.

Stanley Huff, Princeton University: assistant professor of economics, Denison University.

Joseph Humphrey: instructor in economics, Occidental College.

Thomas Iwand, Pennsylvania State University: associate professor of economics, University of Nebraska, fall 1967.

Elmo L. Jackson: professor of economics, Old Dominion College, fall 1967.

David B. Johnson, University of Virginia: assistant professor of economics, Louisiana State University, fall 1967.

Stanley R. Johnson: associate professor of economics, University of Missouri.

Paul Jonas, Brooklyn College: associate professor of economics, University of New Mexico.

Lamar B. Jones, Virginia Polytechnic Institute: assistant professor of economics, Louisiana State University.

John H. Keith, Jr.: instructor in economics, Dartmouth College.

James Kindahl, University of Chicago: associate professor of economics, University of Massachusetts, fall 1967.

Paul G. King, University of Illinois: assistant professor of economics, Denison University.

Burton H. Klein: professor of economics, California Institute of Technology.

Anthony Y. C. Koo: professor of economics, Michigan State University, September 1967.

George M. Lady, Johns Hopkins University: assistant professor of economics, Rice University.

Robert J. Lawrence, University of Texas: research staff of Board of Governors, Federal Reserve System.

Larry C. Ledebur, Florida State University: assistant professor of economics, Denison University.

Chung H. Lee, Miami University: lecturer in economics, University of Essex, England.

Tong Hun Lee, University of Tennessee: professor of economics, University of Wisconsin, Milwaukee, September 1967.

- An-Yhi Lin: research associate, department of economics, Iowa State University.
- Thomas Love: assistant professor of economics, University of Massachusetts, fall 1967.
- Ruth Mack: visiting professor of economics, City College of New York.
- Thomas E. Manore: assistant professor of business management, Old Dominion College, fall 1967.
- James A. Maxwell: professor of economics, University of Connecticut.
- Donald C. Mead: associate professor of economics, Amherst College, fall 1967.
- Charles R. Miller: associate professor of business management, Old Dominion College, fall 1967.
- George N. Monsma, Jr.: assistant professor of economics, Amherst College, fall 1967.
- Brian Motley: assistant professor of economics, University of Wisconsin, fall 1967.
- Owen B. Murphy: assistant professor of economics, Albany Junior College, Georgia.
- Wallace M. Nelson: associate professor of economics, Rollins College, Florida.
- William G. Nelson, Youngstown University: purchasing agent, University of Pittsburgh.
- Robert E. Olley, University of Saskatchewan: visiting assistant professor of economics, Queen's University, fall 1967.
- Robert M. Olsen, Northwestern University: assistant professor, School of Business, University of Kansas.
- Larry Orr: assistant professor of economics, University of Wisconsin, fall 1967.
- John D. Patrick, Federal Reserve Bank of New York: instructor in economics, Swarthmore College, fall 1967.
- Mark V. Pauly: assistant professor of economics, Northwestern University, fall 1967.
- Allen Perlman: assistant professor, School of Business, University of Kansas.
- Louis R. Pondy: assistant professor of business administration, Duke University, fall 1967.
- Ibrahim I. Foroy, United Nations Conference on Trade and Development, Geneva: assistant professor of economics, San Diego State College, fall 1967.
- Richard L. Porter, Marquette University: visiting professor of economics, Oklahoma State University.
- Martin F. J. Prachowny: assistant professor of economics, Queen's University, fall 1967.
- Cadwell Ray: assistant professor of economics, University of Massachusetts, fall 1967.
- Stanley Reiter: professor of economics, Northwestern University, fall 1967.
- Idrian N. Resnick: lecturer in economics, Princeton University, September 1967.
- Charles Richey: assistant professor of economics, Hiram College.
- H. Raymond Rodosevich: assistant professor, School of Business, University of Kansas.
- Gerald Rosenthal: associate professor of economics, Brandeis University.
- Philip Ross, University of Pittsburgh: professor of industrial relations, State University of New York, Buffalo, September 1967.
- Bernard Saffran, University of California, Berkeley: associate professor of economics, Swarthmore College, fall 1967.
- Lars G. Sandberg: associate professor of economics, Dartmouth College.
- Dean S. Sanders, University of Michigan: assistant professor of economics, Miami University.
- U. Sankar: assistant professor of economics, University of Wisconsin, Milwaukee, September 1967.
- Bikas C. Sanyal: research associate, department of economics, Iowa State University.
- Paul Schatz: professor of insurance, Samford University, Birmingham, Alabama.
- Robert N. Schoepfle: assistant professor of economics, University of Connecticut.
- Nicholas W. Schrock, University of Oregon: assistant professor of economics, San Diego State College, fall 1967.
- R. G. Scott: assistant professor of economics, University of California, Santa Cruz.

- Charles E. Seagrave: assistant professor of economics, Rice University, September 1967.
- Joel Segall, University of Chicago: visiting professor of finance, Graduate School of Business Administration, University of Washington.
- David O. Sewell: assistant professor of economics, Queen's University, fall 1967.
- Sue O. Shaw, visiting lecturer in economics, Vanderbilt University, 1967-68.
- Dennis E. Smallwood, Yale University: assistant professor of economics, Princeton University, September 1967.
- Eugene Smolensky, University of Chicago: associate professor of economics, University of Wisconsin, fall 1967.
- Ronald Soligo, Yale University: associate professor of economics, Rice University, September 1967.
- Gordon R. Sparks, Massachusetts Institute of Technology: associate professor of economics, Queen's University, fall 1967.
- Zane Spindler: instructor in economics and commerce, Simon Fraser University, fall 1967.
- J. Kirker Stephens, University of Illinois: assistant professor of economics, University of Oklahoma, September 1967.
- Dale E. Swan: assistant professor of economics, Southern Methodist University, 1967-68.
- Neil M. Swan: assistant professor of economics, Queen's University, fall 1967.
- Robert L. Swinth, Carnegie Institute of Technology: associate professor, School of Business, University of Kansas.
- Ralph L. Thomas: professor of economics, California State College, California, Pennsylvania.
- Samuel L. Thorndike, Jr., Columbia University: assistant professor of economics, University of Wisconsin, Milwaukee, September 1967.
- Adrian W. Throop: assistant professor of economics, Dartmouth College.
- John O. Tollefson: assistant professor, School of Business, University of Kansas.
- Jack Topiol: appointment in economics, Lafayette College.
- Vladimir Trembl: associate professor of economics, Duke University, 1967-68.
- Paul B. Trescott, The Rockefeller Foundation: professor of economics, Miami University.
- Sheila Tschinkel: assistant professor of economics, University of Connecticut.
- Hiroki Tsurumi: assistant professor of economics, Queen's University, fall 1967.
- Gerald F. Vaughn, Maryland State Planning Department: coordinator, Community and Resource Development, University of Delaware.
- John P. Venieris, University of Oregon: assistant professor of economics, San Diego State College.
- Wayne Vroman: assistant professor of economics, Oberlin College, September 1967.
- Frederick S. Weaver: assistant professor of economics, University of California, Santa Cruz.
- H. Martin Weingartner: professor of business administration, University of Rochester.
- Stephen W. Welch: assistant professor of economics, University of Connecticut.
- Robert Welsh, University of Kentucky: associate professor of marketing, Ohio State University Contract Team in Brazil.
- Jerome D. Wiest, University of California: associate professor of management science, Rice University.
- Frederick D. Whitehurst: assistant professor of accounting, Old Dominion College, fall 1967.
- William E. Whitelaw: assistant professor of economics, University of Oregon.
- Harold O. Wilson: visiting assistant professor of business administration, Vanderbilt University.
- Robert W. Wisner: assistant professor of economics, Iowa State University.
- James E. Zinser: assistant professor of economics, Oberlin College, September 1967.

Leaves for Special Appointments

Werner Baer, Vanderbilt University: Vanderbilt-overseas assignment, University of São Paulo, Brazil, 1967-68.

Jack N. Behrman, University of North Carolina: visiting professor, Harvard Business School.

Harry G. Brainard, Michigan State University: advisor to the Turkish Academy of Economic & Commercial Sciences, Ankara, Turkey, July 1967-July 1969.

Thomas F. Dernburg, Oberlin College: Council of Economic Advisers, September 1967.

Stanley L. Friedlander, City College of New York: President's Council of Economic Advisers, Washington, D.C.

Bela Gold, Case Institute of Technology: visiting professor, The Imperial College of Science and Technology, London.

Douglas H. Graham, Vanderbilt University: Vanderbilt-overseas assignment, Vargas Foundation, Rio de Janeiro, Brazil, fall 1967.

C. Elton Hinshaw, Vanderbilt University: Vanderbilt-overseas assignment, University of São Paulo, Brazil, 1967-68.

John M. Hunter, Michigan State University: Midwest Universities Consortium International Activities Inc.—Brazil Higher Education Project, February 1967-September 1968.

Herbert Kisch, Michigan State University: visiting professor, University of Berlin, 1967-68.

Gian S. Sahota, Vanderbilt University: Vanderbilt-overseas assignment, University of São Paulo, Brazil, 1967-68.

John R. Shea, University of Santa Clara: Ohio State University Human Resource Development Project, USAID, La Paz, Bolivia.

Anthony M. Tang, Vanderbilt University: Vanderbilt-overseas assignment, Chinese University of Hong Kong, fall 1967.

Clems B. Thoman, University of Nebraska: visiting professor of economics, Pahlavi University, Shīvaz, Iran.

Richard S. Thorn, University of Pittsburgh: advisor to the director, International Monetary Fund Bureau of the Budget, Teheran, Iran.

William O. Thweatt, Vanderbilt University: Vanderbilt-overseas assignment, University of São Paulo, Brazil, 1967-68.

Arthur W. Wright, Oberlin College: Economic Growth Center, Yale University.

Resignations

Raul M. Branco, University of Texas, September 1967.

T. M. Brown, Queen's University, 1967.

Brian V. Hindley, Queen's University, 1967.

Wallace L. Nelson, Jr., University of Wyoming.

Ray C. Roberts, Jr., Old Dominion College.

Raymond S. Strangways, Old Dominion College.

Gerald I. Weber, University of Illinois.

Miscellaneous

Edward Ames, professor of economics, Purdue University: named Loeb Distinguished Professor of Economics.

James I. Stewart: appointed a Queen's Counsel on the New Year's Honours List, Toronto, Ontario.

Aaron W. Warner, professor of economics, Columbia University: named to Chair, Joseph L. Bottenwieser Professor of Human Relations.

VACANCIES AND APPLICATIONS

The Association is glad to render service to applicants who wish to make known their availability for positions in the field of economics and to administrative officers of colleges and universities and to others who are seeking to fill vacancies.

The officers of the Association take no responsibility for making a selection among the applicants or following up the results. The Secretary's office will merely afford a central point for clearing inquiries; and the *Review* will publish in this section a brief description of vacancies announced and of applications submitted (with necessary editorial changes). Since the Association has no other way of knowing whether or not this section is performing a real service, the Secretary would appreciate receiving notification of appointments made as a result of these announcements. It is optional with those submitting such announcements to publish name and address or to use a key number. Deadlines for the four issues of the *Review* are February 1, May 1, August 1, and November 1.

Communications should be addressed to: The Secretary, American Economic Association, 629 Noyes Street, Evanston, Illinois, 60201.

Vacancies

Labor economists and/or statisticians: The measurement of the economic damages suffered by those who are wrongly injured or killed is a new area for the application of economic and statistical knowledge and research techniques. This field has been pioneered successfully and Associated Appraisers of Impaired Earning Capacity is now providing this service to attorneys on a nationwide basis. Those in it appraise the losses and are required to testify as an expert in court trials and must withstand hostile cross-examination. It is one of the highest-paid forms of work in the profession and it is possible to engage in it as a part-time activity. Requirements: (1) minimum status of associate professor; (2) experience in research in collective bargaining agreements and fringe benefit programs; (3) location in or near a major metropolitan area. Openings now available in following areas: Boston, Philadelphia, Pittsburgh, Chicago, Minneapolis, St. Louis, New Orleans, Kansas City, Oklahoma City. Waiting list open in other areas. Send résumé and list of publications to: Philip Eden, President, Associated Appraisers of Impaired Earning Capacity, 1303 Walnut Street, Berkeley, California, 94709.

Economist: Ph.D. preferred, doctoral candidates and those with master's degree will be considered. Principles of economics, labor economics, public finance, history of economic thought, macroeconomics. Rank of instructor or assistant professor, depending on advanced degree and teaching experience. Salary range, \$7,500-\$10,000. Liberal fringe benefits. Please send résumé and names and addresses of two references to: Chairman, Department of Economics and Business Administration, Lebanon Valley College, Annville, Pennsylvania, 17003.

Economists, mathematicians, statisticians, operations analysts: Needed by the Research Analysis Corporation to participate in defense-related studies of resource allocation techniques and applications. Areas of interest include systems analysis of defense forces, weapon systems, and manpower and material resources, and its constituent elements of cost-effectiveness analysis and military cost analysis. A strong capability is maintained in computer-assisted model building. Staff members are assisted in acquiring a working knowledge of computer techniques if they do not already have it. Candidates should have at least a master's degree. For additional information, send résumé to: Mr. John G. Burke, Supervisor of Professional Staffing, Research Analysis Corporation, McLean, Virginia, 22101.

Economist: September, 1967. Principles and advanced course to be selected. Twelve-hour load. Assistant or associate. Ph.D. required. Small college of about 2,000 enrollment where emphasis is placed on teaching. Write to: Dick Smith, Head, Department of Social Science, Tarleton State College, Stephenville, Texas, 76402.

Economists and econometricians: We seek several outstanding men or women for the professional staff of a management consulting firm whose principal clients are blue chip industrial companies. Graduate training in economics at a leading university and several years of experience in business, consulting, or teaching required. New York City location. Ten percent travel. Salary open and depends on qualifications and previous achievements. P335

Teaching opportunities abroad: University positions, instructor to professor level, in the developing nations of Asia, Latin America, and primarily Africa. Two-year contracts. Salary dependent on level and location; transportation provided. Write to: Overseas Educational Service, 522 Fifth Avenue, New York, New York, 10036. An Equal Opportunity Employer.

Accountants: With continued growth and expanding academic programs, the Accounting Department, Texas A. and M. University has openings for two additional staff members. One, an outstanding tax and auditing specialist with a capability in computers as related to accounting in general and auditing in particular. Applicants should possess terminal degree and preferably be in mid-career and interested in a balanced program of teaching, research, and publications. Salary to \$16,500 for nine months with opportunity for additional summer term teaching at a comparable rate. Second, an assistant professor interested in principles and theory, cost, and computer applications in accounting. Applicant should possess terminal degree. Salary to \$10,750 for nine months with opportunity for additional summer term teaching. Applicants for both positions may send credentials to: Dr. Jack W. Coleman, Head, Accounting Department, School of Business, Texas A. and M. University, College Station, Texas, 77843.

Finance: With continued growth and expanding programs, the Finance Department has an opening for an additional staff member. This is for an assistant professor with salary to \$10,750 for nine months with opportunity for additional summer term teaching. Requirements call for a terminal degree. Appointee should be interested in specialization in the institutional aspects of finance. Applicants for this position may forward their credentials to: Dr. John E. Pearson, Director, School of Business, Texas A. and M. University, College Station, Texas, 77843.

Transportation economist or transportation specialist: U.S. Army Corps of Engineers, Civil Works Directorate, requires several transportation economics or transportation specialists to fill staff positions in division and district offices in various parts of the country. Positions are from grade level GS-5 (\$5,331) to GS-13 (\$12,873) and are a part of the federal Civil Service program. Basic requirements are a degree in economics or business administration and appropriate experience or training for performing the following duties: supervises or produces economic evaluation studies of proposed waterway or harbor improvements; structures potential area of influence of proposed improvement, determines movements of commodities in area of influence, and assesses economic efficiencies of moving these commodities by various carrier modes—water, rail, road, and pipeline. Should be familiar with cost and rate structures of these carrier modes as well as evolving technologic changes affecting their interrelationships in an overall transportation system for a region and for the entire nation. Applicants should apply to: Mr. N. A. Back, Chief, Economics and Evaluation Branch, Civil Works Directorate, Office, Chief of Engineers, Washington, D.C., 20315.

Economists: Many developing countries turn to the United Nations and its specialized agencies for help and advice in dealing with their problems. Consequently, the United Nations needs the services of highly qualified economists in almost every field of specialization for its technical assistance and pre-investment programs. These overseas assignments in the developing countries vary from a few months to several years, although most of them are for "one year with possibility of extension." Positions with the U.N. Development Program offer economists with graduate degrees and 10 or more years of practical experience an unusual opportunity to participate in the stimulating programs of economic development which characterize a large number of emerging countries. Such assignments often can be fitted into the university professor's sabbatical year; for longer assignments universities have been willing to grant leaves of absence. This program provides a unique opportunity for university economists to fill interesting and worthwhile jobs which will benefit the developing countries and contribute to their academic careers. The United Nations

also seeks economists and econometricians for research and operational posts at its headquarters and Regional Economic Commissions. These posts require candidates for an M.A. or Ph.D. in economics or econometrics and several years of experience which has involved substantial economic research. Most appointments are for a minimum of two years, although a limited number are for shorter periods and can be worked into sabbatical years. U.S. citizens should send résumés to: Director, Office of International Organization Recruitment, Department of State, Washington, D.C., 20520. Non-U.S. citizens should apply directly to: Office of Personnel, United Nations, New York, New York, 10017.

Economists: Office of International Operations, Internal Revenue Service, has unique and intellectually challenging career opportunities for economists in Washington, D.C. Duties involve the application of economic analysis to intercorporate affairs between related corporations to determine whether they reflect market or arm's length standards. Function is to provide analysis and recommendations on the "reasonableness" of intercorporate prices, and whether or not the corporations involved have failed to clearly reflect their true taxable income. These studies cover the entire spectrum of business activity and will have an important bearing on the development of tax law guidelines and precedents involving intercorporate pricing in the expanding field of international commerce. Positions are available at entrance salaries ranging from \$10,000 to \$15,000. Position and starting salary will depend upon educational background and professional experience. For further details, write to: Director of International Operations, Attention of Chief, Economic Advisory Branch, Internal Revenue Service, Washington, D.C., 20225.

Fishery economists: Wide variety of economic research ranging from international agreements, quotas, and tariffs to price analyses, business management of firms, cost-benefit analyses, and whole field of the economics of natural resources. Positions are in the federal Civil Service at Grades GS-9 (\$7,696) to GS-14 (\$15,106). Basic requirements are Ph.D. or master's in economics or agricultural economics; training in international, natural resource, and/or quantitative economics would be helpful. Civil Service Commission Form 57 (application for federal employment) should be sent to: Assistant Director for Economics, Bureau of Commercial Fisheries, U.S. Department of the Interior, 1815 N. Fort Myer Dr., Arlington, Va., 22209.

Economics: Head of department, Ph.D., several years of teaching experience at college or university level. Present eight-man department. Catholic-related, coeducational midwestern university; 2,500 students (500 graduate) in School of Business. T.I.A.A., life insurance, hospitalization, other fringe benefits. Salary commensurate with education and experience. Apply to: Professor William J. Hoben, Dean of Business Administration, University of Dayton, Dayton, Ohio, 45409.

Marketing: Position of lecturer in undergraduate business management program. Combination of marketing and marketing research, with additional field in managerial economics or quantitative methods. Advanced degree in business administration (Ph.D., M.A., or M.B.A.) with some additional experience. Ability to use Chinese language highly desirable but not required. Unusual opportunity in rapidly developing academic institution. Minimum term of appointment two years. Salary and details flexible. For information, write: Registrar, New Asia College, Chinese University of Hong Kong, 6 Farm Road, Kowloon, Hong Kong.

Economics: Head of department; Ph.D. Rank (full, associate, or assistant professor) and salary appropriate to education and experience. Load, 8 to 12 hours. Most courses on alternate-year basis. Teaching assignment flexible, presently includes principles, economic thought, comparative economic systems, public finance, labor economics and collective bargaining, national income analysis, general economic history of Europe and America. Will also consider person approaching or having recently reached emeritus status, in which case would implement rotating headship; emeritus would qualify as visiting professor. Commence September, 1967. Write to: C. L. Kanatzar, Dean of Faculty, MacMurray College, Jacksonville, Illinois, 62650.

Economics, labor: Ph.D. to teach economics and labor courses at accredited undergraduate college on Long Island in the New York City area. Appointment effective August, 1967, in rank of associate professor. Starting salary \$12,959. Additional fringe benefits. Send complete résumé to: Captain Lawrence Jarrett, Head, Department of Maritime Law and Economics, U.S. Merchant Marine Academy, Kings Point, New York, 11024.

Accounting, finance, management: One position available at a four-year, liberal arts college. Rank and salary open. Opportunity to become head of department and/or occupy chair of business administration (doctorate required for chair). Applicants with master's and no experience will be considered at the rank of instructor. Write to: Dr. Dale J. Shaw, Academic Dean, Jamestown College, Jamestown, North Dakota, 58401.

Transportation economist: The national Economics Division of the Office of Business Economics has an opening for a transportation economist to work in the construction of input-output tables. Grade to GS-13 is available, depending on training and experience. Applications (Application for Federal Employment, Standard Form 57, obtainable at all U.S. Post Offices) should be addressed to: Mr. Charles Pierce, Office of Personnel, Room 5230 Main Commerce Building, Washington, D.C., 20230. An Equal Opportunity Employer.

Labor economist: Teaching position in an expanding economics department. Salary, \$9,500 to \$12,000 for academic year. Ph.D. or near Ph.D. required. For further information, write and send résumé to: Phillip A. May, Department of Economics, School of Arts and Sciences, Northern Michigan University, Marquette, Michigan, 49855.

Economic statistician: Under direction of chief, Research and Analysis Division, conducts research and prepares analyses of economic conditions and trends and statistical indicators relevant to the planning and development programs of the state. Requires master's degree in economics or economic statistics and four years of progressively responsible experience in economic research involving collecting, manipulating, and analyzing economic data. Salary range, \$9,840-\$12,552 per year. File applications with: State of Hawaii, Department of Planning and Economic Development, 426 Queen Street, Honolulu, Hawaii, 96813.

Economist I: Under direction of chief, Research and Analysis Division, conducts research and prepares analyses and reports on macro- and microeconomic conditions relevant to the planning and development programs of the state. Requires four years of responsible professional experience involving work in economics and a master's degree in economics or business administration. Specialization in regional economics, econometrics, or statistics helpful. Salary range, \$9,840-\$12,552 per year. File applications with: State of Hawaii, Department of Planning and Economic Development, 426 Queen Street, Honolulu, Hawaii, 96813.

Economics: Assistant dean, College of Business. Ph.D. or D.B.A. in business or economics required. Three to 5 years of full-time teaching experience in college or university. Administrative experience given special consideration. Limited teaching opportunity. Initial annual salary \$17,000-\$18,000. Effective date September 1, 1967. Contact: Deal Earl A. Roth, College of Business, Eastern Michigan University, Ypsilanti, Michigan, 48197.

Economics, business: Rapidly expanding new university, favorably located in the Vancouver metropolitan area, aiming at excellence in undergraduate teaching and strong graduate program, invites applications at all rank levels. Doctorate or near-doctorate required. Additional business administration specialists sought for the current academic year in accounting, finance, production, organization, quantitative methods, and international business. Additional economics specialists sought for 1968 in economic history, educational economics, comparative systems, and regional economics. Write to: Dr. Parzival Copes, Head, Department of Economics and Commerce, Simon Fraser University, Burnaby 2, British Columbia, Canada.

Economist: Ph.D. completed by September, 1967. Appointment at any professional rank, depending upon qualifications. Salary level \$11,000-\$15,000 plus. Immediate teaching assignment in principles and international economics or money and banking. Interests in economics of technology and quantitative analysis appropriate. Willing to consider visiting professor appointment for senior man. Write to: Dascomb R. Forbush, Chairman, Department of Economics, Clarkson College of Technology, Potsdam, New York, 13676.

Economists: The state of Virginia has recently established a Division of Planning with broad research responsibilities. Opportunities are open for original work in state and local finances, regional economics, and operations research. The work is particularly challenging for young men wishing to gain research experience in an organization with few bureaucratic restraints and good facilities and financing. Posi-

tions are open for persons with training in economics at the M.A., near-Ph.D., or Ph.D. level. Salary range fairly close to federal GS-9 through GS-12. For additional information, send résumé to: Chief, Research Section, Division of Planning, 805 State Office Building, Richmond, Virginia, 23219.

Economic statistician: Expanding research and statistics unit of a midwestern state government has an opening for a fiscal analyst, working primarily in forecasting state revenues. He will apply theory to seek relations of flows of state revenue with other variables and use statistical techniques to test and quantify these relations. Ample computer capacity and programming assistance is available. Salary begins at about \$9,600 with annual increases. P337

THE INCIDENCE OF THE CORPORATION INCOME TAX IN U.S. MANUFACTURING, 1925-62

By ROBERT J. GORDON*

The best-known empirical study of the shifting of the corporation income tax is that of Krzyzaniak and Musgrave [18] (K-M for short), who conclude that in the short run in U.S. manufacturing more than 100 per cent of the burden of the corporation income tax is shifted forward to consumers. The K-M method is to measure the effect of alternative independent variables, including tax liabilities, on the pre-tax rate of return in a time series regression covering the years 1935-42 and 1948-59. A positive coefficient on the tax variable would be evidence that, in response to an increase in the corporation income tax rate, corporations raise prices and increase their pre-tax profits, thus shifting to consumers some of the burden of the tax. An insignificant coefficient on the tax variable would indicate that corporations are unable to achieve this discretionary improvement in their pre-tax profits and thus suffer the full burden of the tax.

In the K-M study the coefficient on the tax variable is positive and significantly greater than 100 per cent, implying that corporations respond to an increase in tax liabilities by raising pre-tax profits by *more* than the tax liability. Following the imposition of a tax of 50 per cent, for instance, the pre-tax rate of return would more than double. If K-M are correct, the following is true:

1. The corporation income tax does not reduce the rate of return and thus does not reduce investment (to the extent that the rate of return is an important determinant of the demand for investment).
2. Since the corporation income tax does not reduce dividend payments, there is no *de facto* double taxation of dividends.
3. The corporation income tax is not progressive and has the regressive effect of a general sales tax on the goods and services produced by corporations; the relative tax burden on each product depends on the

* The author is a Ph.D. candidate at the Massachusetts Institute of Technology. He wishes to thank E. C. Brown, F. M. Fisher, R. E. Hall, D. M. Holland, Edwin Kuh, J. G. Gurley, and M. H. David for their helpful suggestions.

profitability, the use of equity capital, and vertical integration among the firms in the industry.

4. The effect of a value added tax on the average level of prices and profits is the same as that of the fully shifted corporation income tax, since both are equivalent to a tax on sales. Thus the substitution of the value added tax for the corporation income tax would not change profits or domestic prices, although it would permit the reduction of export prices.

5. Investigators like J. W. Kendrick and R. Sato [16] cannot use the income share of capital in long-run production functions to compute the elasticity of output to changes in capital input, because shifting raises pre-tax rates of return above the marginal product of capital.

6. An increase in corporation income tax rates is a perverse tool for short-run stabilization policy in inflationary periods, since corporations react immediately by raising prices and thus work against the attempt of policymakers to stabilize prices.¹

7. The major reason for lower corporate rates of return in the 1930s relative to the 1950s was the lower corporation tax rate in the earlier decade, not the much less intensive use of plant and equipment.

Although the K-M model has been extensively criticized, no study has yet presented evidence which modifies the substance of their conclusion.² Most commentators have confined themselves to critiques of the K-M study. Three criticisms are most frequently made. First, K-M's regressions attempt to explain the rise in the before-tax rate of return in manufacturing from the 1930s to the 1950s, but they do not include among their independent variables any measure of the increase since the 1930s in the pressure of demand on capacity. The K-M independent variables other than the tax rate, in addition, appear to have been chosen for their contribution to the fit of the equations and are not derived from a fully articulated model.³ A final problem in the K-M study is the discrepancy between the low measures of shifting obtained when an income share measure of profits is used as the dependent variable and

¹ The higher tax rate, of course, will reduce the pressure of excess demand in the economy. But this could be achieved as well by a tax increase which does not directly result in price increases, i.e., an increase in the personal income tax rate, and which is thus more consistent with the goal of price stability.

² The best critiques to date are the papers by R. E. Slitor [22] and R. Goode [5]. The study by Challis Hall [8] does not estimate a tax-shifting coefficient and the only support of the hypothesis of zero shifting is a slightly higher R^2 than in the full-shifting case. The cross-section regressions by R. Kilpatrick [17] are claimed to support the K-M conclusion of full shifting and are discussed more fully below in Part III.

³ K-M begin with an eight-equation general macro model which is left unexplained ("it cannot be our purpose here to develop a general macro model" [18, p. 35]). No functional forms are specified except for the appearance here and there of a lagged variable. The method of approach is "experimentation" to "find variables which are highly correlated with the rate of return but not with each other" [18, p. 33].

the high coefficients of shifting which result when the rate of return on assets is the dependent variable.

This paper presents a result opposite to that of K-M and finds that on the average the corporation income tax is not shifted in the short run in U.S. manufacturing. The tool of analysis, as in the K-M study, is a set of time-series regression equations in which the corporation profit rate is the dependent variable. Unlike the K-M study, the independent variables here are derived from a model of the probable profit performance of firms that practice mark-up pricing behavior. The coefficient on an independent tax variable is examined for evidence that corporations raise their mark-up margins in response to an increase in the tax rate, thus shifting the burden of the tax forward to consumers.

The period of fit covers the full time span of the Internal Revenue Service data [25], extending from 1924 to 1962, and the regression results are computed by a nonlinear method which is more efficient than the K-M instrumental technique. In the results for manufacturing as a whole the fitted tax shifting coefficients are found to be not significantly different from zero for either an income share or a rate of return concept of profits. The fitted coefficients measure the incidence of the corporation income tax and suggest that corporations suffered the full burden of the tax during the period of study. While tests for each of ten two-digit manufacturing industries reveal no evidence of tax shifting on the average, the industry tax shifting coefficients vary over a considerable range and are significantly correlated with industry concentration ratios. In addition, it is shown that the recent study by Kilpatrick [17] does not support its conclusion of nearly full shifting for the manufacturing aggregate. Finally, the results of this study apply only to short-run shifting and do not rule out the possibility that corporations may be able to shift the burden of the tax in the long run.

I. Tax Shifting and the Theory of the Firm

A firm maximizing profits as in traditional theory would not react to the imposition of a corporation income tax by raising prices, because its price is set by equating marginal revenue and marginal cost, and the tax affects neither MR nor MC.⁴ But since the pioneering empirical work of R. L. Hall and C. J. Hitch [10] and others, it has been recognized that most businessmen do not usually behave as the marginalist theory predicts. They do not know what their marginal curves look like, particularly the marginal revenue curve, and they usually set prices by adding a "mark-up margin" to average total cost at some "normal" level of output. Instead of maximizing profits they attempt to maintain some

⁴ Except to the extent that the tax law does not allow a deduction for imputed interest on working capital, which is a cost of production.

target ratio of profits to sales.⁵ If this desired ratio is computed after taxes, the profits tax becomes an element of average cost to be marked up just like any other kind of cost, and mark-up pricing behavior appears to lead automatically to the conclusion that full tax shifting will result.

But in fact shifting may not automatically occur in the mark-up case. It will not if price is already at the optimum profit-maximizing level before the tax is imposed. The K-M contention that the tax is fully shifted implies that producers always set their prices *below* the profit-maximizing level, since, if prices are already at or above this level when the tax is imposed, a further increase intended to recoup the tax will depress profits. Firms may keep their prices below the optimum level for two reasons:

1. By doing so they may be able to thwart entrants or the antitrust division and thus maximize *long-run* profits. But in this case an increase in tax rates believed to be permanent would not lead to shifting because firms would still want to maintain their price at a sub-optimum level.

2. A margin of unexploited profits may also result as a normal characteristic of the oligopolistic game. A price leader, fearful that its price increase may not be followed, may delay desired price increases until the industry as a whole receives a "signal" which simultaneously induces all firms to desire higher prices. Either expensive wage agreements or increases in the corporation income tax would qualify as appropriate signals for this kind of behavior.

This discussion of mark-up pricing behavior makes the full shifting of the corporation income tax a plausible but not a certain result, and for further information on the degree of shifting we must turn from general theoretical analysis to a specific model suitable for empirical testing. Since the tax liability is not known until the level of profits is fixed, we shall first describe the determination of profits for a representative firm

⁵ The assumption of this paper that businessmen practice markup pricing (sometimes called the "full cost" principle of pricing) is supported by numerous empirical studies. The following are representative conclusions: "It is impossible not to be struck by the devastating completeness of entrepreneurs' uncertainty about matters usually assumed to be known in the textbooks. In this fog of uncertainty the full cost principle may provide a guiding beacon—indeed it often does so" [11, pp. 5-6]. "We concluded that the twelve firms studied did normally fix the price of their products with the guidance of the full cost principle" [2, p. 142]. "Generally speaking, the entrepreneurs in our sample aimed at earning a standard gross margin rather than maximising the current rate of profit" [2, p. 146]. "There can be no doubt that it is an almost universal custom to use as a basis for price fixing a figure . . . which would be described by an economist as a long-period average cost. It is equally indisputable that in many cases there exists within the firm a recognised profit margin (usually expressed as a percentage of average cost) which remains stable over periods long enough to be significant and which is generally accepted as normal" [20, p. 114]. "The businessmen's views on price policy were found to be almost unanimous. . . . To this estimate of the total cost of each article was added a profit margin, based largely on convention" [7, p. 150].

practicing mark-up pricing in a no-tax world. Then a corporation income tax will be introduced, and we shall test the hypothesis that its burden is shifted.⁶

A. *Profits in a Representative Firm*

At any given time our representative firm produces output Q_t in a plant with capacity Q_t^* . Its production-line employees each produce q_t^p units of output, and their average productivity q_t^p increases over time. The firm's demand for production workers can be written

$$(1) \quad L_t^p = Q_t/q_t^p.$$

The work of nonproduction or "fixed" employees (maintenance, research, and clerical employees) is not directly associated with actual output Q_t ; instead each "fixed" worker is needed to maintain q_t^f units of the plant's capacity output Q_t^* .⁷ The demand for fixed labor, then, is

$$(2) \quad L_t^f = Q_t^*/q_t^f.$$

If b units of materials input are required to produce a unit of output, the demand for materials M_t is

$$(3) \quad M_t = bQ_t.$$

Letting w_t^p and w_t^f denote the wage rates of the two different types of labor and p_t^m the price of materials, we can represent the firm's operating costs C_t by its wage bill plus materials costs.

$$(4) \quad C_t = w_t^p L_t^p + w_t^f L_t^f + p_t^m M_t = \left(\frac{w_t^p}{q_t^p} + b p_t^m \right) Q_t + \frac{w_t^f}{q_t^f} Q_t^*.$$

⁶ To test the effect of the corporation income tax on profit rates, we must be able to estimate the level of profit rates in the absence of the tax. Obviously we must assume that without a corporation income tax government revenues are maintained by some other kind of tax. Otherwise a diminution of government revenues would result in a change either in government spending or in the surplus-deficit position and thus in all the economic magnitudes which determine profits.

⁷ The distinction between production and nonproduction workers was suggested by the studies of Kuh [19], Wilson and Eckstein [26], Gallaway [4], and others, which show that the productivity of labor declines during cyclical contractions and rises during the early stages of cyclical expansions, partly because the work force consists of many nonproduction workers whose services are demanded in proportion to capacity rather than output. The distinction between the two types of workers is important whenever the growth of capacity differs from that of output. For instance, the rapid growth of new capacity in 1956 and 1957 was accompanied by a large increase in nonproduction worker employment at a time when real output was relatively stagnant. This has been cited by Schultz [21, pp. 122-25] as an important reason for the slow growth of productivity during those years.

The firm sets its output price p_t by multiplying its average total cost by a markup fraction m . To avoid frequent changes in price resulting from temporary changes in output, m is applied to average cost at capacity output, c_t^* .

$$(5) \quad p_t = mc_t^* = m \left(\frac{w_t^p}{q_t^p} + b p_t^m + \frac{w_t^f}{q_t^f} \right).$$

Total revenue is then

$$(6) \quad R_t = p_t Q_t = m \left(\frac{w_t^p}{q_t^p} + b p_t^m + \frac{w_t^f}{q_t^f} \right) Q_t.$$

We define cash flow Z_t' (the prime represents the absence of taxes) as the difference between revenue R_t and operating cost C_t .

$$(7) \quad Z_t' = R_t - C_t = \left[(m-1) \left(\frac{w_t^p}{q_t^p} + b p_t^m \right) + m \frac{w_t^f}{q_t^f} \right] Q_t - \frac{w_t^f}{q_t^f} Q_t^*.$$

Unfortunately data on the wage bill by industry do not distinguish between w_t^p and w_t^f , and neither wage cost nor materials cost data are available for 18 of the 36 years which we want to include in the regressions, so that we cannot estimate (7) in its present form.⁸ To approximate the wage rates we shall assume that wages are a simple function of the average trend productivity of labor (q_t^p and q_t^f) and of an index of the general level of prices in the economy p_t^g . This assumption is valid if changes in the wage differential between production and nonproduction workers are proportional to changes in the productivity differential between them, and if the profit margin m is constant. This latter condition is, of course, completely consistent with the markup theory used to derive (7). In addition we shall assume that materials prices are proportional to the general price index p_t^g . This assumption is more tenable for manufacturing as a whole than for separate industries. Specifically, these assumptions are written:

$$(8) \quad w_t^p = e p_t^g q_t^p,$$

$$(9) \quad w_t^f = f p_t^g q_t^f,$$

⁸ Data on wage and materials costs by industry are contained in the *Census of Manufactures* and the *Annual Survey of Manufactures*, which are available only for the following dates: 1919-39 biannually, 1947, and 1949 to the present.

$$(10) \quad p_t^m = g p_t^o.$$

Substituting (8), (9), and (10) into (7), and writing p_t/p_t^o as h_t , we obtain

$$(11) \quad Z_t' = [(m-1)(e+bg) + mf] \frac{p_t Q_t}{h_t} - f \frac{p_t Q_t^*}{h_t}.$$

The form to be estimated would be

$$(12) \quad Z_t' = \alpha_1 \frac{R_t}{h_t} + \alpha_2 \frac{R_t^*}{h_t} + u_t$$

where $R_t = p_t Q_t$, $R_t^* = p_t Q_t^*$, and u_t is the error term.

To estimate (12) with industry data we must assume that all manufacturing firms follow pricing practices similar to those of our representative firm, and that (12) represents the behavior of profits in every manufacturing industry. (12) is an inappropriate form for time series estimation, however, because in a growing economy the independent variables will be highly collinear. It is reasonable to assume that the error term grows with the size of the economy, and that we can therefore improve the efficiency of our estimates by rewriting (12) in a standardized form.⁹ Let us define a new error term u_t' which is proportional to a scale variable. Since u_t' might grow proportionately with either assets (K_t) or sales (R_t), there is no a priori way to choose between $\sigma^2 K_t^2$ and $\sigma^2 R_t^2$ as the specification of the error variance. We shall make estimates for each assumption, standardizing first by K_t (in which case the dependent variable is the rate of return on assets) and then by R_t (so that the dependent variable becomes an income share concept).¹⁰

As an additional modification to (12), recall that we were forced to assume (8), (9), and (10) because of data limitations. We should recognize that prices and costs, while highly correlated in the long run, may have different short-run cyclical patterns. If prices increase faster than wages in the first stages of a business expansion and wages increase more rapidly later, profits will vary positively with differing rates of change of output $\Delta Q_t/Q_t$. Another independent determinant of profits may be the effect of price changes $\Delta p_t/p_t$ on inventory valuation profits. Although $\Delta Q_t/Q_t$ and $\Delta p_t/p_t$ are likely to be highly correlated, it is possible that in some periods of stable output and rising prices (e.g., 1946-48 and 1955-57), or of rising output and falling prices (e.g., 1926-29), their separate effects can be distinguished. A given percentage change in out-

⁹ Johnston [13, p. 211].

¹⁰ The numerator of the "rate of return" in this study is cash flow, Z_t , which was first defined in equation (7). It includes profits, depreciation, depletion, and interest paid.

put or prices presumably affects large and small companies in the same way, so that these variables enter our estimating equations in unstandardized form. The final descriptions of the rate of return and income share concepts in the no-tax case are then:

$$(13) \quad \frac{Z'_t}{K_t} = \alpha_1 \frac{R_t}{h_t K_t} + \alpha_2 \frac{R_t^*}{h_t K_t} + \alpha_3 \frac{\Delta p_t}{p_t} + \alpha_4 \frac{\Delta Q_t}{Q_t} + u'_t.$$

$$(14) \quad \frac{Z'_t}{R_t} = \alpha_1 \frac{1}{h_t} + \alpha_2 \frac{R_t^*}{h_t R_t} + \alpha_3 \frac{\Delta p_t}{p_t} + \alpha_4 \frac{\Delta Q_t}{Q_t} + u'_t.$$

We should expect that if our theory is a valid representation of a real world in which firms by markup behavior attempt to keep Z/R relatively constant, then (14) will result in a poorer fit than (13) (i.e., Z/R can be described more adequately than Z/K by a constant term alone).

B. Taxes and Nonlinear Estimation

By shifting the burden of the corporation income tax our representative firm can reduce the impact of any given tax rate on its after-tax profits. Denoting profits net-of-tax by π_t^n , profits in the absence of tax by π_t' , and the proportion of tax liabilities T which the firm shifts by the parameter α_5 , we can write:

$$(15) \quad \pi_t^n = \pi_t' - T_t + \alpha_5 T_t.$$

If no part of the tax burden is shifted, $\alpha_5 = 0$ and $\pi_t^n = \pi_t' - T_t$. If the firm is able to shift the entire burden of the tax, $\alpha_5 = 1$ and $\pi_t^n = \pi_t'$, i.e., net-of-tax profits are just as large as profits would have been in the absence of the tax. Using the two definitions

$$(16) \quad \pi_t^g = \pi_t^n + T_t$$

$$(17) \quad T_t = v_t \pi_t^g$$

(where the superscript g stands for "gross-of-tax" and v_t is the tax rate), and dividing by K_t , (15) becomes

$$(18) \quad \frac{\pi_t^g}{K_t} = \frac{\pi_t'}{(1 - \alpha_5 v_t) K_t}.$$

(18) cannot be estimated by ordinary least squares, because the parameter α_5 appears in the denominator. K-M tried to escape the problem of nonlinear estimation by using the instrumental variables technique to estimate

$$(19) \quad \frac{\pi_t^g}{K_t} = \frac{\pi_t'}{K_t} + \alpha_5 v_t \frac{\pi_t^g}{K_t} + u'_t.$$

The independent variable $v_t \pi_t^q / K_t$ is a function of the dependent variable π_t^q / K_t and is thus correlated with the term u_t' . To avoid this difficulty K-M used the tax rate v_t as an instrument for $v_t \pi_t^q / K_t$. This procedure is an unreliable approximation to (18), as we shall see below in Part II.

We shall estimate (18) directly by an iterative method which is more efficient than the indirect K-M instrumental variable technique.¹¹ Using the definition $Z_t' = \pi_t' + D_t$, where D_t is depreciation, depletion, and interest paid, we can substitute (13) into (18). We obtain the complete equation derived from the preceding theoretical discussion for the estimation of the tax-shifting coefficient α_5 . (We give just the form for standardization by K_t from (13) and do not write separately the similar form derived from (14) for standardization by R_t .)

$$(20) \quad \frac{\pi_t^q}{K_t} = \alpha_1 \frac{R_t}{(1 - \alpha_5 v_t) h_t K_t} + \alpha_2 \frac{R_t^*}{(1 - \alpha_5 v_t) h_t K_t} + \alpha_3 \frac{\Delta p_t}{(1 - \alpha_5 v_t) p_t} \\ + \alpha_4 \frac{\Delta Q_t}{(1 - \alpha_5 v_t) Q_t} - \frac{D_t}{(1 - \alpha_5 v_t) K_t} + u_t'.$$

The first step in the estimation procedure is to linearize (20) by means of a Taylor series expansion around an arbitrary initial set of parameters. The resulting linear form is then used to estimate the difference between the true parameters and the arbitrary initial set. The procedure is completed after several iterations when the estimated difference between the true and fitted parameters is reduced to negligible size.

The technique of linearizing by means of a Taylor series expansion can be seen most clearly if we first perform it for a nonlinear function written in general form:

$$(21) \quad y_t = F(\beta_1, \dots, \beta_n; X_1, \dots, X_n) + u_t$$

where y_t is the dependent variable, the β_i are the coefficients to be estimated and the X_i are the independent variables. Consider an initial trial set of parameters

$$(22) \quad P^0 = (\beta_1^0, \dots, \beta_n^0)$$

where the superscript stands for the iteration number. In practice the initial set of parameters can be guessed from past experience or set equal to some arbitrary number. Each of the true parameters β_i which we are trying to estimate in (21) consists of our initial trial guess β_i^0 and an initial error $\Delta \beta_i^0$:

¹¹ A discussion of the general properties of nonlinear estimators can be found in [3, Ch. 10], and [12, p. 278].

$$(23) \quad \beta_i = \beta_i^0 + \Delta\beta_i^0.$$

Given β_i^0 from an initial trial, by estimating the initial errors $\Delta\beta_i^0$ we will be able to improve our estimates of the true coefficients β_i . Successive iterations should reduce the estimates of the successive errors $\Delta\beta_i^{(n)}$, $\Delta\beta_i^{(n+1)}$, ... to negligible size. We can use ordinary least squares to estimate the errors $\Delta\beta_i^0$ if we expand (21) in a Taylor series around the initial set of parameter estimates β_i^0 , retaining only the first order terms. First we substitute (23) into (21) to obtain an expression for y_i in terms of β_i^0 and $\Delta\beta_i^0$:

$$(24) \quad y_i = F(\beta_1^0 + \Delta\beta_1^0, \dots, \beta_n^0 + \Delta\beta_n^0; X_1, \dots, X_n) + u_i.$$

Next we perform the Taylor series expansion:

$$(25) \quad y_i = F(\beta_1^0, \dots, \beta_n^0; X_1, \dots, X_n) + \sum_{i=1}^n \Delta\beta_i^0 \frac{\partial F}{\partial \beta_i}(\beta_1^0, \dots, \beta_n^0; X_1, \dots, X_n) + u_i.$$

Now we simply substitute (20) into (25) and combine terms to obtain the actual form used in this paper for the estimation of the tax-shifting coefficient α_5 . For instance, the equation fitted for iteration number $(n+1)$ is:

$$(26) \quad \frac{\pi_t^0}{K_t} + \frac{D_t}{X_t^{(n)}K_t} = \alpha_1 \frac{R_t}{X_t^{(n)}h_tK_t} + \alpha_2 \frac{R_t^*}{X_t^{(n)}h_tK_t} + \alpha_3 \frac{\Delta p_t}{X_t^{(n)}p_t} + \alpha_4 \frac{\Delta Q_t}{X_t^{(n)}Q_t} + \Delta\alpha_5^{(n+1)} \frac{v_t}{[X_t^{(n)}]^2} \left[\alpha_1^{(n)} \frac{R_t}{h_tK_t} + \alpha_2^{(n)} \frac{R_t^*}{h_tK_t} + \alpha_3^{(n)} \frac{\Delta p_t}{p_t} + \alpha_4^{(n)} \frac{\Delta Q_t}{Q_t} - \frac{D_t}{K_t} \right] + u_t'.$$

The superscripts refer to the iteration number at which each term is evaluated, and $X_t^{(n)}$ stands for $(1 - \alpha_5^{(n)}\eta_t)$. The standard error of $\Delta\alpha_5$ in the final iteration is the standard error of the shifting parameter α_5 which is presented in the tables of results. (A similar form is derived from (14) for standardization by R_t).¹²

¹² The estimates of (26) were calculated on the IBM 1620 at the M.I.T. Sloan School of Management using a set of programs for nonlinear estimation written by the author. Each iteration was begun by setting all parameters equal to zero, and convergence was considered complete when the parameter $\Delta\alpha_5$ in (26) became less than .005 in absolute value. Three to four iterations were usually necessary to achieve this standard of convergence.

II. The Results

A. Comparison with Krzyzaniak and Musgrave

The K-M conclusions are radically different from our own. Since the two studies cover different time spans and include different variables in regressions estimated by different methods, we shall begin with the published K-M result and then change step-by-step to our results based on Part I above. Equation (I-1A) in Table 1 is the K-M so-called "standard model" [18, pp. 44-45], an estimate of the general model (18) by the instrumental variable technique (19).¹³ The coefficient of the tax variable $v\theta_i^m$ represents the well-known conclusion of the K-M book that the corporation income tax is shifted forward by almost 136 per cent of tax liabilities. Since the data we use have not been collected for 1942, that year is excluded in equation (I-1B), to facilitate comparison of the K-M results with ours. The removal of 1942 raises the tax shifting parameter to 1.455 and raises the Durbin-Watson statistic to 3.32, enough to allow the rejection of the hypothesis of no negative serial correlation.

NOTATION FOR TABLES 1-3

| | |
|------------------|---|
| ΔC_{t-1} | Annual lagged change in the ratio of consumption to GNP [18, p. 75]. |
| $D-W$ | Durbin-Watson statistic adjusted for omission of war years. |
| h_t | Ratio of industry wholesale price index p_t to wholesale price index for manufacturing aggregate (for computation see data appendix). |
| J_t | Ratio of tax accruals (all levels of government) other than corporate tax, minus government transfers, to GNP [18, p. 75]. |
| K_t | Total assets (book value in current dollars), from <i>Statistics of Income</i> . |
| p_t | Wholesale price index (for computation see data appendix). |
| Q_t | Hybrid real output (for computation see data appendix). |
| r_t^m | K-M measure of rate of return [18, p. 74]. |
| R_t | Gross sales from <i>Statistics of Income</i> . |
| R_t^* | Capacity real output times p_t (for computation see data appendix). |
| \bar{R}^2 | R^2 adjusted for degrees of freedom. |
| v_t | Tax rate (see data appendix). |
| $v\theta_i^m$ | Tax liabilities/capital [18, p. 74]. |
| V_{t-1} | Lagged ratio of inventories to sales in manufacturing [18, p. 75]. |
| Z_i^* | This dependent variable is written out in full in equation (26) above. |
| Z_i^q | Cash flow before tax = Profits before tax + Depreciation + Depletion + Interest paid. |

¹³ In all our results the Durbin-Watson statistic is adjusted for the omission of the observations for the war years.

In equation (I-1C) the K-M instrumental variable method is replaced by the more efficient nonlinear estimation technique described above. The result reveals the inaccuracy of the K-M approximation. The shifting parameter is reduced from 1.455 to .921, while the constant and the parameter on V_{t-1} are raised considerably. The instrumental equation (I-1B) also substantially exaggerates the goodness of fit of the K-M variables; the variance around the regression is over five times larger in (I-1C) than in the instrumental approximation (I-1B).¹⁴

Differences in specification between the K-M study and the present one are much more important than the different methods of estimation. The K-M variables were not derived from a stated set of hypotheses about profit behavior. A quick look at the data indicates that the significant t -coefficients in equation (I-1C) arise from historical coincidences. The change in the ratio of consumption to GNP (ΔC_t) tends to be positive in recessions (as predicted by most theories of the consumption function). Since profits tend to be high in the first post-recession year, the coefficient of the *lagged* K-M variable (ΔC_{t-1}) tends to be positive, as in Table 1. But the positive correlation between the rate of return and ΔC_{t-1} is just a coincidence owing to the fact that postwar recessions have lasted only one year. K-M's coefficient on ΔC_{t-1} would have been different if they had included all of the 1930s in their sample.

K-M could have justified the inventory-sales ratio (V_{t-1}) by considerations similar to ours in Part I. Inventories are a relatively fixed cost, and one would expect profits to increase with a decrease in the ratio of inventories to sales. But it makes no sense to lag the variable one year—this makes the lagged inventory-to-sales ratio reach a cyclical *peak* during the first post-recession year, when in fact one of the main reasons for high profits in the initial post-recession year is the *low* ratio of inventories to sales.¹⁵ The coefficients on V_{t-1} are significantly negative

¹⁴ The inaccuracy of the K-M instrumental technique can be demonstrated by two related experiments. First, it is known that the direct nonlinear procedure finds a local minimum of the residuals, but this does not exclude the possibility that the instrumental estimate in (I-1B) might be another local minimum. To test this possibility the direct nonlinear iteration procedure was initiated at the parameter values of I-1B and immediately converged to the values of I-1C, indicating that the values of I-1B are not a local minimum.

Second, the parameter values of I-1B, fitted by the instrumental variables technique, were substituted directly into the original theoretical equation (18). The resulting \bar{R}^2 between actual and fitted values was only .086, compared to .812 using the values from I-1C. The instrumental estimates are especially inaccurate for the Korean war period. In 1951, for instance, the fitted value of the rate of return is

$$\frac{1951}{(1 - \alpha_{1951})K_{1951}} = \frac{.052}{[1 - (1.455 \times .6775)]} = 365.9 \text{ per cent,}$$

compared with the actual 1951 value of 22.4 per cent.

¹⁵ The following are the annual postwar inventory/sales ratios for U.S. manufacturing for

despite this misspecification because the levels of both profit rates and V_{t-1} changed during World War II.

There is no justification for the third K-M variable, the ratio of tax accruals to GNP (J_t). If it expresses the thought that profits respond to aggregate demand, which usually rises when government spending expands, then government spending would be a better variable, and we would expect the coefficients to be positive. But in Table 1 the coefficients on J_t are all *negative*. The statistical significance of the negative coefficients on J_t is due to another coincidence: the dependent variable (the rate of return) declined somewhat from the early postwar years to the late 1950s, while the tax rate rose (from 38 per cent to 52 per cent). Thus the negative coefficient on J_t pulls down the value of the dependent variable predicted by taxes alone and results in an improved fit.

The second part of Table 1 shows the fitted results for our theory derived above in Part I, with the 19 observations which cover the K-M time span of 1935-41 and 1948-59.¹⁶ Equation (I-2K) is the fitted version of equation (26) above, with profits standardized by total assets (the rate of return concept). Equation (I-2R) is the same with profits standardized by revenue (the income share concept). The variance around the regression in (I-2K) is only about one-quarter of that in the K-M version (I-1C) estimated by the same nonlinear technique, and the Durbin-Watson test is more favorable. All the coefficients have the expected sign in both (I-2K) and (I-2R). As anticipated from our markup hypothesis of firm behavior, the income-share variable has less variance than the rate of return variable. Since the former can be better predicted than the latter by a constant alone, the \bar{R}^2 in (I-2R) is smaller than in (I-2K). Also, the theory above allowed no place for a constant term and in accord with this a priori expectation the fitted constants in (I-2K) and (I-2R) were insignificant (and the equations are shown in Table 1 as recomputed with the constant term suppressed). Most important of all, the parameter of tax shifting is not significantly different from zero.

K-M claim that years before 1935 cannot be included in a study of profits because the "inclusion of the early thirties would have been undesirable, and comparable data for the twenties are not readily available" [18, p. 23]. While the inclusion of the war years may be undesir-

the K-M years, 1948-59, as given in the 1966 *Economic Report of the President*, p. 254:

| | | | | | |
|------|-------|------|-------|------|-------|
| 1948 | 1.57 | 1952 | 1.78 | 1956 | 1.73 |
| 1949 | 1.75 | 1953 | 1.76 | 1957 | 1.80 |
| 1950 | 1.48* | 1954 | 1.81 | 1958 | 1.84 |
| 1951 | 1.66 | 1955 | 1.62* | 1959 | 1.70* |

An asterisk marks the values for the initial post-recession years, 1950, 1955, and 1959.

¹⁶ The data are described in the appendix.

able because of price and wage controls, such tampering with the marketplace was relatively minor during the early 1930s, and thus there is no obvious reason why the early 1930s should be omitted.¹⁷ Data for most of the 1920s are available or can be constructed. Hence, in the third section of Table 1, equations (I-3K) and (I-3R), the time period has been extended from 1935-41+1948-59 to 1925-41+1946-62 (making 34 observations instead of 19). The results for the longer period are strikingly similar to those for the shorter period, indicating that the pre-1935 behavioral relationships are not very different from the post-1935 results. All coefficients have the expected signs, and all are highly significant except for the price change coefficient in (I-3K) and the tax-shifting parameters. As in the shorter period the tax-shifting coefficients are very low and are not significantly different from zero. The values of the coefficients for each variable are roughly the same in both the rate of return (I-3K) and the income share (I-3R) formulation. The Durbin-Watson test is inconclusive in (I-3K) and allows us to accept the hypothesis of no serial correlation at the 5 per cent level in (I-3R).

B. *The Detailed Results by Industry*

The data available in [25] for the 1920s include only eleven two-digit manufacturing industries. Excluding the Miscellaneous category, whose composition frequently changes, we are left with ten two-digit industries for which IRS data are available since 1924. After 1936 the data for twenty two-digit industries are published, but fortunately it was easy to combine these into the original ten for this long-period time series study. The construction of a wholesale price series (for the $\Delta p_i/p_i$ variable) for these ten industries was much less straightforward, as is explained in the data appendix. Table 2 shows two equations for each of the ten industries; as in Table 1 the set of "K" equations is standardized by total assets and the "R" equations by gross sales. As expected from our markup hypothesis of firm behavior, the markup fraction varies less over time than the rate of return, so that the dependent variable in the "R" equations has less variance than in the "K" equations. Since the former can be better predicted than the latter by a constant term alone, it is not surprising to see that in every industry the \bar{R}^2 for the "R" equation is lower than that for the "K" equation.

The significance of the parameters α_1 through α_5 in Table 2 should be judged by a one-tailed *t* test, for which the five per cent value is 1.64 and the one per cent value is 2.32. By this standard all of the 20 esti-

¹⁷ It did not appear worthwhile to adjust for the discontinuation of consolidated returns in 1934. Michael Gort [6, p. 297] comments that the changes in gross income shown in the *Statistics of Income* for 1934 raise doubts about the consistency of the classification principles used in 1933 and 1934.

ated α_1 coefficients in Table 2 are significant at the one per cent level. Seventeen of the 20 coefficients α_2 are significant at the one per cent level, while three are insignificant. Fourteen of the α_3 price change coefficients are significant at better than the five per cent level, as are 12 of the α_4 output change coefficients. Only in the Chemical and Petroleum industry is neither price nor output change significant. All insignificant coefficients have the expected sign—positive for α_1 , α_3 , and α_4 , and negative for α_2 .

Of the 20 tax-shifting parameters, eight are significantly positive at the one per cent level, two are significantly negative at the one per cent level and one at the five per cent level. The remaining nine are insignificant. Overall, the industry results in Table 2 give a description of tax-shifting behavior very similar to that of the aggregate equations in Table 1. In the aggregate equations for the full set of 34 observations, (I-3K) and (I-3R) in Table 1, the estimated tax-shifting parameters are .115 and .057 respectively, while in Table 2 the weighted averages of the equivalent tax parameters are .110 and .003.¹⁸ Thus the aggregate and industry equations tell a consistent story—tax shifting in manufacturing is not significantly different from zero, although it is significantly greater than zero in the Paper, Chemicals and Petroleum, Rubber, and Stone industries, and significantly less than zero in the Printing industry and in one equation for the Food industry.

Although the markup theory presented in Part I is supported here to a substantial degree, in several industries it was necessary to make modifications on the *a priori* equations (13) and (14). First, in the Food, Textile, and Printing industries, the fit of the "K" equations was substantially improved by adding a constant term (the markup theory as developed above is supported to the extent that the constant terms were insignificant in the other seven industries, and for these industries the equations, as shown in Table 2, were recomputed without a constant term). The second modification to the original theoretical equations (13) and (14) in the Food, Lumber, Paper, Printing, and Metal industries was to set

$$h_t = 1, \quad t = 1, \dots, 34$$

where h_t , as defined above, is the price index for the industry's output divided by the price index for aggregate manufacturing output. This was made necessary because for these five industries our original assumption about h_t exaggerated the effect of relative prices on profits and thus worsened the \bar{R}^2 and Durbin-Watson statistics. For the remaining five industries h_t was included and the results were satisfactory. Neither

¹⁸ They are weighted by 1935-39 value added, the weights used by the Federal Reserve Board Index of Industrial Production during the middle of our period.

of these modifications had an appreciable effect on the tax-shifting parameters.¹⁹

III. *Tax Shifting and Industry Concentration*

The hypothesis of forward tax shifting requires that firms have sufficient market power successfully to increase pre-tax profits following a tax rate increase. Robert W. Kilpatrick [17] has recently suggested that, if the tax rate is lower in period m than in another period n , a significant cross-section correlation between an industry's concentration ratio C_i and the change in its profit rate over the interval from m to n (r_n/r_m) _{i} is de facto evidence of tax shifting. Kilpatrick tested the model

$$(27) \quad \left(\frac{r_n}{r_m} \right)_i = a + bC_i + u_i$$

for about 100 industries with an initial time period of 1947-49, when the corporate tax rate was 38 per cent, and the terminal time period 1955-57, when the rate was 52 per cent. Experiments were run for explanatory variables in addition to C_i , such as changes in sales and assorted cost factors. Kilpatrick's equations were unable to explain more than a small fraction of the interindustry variance of r_n/r_m (the \bar{R}^2 values were in the .20 to .30 range), but the coefficients on C_i were significantly greater than zero. And on the assumption $a=1$, Kilpatrick was led by these significant coefficients to accept the hypothesis of tax shifting in the 60-80 per cent range in manufacturing.

Two important questions may be raised regarding Kilpatrick's results. Although market power is necessary for tax shifting to exist, it is not a sufficient condition. During any given span of years, the profits of firms in concentrated industries may rise more (or fall less) than those of firms in more competitive industries *independently* of changes in the tax rate. Thus profit rates fell much less between 1929 and 1933 in the concentrated tobacco and aluminum industries than in the unconcentrated textile industry. In short, Kilpatrick might have found the same sig-

¹⁹ The modifications mentioned in this paragraph are the most important weaknesses in the results, but there do not seem to be any other major econometric problems. If profit rates influence the independent variables at all, it is through the indirect effect of profits on the demand for investment goods and on dividend payments, and thus through them on output, utilization, etc. This chain of causation is probably extended over several years, and it is likely that serious simultaneity problems are absent. Multicollinearity among the independent variables has been eliminated by standardizing the equations by K_i and R_i . It is surprising to find that the correlation between $\Delta p_i/p_i$ and $\Delta Q_i/Q_i$ is quite low (.32 for the aggregate).

One minor difficulty results from assumptions (8), (9), and (10), which impart a slight downward bias of approximately 10 per cent to our estimates of α_5 in this study. A correction for this bias would raise the tax-shifting parameter in (I-3K), for example, from .11 to .12. This bias was discovered after the computations were completed and was not considered serious enough to warrant changing the tables.

nificant coefficient on C_i if he had tested his hypothesis for two periods with similar tax rates, or between two periods when tax rates *fell*. The second question relates to Kilpatrick's assumption that $\alpha=1$ in (27) above, so that any positive coefficient on C_i could be interpreted as evidence of positive shifting. The tacit assumption is that shifting would be zero only for a perfectly competitive industry with $C_i=0$. But the results in this paper suggest that this assumption is wrong. We can fit a

Column (2): Average for 1947, 1954, and 1958 for each industry of the percentage of sales in each of its constituent four digit industries accounted for by the top four firms (Concentration ratios). Source: [1, p. 335], combined into ratios for our ten industries using as weights industry value added in 1947, 1954, and 1958.

Column (3): Average for all years of ratio of Cash flow before tax to Total assets (Z/K).

Column (4): Average for all years of ratio of Cash flow before tax to Gross sales (Z/R).

Column (5): Average for all years of ratio of Total assets to Gross sales (K/R).

cross-section regression for our ten industries to measure the dependence of the average rate of tax shifting TS_i on the concentration ratio C_i .²⁰

$$(28) \quad TS_i = -.435 + 2.017C_i; \quad \bar{R}^2 = .381 \\ [-1.360] \quad [2.221]$$

The data for this regression are shown in the first two columns of Table 3. The result is that although the coefficient on the concentration ratio is significantly greater than zero, as in Kilpatrick's study, the constant here is negative, admitting the possibility of a positive relationship between tax shifting and concentration but nevertheless an *average* rate of tax shifting for all manufacturing industries which is not significantly different from zero.

The "negative shifting" for relatively unconcentrated industries suggested by (28) is not necessarily related to the increase in the tax

²⁰ As in all our results the numbers in brackets are *t*-statistics, not standard errors.

rate since the 1920s. An increasing ratio of sales to assets over time will lead to a rising pre-tax rate of return on assets if a constant markup policy is followed. In unconcentrated industries the rising rate of return will attract new entrepreneurs who are unable to enter more concentrated high-barrier industries. Thus the before-tax rate of return in unconcentrated industries may not rise with the increasing productivity of assets, and in fact the rate of return may be so depressed (driven down by a surfeit of entrants who are frustrated by barriers in other fields), that a regression shows negative tax shifting. Note that entry can occur even without an initial rise in the *after-tax* rate of return if all alternative investment yields are equally reduced by the tax. This may be true in the United States where corporation income tax and personal income tax rates (the latter applying to income from unincorporated business and financial assets except for capital gains) have increased simultaneously.

Most of this paper has concentrated on the reasons for changes in profit rates over time for a given industry. Here we can briefly inquire into the determinants of the level of the markup margin (Z/R) at any given time. While the markup margin was much more constant than the rate of return on assets (Z/K) over time for each industry, the *average* level of the rate of return shows considerably less interindustry variance than the average markup margin. Except for Textiles and Leather, competition among industries for investment funds, as economic theory would predict, has caused average levels of the rate of return to cluster around a fairly constant level (11-14 per cent). Although the average levels of markup margins vary much more than rates of return, the former can be explained reasonably well by capital-intensiveness and industry concentration:

$$(29) \quad (Z/R)_i = -0.046 + .118 (K/R)_i + .090 C_i; \quad \bar{R}^2 = .869$$

$$\quad \quad \quad [-2.097] \quad [6.106] \quad [2.420]$$

IV. Conclusion

By following a markup pricing policy during a period in which the average productivity of assets grew, manufacturing corporations were able to maintain a fairly constant ratio of pre-tax profits to sales. Thus their average pre-tax rate of return on assets rose with the rising productivity of assets. Corporate rates of return in manufacturing were improved by the growing productivity of capital in much the same way that wages increased with the growing average productivity of labor. But firms on the average were not able to go beyond this and shift the burden of increased corporation income tax rates. This conclusion is more plausible than the contention by Krzyzaniak and Musgrave that corporations succeeded in shifting more than 100 per cent of their tax liability. In a period during which strong labor unions possessed coun-

tervailing power, why would they have *allowed* corporations fully to shift the burden of the corporate tax? The aggressive corporate behavior postulated by Krzyzaniak and Musgrave would have resulted not in successful tax shifting, but in subsequent union wage demands, an inflationary spiral, and an *unchanged* pre-tax corporate rate of return.

The incidence of the corporation income tax is determined by the effect of the tax on the corporate income share. Corporations suffer the full burden of the tax unless they can increase their pre-tax income share in response to a tax rate increase. In their second chapter Krzyzaniak and Musgrave were puzzled by the apparent lack of shifting when measured relative to the corporate income share. They were unable to conclude that the burden of the corporation income tax had been shifted from capital to labor, because their high shifting parameter of more than 100 per cent was a measurement relative to the corporate rate of return, not the corporate income share. The changing productivity of both labor and capital during the period prevents any conclusion from rate-of-return data on the extent to which labor suffered the burden of the corporate tax. The inconsistency between the rate of return and income share measures of tax shifting in the Krzyzaniak and Musgrave study was due to an inadequate specification of the determinants of the rate of return on assets.

The present study contributes to clearing up this mystery which Krzyzaniak and Musgrave were unable to solve. The model of markup pricing behavior specifies productivity as an input, and as a result consistent tax shifting coefficients are obtained relative to *both* the corporate rate of return and the income share. This paper thus offers a general parameter measuring the incidence of a tax burden on factor shares, and concludes that between 1925 and 1962 corporations suffered the full burden of the tax.

This study also points out a weakness in the recent study by Kilpatrick [17]; evidence that changes in profits are related to market power does not imply that on the average in manufacturing the corporate tax is shifted. Markup pricing behavior does not necessarily involve forward tax shifting, because if businessmen are operating at what they think is an optimal price-output combination, the mere introduction of a profits tax will not change this combination. We found that industries with high concentration ratios tend to have higher tax-shifting parameters than less concentrated industries, but this result can be interpreted merely to mean that during the last 40 years, a period of rising tax rates, the rate of return of firms in concentrated industries where barriers to entry are high has risen relative to industries where the rate of return is more subject to the depressing effects of entry.

No conclusions are reached in this study about the degree of *long-run* tax shifting. Even if, as concluded here, corporations do not raise prices

to shift the tax in the short run, they may nevertheless be able to shift the tax in the long run by reducing their investment and substituting other factors for capital. A reduction in the desired ratio of capital to output implies an increase in the average productivity of capital, which is shown in this study to be a major determinant of the pre-tax rate of return on assets. If it could be demonstrated that the increased corporation income tax rate since the 1920s has been the principal cause of the increased average productivity of capital over our period, this would suggest that the tax has been shifted in the long run.²¹ A final conclusion on this issue must await a thorough study of the causes of the increase in the average productivity of capital between the 1920s and 1950s, taking account not only of changes in tax rates, but also of the rate and bias of technological change, the change in the price of capital goods relative to output, changes in the industrial composition of demand, and other factors.²²

²¹ But evidence that the higher tax rate reduced investment would not necessarily change our conclusion about the incidence of the tax—that corporations have suffered the full burden. A reduction in investment would have increased the rate of return, but only at the cost of a smaller capital base relative to sales. For corporations to have escaped some of the burden of the tax, the pre-tax corporate income share would have had to rise, which would have occurred only if the aggregate production function were characterized by an elasticity of substitution smaller than one. If this were true, the boost to the income share induced over our period by the higher tax rate would have resulted in significantly positive coefficients on the tax parameter in the income-share equations of Table 1, but in fact the coefficients are not significantly different from zero.

²² The causes of changes in the capital-output ratio over this period are the subject of the author's current research. There are at least two pieces of evidence which suggest that the corporation income tax rate has not been the main cause of the increase in the average productivity of capital since 1920, and thus that the tax has not been substantially shifted in the long-run. First, most of the increase in R^*/K in this study occurs before 1940, while the main increase in the tax rate occurred after that date. This sequence would have to be reversed for long-run tax shifting to have occurred.

Second, a calculation has been made to determine the effect of changes in the corporation income tax rate on investment for a profit-maximizing firm, using the investment theory developed by Jorgenson [14] [15]. In this theory the desired stock of capital and hence desired investment is influenced by the tax through the effect of the latter on the real price of capital services. The real price of capital services can be shown to be independent of the corporation income tax rate if there is no accelerated depreciation and if the pre-tax interest rate is unchanged by the tax.

Consider the following version of equation (6) in the recent paper by Hall and Jorgenson [9], adapted here to allow for tax shifting, to exclude the tax-credit term, and to state explicitly that r is the pre-tax interest rate.

$$(30) \quad \frac{c}{p} = \frac{(1 - wvz)q}{(1 - wv)p} [r(1 - wv) + \delta]$$

c/p is the real price of capital services, q/p is the real price of investment goods, v is the tax rate, z is the present value of the depreciation deduction, r is the pre-tax interest rate, δ is the depreciation rate, and w is a tax-shifting parameter ($w=0$ for full shifting and $w=1$ when shifting is completely absent, thus $w=1-\alpha_s$). A calculation of c/p for (30) with data similar to that used in [9] shows that c/p is the same for all values of w between 0 and 1.3. Thus this calculation casts doubt on the usual assumption that a corporation income tax which is not shifted in the short run necessarily reduces investment.

DATA APPENDIX

A. Financial Series from *Statistics of Income* [25].

1. "Total assets," K_t . Includes fixed assets, inventories, and liquid assets.
2. "Gross sales," R_t . This figure should not be confused with Gross Receipts, which includes receipts from sources other than sales.
3. "Depreciation, depletion, and interest paid," D_t .
4. "Net profits before taxes," π_t^e . Includes all corporations, including those reporting no net income.

B. Constructed Series.

1. "Total apparent tax rate," v_t . Sometimes, particularly in 1941 and 1950, tax rates were raised in the latter part of the year, but corporations were liable for payment at the increased rate for their profits of the entire year. Thus the *ex post* ratio of tax liabilities to taxable profits is an overestimate of the tax rate which management *thought* was in effect at a given time. To correct this, our "apparent" tax series is an average of the legal tax rates for each year, weighted by the proportion of the year over which they were in effect. Also, we can't consider the legal excess profits tax rate (used by Krzyzaniak and Musgrave) to reflect the actual burden of the tax on all corporations in an industry, since not all corporations earned excess profits. The excess profits tax rate is multiplied by an estimate of the ratio of corporate profits subject to the tax to all corporate profits.

2. "Wholesale price index," p_t . This was a difficult series to construct, because the reported Industry subgroups in the BLS wholesale price index have changed repeatedly, and because the weights necessary to combine them to correspond to our industry classification have changed over time. A detailed documentation of the methods and weights used for each industry is available on request.

3. "Hybrid real output in constant dollars," Q_t . Since the Index of industrial production (I.I.P.) and the Wholesale price index (W.P.I.) were computed in completely different ways with different industry definitions and differing assumptions about quality and productivity change, it is not surprising to find that the I.I.P. and Sales deflated by W.P.I. show different trends in the growth of real output for some industries. I selected deflated Gross sales as the better measure of the trend of real output, but I

lean to I.I.P. as the better indicator of cyclical variation, particularly in some of the postwar recessions. To achieve the best compromise a hybrid measure was constructed, which equals deflated Gross sales in selected base years, but the movements of which in nonbase years are proportional to I.I.P.

4. Capacity series, R_t^* . Any attempt to construct capacity and utilization series by industry is bound to be based to a considerable extent on guesswork. In previous studies the general procedure in computing capacity has usually been to take a given year, to assume that utilization was 100 per cent during that year, and that capacity output grew at a fixed trend rate between one capacity year and another. We cannot use existing utilization indices for this study since they extend back only to 1947, and in addition the usual procedure needs to be refined somewhat to take account of the fact that utilization is not the same in all "full capacity" years, and of the probability that the growth of capacity between base years is uneven.

A very brief description of the procedure is as follows (a more complete documentation is available from the author on request). My first step was to select years during which utilization probably reached a cyclical peak. The years chosen for each industry were different, but they had the common characteristic that output was rising rapidly to a plateau substantially higher than previous output peaks, while real capital was rising relatively slowly. Next, for each industry I guessed a number between .90 and .98 as the average utilization rate during each peak year. Outside evidence, e.g., the monthly pattern of output within the year and comment in contemporary business periodicals, was used as a guide in the selection process. This procedure results in a capacity figure for each industry for each year of peak utilization.

Finally, the change in capacity between years of peak utilization is not assumed to be linear as in many previous studies of postwar utilization. The annual rate of growth of capacity equals the rate of growth of real fixed capital in each year plus the rate of growth of the ratio of capacity to fixed capital from the previous year of peak utilization to the next.

The data for real fixed capital are book value figures from [25] for each industry, adjusted for changes in the definition of capital and deflated by an unpublished Department of Commerce implicit price index for the stock of fixed capital in manufacturing.

Capacity in current dollars, R_t^* , equals real capacity as calculated above times p_t .

THE ROLE OF A STOCK MARKET IN A GENERAL EQUILIBRIUM MODEL WITH TECHNO- LOGICAL UNCERTAINTY

By PETER A. DIAMOND*

Moving from the certainty model of general equilibrium to one with uncertainty, the constructors of the model¹ with contingent commodity markets have given considerable insight into the problems of uncertainty for an economy. However, the construction of perfect insurance markets, where all risks are insurable, does not lend itself well to understanding the economy's imperfect solution of these problems. The model presented here is an example of an imperfect solution where a stock market permits the sharing of risks, but only incompletely. This will permit examination of the handling of risks by such an economy, as well as the shortcomings of this handling. An important element in any model involving uncertainty is the source of probabilities used in decision making and the ultimate location of risk-bearing. In the contingent commodity model, firms bear no risks in the sense that no probability distributions are needed to calculate firm decision rules or profits accruing to firm owners, and all risks are borne by consumers. With a stock market, however, where shareholders receive residual profits after the completion of production under technological uncertainty, firm owners do bear risks and need to use their subjective probabilities in determining their portfolio structures. Paralleling the contingent commodity model, however, firms planning production to maximize stock market value employ no probabilities in their calculations, relying instead on determinate, concurrent market phenomena, the prices inherent in the stock market.

By means of a one-period one-commodity model it is shown that firm behavior based on this rule, combined with trading in the stock market to maximize expected utility, results in a competitive economy's achieving a constrained Pareto optimum. The constraint does not arise from an inability of individual firms to use the pooling advantages implied by the law of large numbers, for with stock market value maximization by firms and portfolio diversification by wealth owners, all of the economy's

* The author is associate professor of economics at M.I.T. He wishes to thank Bernard Saffran for many helpful comments on this paper and the Social Science Research Council, the Guggenheim Foundation, and the National Science Foundation for financial assistance during the time he worked on this paper. During part of this time he was an Overseas Fellow at Churchill College, Cambridge. Errors and opinions belong solely to the author.

¹ The contingent commodity model of an exchange economy is presented in Arrow [1]. The model with production is in Debreu [4].

averaging possibilities are brought to bear on each production decision. Rather, the constraint, that consumption patterns across the states of nature be linear combinations of firm output patterns, arises from an inability to distinguish finely among the states of nature in the economy's trading.

The highly restrictive one-period one-good model is not employed simply for heuristic purposes, for an increase to two periods or goods in a seemingly natural way (the stock market reopening at the start of the second period or commodities traded after the completion of production) introduces a different element from technological uncertainty-price uncertainty. In the presence of only technological uncertainty, current trading on the stock market does not affect future probabilities of the states of nature. Nor does it convey information about those probabilities. Thus, in this model, individuals have subjective probabilities at the start of trading which are not altered. However, with price uncertainty current trading does affect future prices and does convey information about the tastes of other consumers which is relevant for subjective probabilities of future prices. It then becomes necessary to consider the extraction of this information, the alteration of subjective probabilities, and the change of market demands in the process of trading. These problems do not arise in the simple model considered. Thus this model is static in the important sense that all trading occurs at one time. (Both the certainty and contingent commodity uncertainty general equilibrium models are static in this sense, as is any perfect foresight model.) The model is static also in the sense that no one learns anything which affects his decisions. (Prices are reacted to, but this is not taken to convey new information which, for example, might lead to a change in subjective probabilities.)

Following a description of the technology is an examination of a centrally planned economy with restricted planning abilities, which therefore achieves a constrained Pareto optimum. In this way the conditions for the constrained optimum are obtained. It is then shown that a competitive equilibrium satisfies these conditions. The validity, in this model, of the Modigliani-Miller propositions is then examined, as well as the treatment of uncertainty for government investment. The appendix contains a brief description of the contingent commodity model in order to present the analogy between production decisions in the two models.

I. *States of Nature*

To introduce technological uncertainty, it is assumed that production functions of the individual firms can be written as functions of the input and a random variable reflecting the state of nature.² Thus the

² In addition to the assumption of a single input and a single output, it is assumed that the

output of the j th firm, if state θ occurs, is a function of the input level to the j th firm³ (which is independent of θ) and the state of nature. Algebraically,⁴

$$(1) \quad y_j(\theta) = f^j(\theta, k_j).$$

Thus, for example, the output of corn if θ inches of rain fall depends on the number of inches of rain and the input of seed. The pattern of output of the j th firm across the states of nature, $y_j(\theta)$, can be thought of as a joint product resulting from the input level k_j . In the special case where the production function is decomposable,

$$(2) \quad y_j(\theta) = f_j(\theta)g_j(k_j),$$

the output pattern (suitably normalized) can be considered a composite commodity since its individual elements are produced in fixed proportions. In this case, a change in input level alters the scale of output but not the pattern of output across the states of nature. It is assumed that the set of firms is fixed for the analysis. This eliminates not only searching for new investment opportunities but also the creation of insurance firms (although existing insurance firms can be fitted into the model [see below, section 5]).

Each consumer is assumed to have his own subjective probability density over the states of nature, $h_i(\theta)$, and a utility function of consumption,⁵ $U_i(c_i)$, and to be interested in maximizing expected utility,⁶

$$(3) \quad V_i = \int U_i(c_i(\theta))h_i(\theta)d\theta.$$

It is assumed that after its occurrence the state θ which has occurred is known by all. In an insurance setting, this rules out some of the prob-

states of nature can be described by a single, continuous random variable. While the assumption of knowledge of the relationship of the random variable to output is restrictive, the ability to parametrize the states of nature on a single variable is not important.

³ Additional inputs contracted for before the state of nature is known add no complication. However, inputs hired after θ is known (e.g., labor to harvest the crop) involve trading more than once, implying price uncertainty, and thus do not fit within this model. Inputs employed after the state of nature is known but hired on a contingent basis before it is known would simply represent the addition of particular contingent commodity markets to the existing stock market. This creates no complication.

⁴ It is assumed that f^j is twice continuously differentiable for all j , with $f_{k^j}^j > 0$, $f_{k^j k^j}^j < 0$.

⁵ It is assumed that U_i is twice continuously differentiable for all i , with $U_i' > 0$, $U_i'' < 0$.

⁶ All integrals are assumed to exist. Writing expected utility in this form (additivity vis-à-vis consumption in the different states of nature with the same utility function, except for a scalar) is highly restrictive, ignoring, for example, the impact of rain on the utility derived from an umbrella. Dropping this assumption alters no results in the text, but does alter the descriptive elements in the appendix.

lems arising from moral hazards. (For a discussion of the informational aspects of insurance, which are lacking in the model, see Arrow [2].)

II. Centrally Planned Economy

Before examining a centrally planned economy, it is necessary to consider the expression of its objectives. A natural extension of the certainty concept is to define Pareto optimality in terms of the expected utilities, V_i . This implies that the planner uses different probabilities in calculating the expected utilities of different individuals, since, in general, the h_i vary among individuals.^{7,8}

If a central planner with control over all economic variables, k_i and $c_i(\theta)$, seeks a Pareto optimum, he will produce an allocation which could be achieved by a competitive economy with a complete set of contingent commodity markets (discussed in the Appendix). The cost elements which limit the set of markets in a competitive economy might also limit the degree of control exercised by a planner. So we shall consider a planner with somewhat limited powers, chosen in a manner so that a competitive economy with a stock market can achieve the same allocation. Thus, by examining the restrictions on a planner which result in the same allocation, we can gain some insight into the limitations inherent in a stock market.

We shall continue to assume that the planner has full control over allocation of the input, but we shall lessen his control over the distribution of output at the completion of production. We shall assume that all distribution instructions are given before production occurs and that they take one of the following two simple forms. Firms are instructed to deliver to given individuals given fractions of their output independent of the state of nature. Let α_{ij} be the fraction of its output the j th firm delivers to the i th individual.⁹ Individuals are instructed to

⁷ This is the concept employed by Arrow [1] and Debreu [4].

⁸ The social welfare function which fits with this definition of Pareto optimum, in the sense that a Pareto optimum is a necessary condition for maximizing the welfare function, is a function of the levels of expected utility. Algebraically we have $W(V_1, V_2, \dots, V_m)$.

An alternative approach to extending the certainty concept of social welfare is to calculate expected social welfare (using a probability distribution chosen in some fashion) where welfare is a function of achieved utilities. This would be written as $\int W(U_1(c_1(\theta)), U_2(c_2(\theta)), \dots, U_m(c_m(\theta)))h(\theta)d\theta$. In general this approach is not consistent with the definition of Pareto optimality given above. (While this approach does not require knowledge of h_i it still requires knowledge of U_i).

Each of these simplifications is well constructed for some of the aspects of social welfare. The latter can take account of the costs, e.g., through envy, in the spread of achieved utilities. The former, however, allows for a concept of justice in terms of expected utilities relative to θ . For this reason the former concept is preferred, and the definition of Pareto optimality given above, which yields optimality results similar to those under certainty, will be employed in calculating efficiency conditions.

⁹ The constraint $\alpha_{ij} \geq 0$ are assumed not to be binding in the maximization below (i.e., everyone receives something from each firm). It is assumed that there are no delivery costs. Further, the constraint $c_i(\theta) \geq 0$, which implies a constraint on α_i is also assumed not to be binding.

deliver to other individuals fixed quantities of output independent of the state of nature. Let α_i be the net quantity the i th individual receives in this fashion. The planner then controls k_j , α_{ij} , and α_i .

These restrictions imply that consumption of the i th individual in terms of the control parameters can be written

$$(4) \quad c_i(\theta) = \alpha_i + \sum_{j=1}^n \alpha_{ij} f^j(\theta, k_j).$$

This, then, is the linearity constraint, that consumption patterns be a linear combination of output patterns, i.e., that consumption be the same linear combination of firm outputs in all states of nature. Using equation (4) for all individuals but the first, the constraint that total consumption equal total output can be expressed by writing the consumption of the first consumer as

$$(5) \quad c_1(\theta) = - \sum_{i=2}^m \alpha_i + \sum_{j=1}^n \left(1 - \sum_{i=2}^m \alpha_{ij} \right) f^j(\theta, k_j).$$

Thus the net flows between individuals add to zero and the fractions of each firm's output received add to one.

With these constraints on consumption patterns and the constraint on available input supply,

$$(6) \quad \sum_{j=1}^n k_j = k,$$

we can express the conditions for a Pareto optimum by maximizing expected utility of the first individual

$$\int U_1(c_1(\theta)) h_1(\theta) d\theta$$

subject to constraints on the expected utility levels of the other $m-1$ consumers

$$(7) \quad \int U_i(c_i(\theta)) h_i(\theta) d\theta = \bar{V}_i.$$

Substituting for $c_i(\theta)$ from equations (4) and (5) and forming the Lagrangian expression,

$$(8) \quad \int U_1 \left(- \sum_{i=2}^m \alpha_i + \sum_{j=1}^n \left(1 - \sum_{i=2}^m \alpha_{ij} \right) f^j(\theta, k_j) \right) h_1(\theta) d\theta \\ + \sum_{i=2}^m \lambda_i \left(\int U_i \left(\alpha_i + \sum_{j=1}^n \alpha_{ij} f^j(\theta, k_j) \right) h_i(\theta) d\theta - \bar{V}_i \right) + \mu \left(k - \sum_{j=2}^n k_j \right),$$

we can calculate the first order conditions. Differentiation with respect to α_i and α_{ij} gives

$$(9) \quad \begin{aligned} - \int U'_1 h_1 d\theta + \lambda_i \int U'_i h_i d\theta &= 0, & i = 2, 3, \dots, m, \\ - \int U'_1 f^j(\theta, k_j) h_1 d\theta + \lambda_1 \int U'_1 f^j(\theta, k_j) h_1 d\theta &= 0 & \begin{matrix} i = 2, 3, \dots, m, \\ j = 1, 2, \dots, n. \end{matrix} \end{aligned}$$

Eliminating λ_i from the equations we have $(m-1)n$ equations

$$(10) \quad \frac{\int U'_i f^j(\theta, k_j) h_i d\theta}{\int U'_i h_i d\theta} = \frac{\int U'_1 f^j(\theta, k_j) h_1 d\theta}{\int U'_1 h_1 d\theta}, \quad \begin{matrix} i = 2, 3, \dots, m, \\ j = 1, 2, \dots, n. \end{matrix}$$

Recalling the interpretation of the output pattern of a firm over states of nature as a joint product, equation (10) expresses the equality among consumers of the marginal rates of substitution for these joint products, where the marginal rate of substitution is expressed in terms of expected marginal utility.

Differentiation of (8) with respect to k_j gives

$$(11) \quad \int U'_1 \left(1 - \sum_{i=2}^m \alpha_{ij} \right) f_k^j h_1 d\theta + \sum_{i=2}^m \lambda_i \alpha_{ij} \int U'_i f_k^j h_i d\theta = \mu, \\ j = 1, 2, \dots, n,$$

where f_k^j is the marginal product of the input (and varies with θ). Eliminating λ_i from the equations (11) we obtain

$$(12) \quad \frac{\int U'_1 f_k^j h_1 d\theta}{\int U'_1 h_1 d\theta} + \sum_{i=2}^m \alpha_{ij} \left[\frac{\int U'_i f_k^j h_i d\theta}{\int U'_i h_i d\theta} - \frac{\int U'_1 f_k^j h_1 d\theta}{\int U'_1 h_1 d\theta} \right] = \frac{\mu}{\int U'_1 h_1 d\theta},$$

where the right-hand side is independent of θ , since θ appears solely as a variable of integration.

In the special case of a decomposable production function, equation (2), we have

$$f_k^j(\theta, k_j) = f_j(\theta) g_j'(k_j).$$

Thus the equality of marginal rates of substitution, equation (10), implies that all the terms on the left-hand side, except the first, vanish. Eliminating μ we have the allocation rule

$$(13) \quad \frac{g'_j}{g'_i} = \frac{\int U'_1 f_1 h_1 d\theta}{\int U'_1 f_j h_1 d\theta}, \quad j = 2, 3, \dots, n.$$

With the interpretation of output patterns as composite commodities, this expresses an equality between the marginal rate of transformation and the marginal rate of substitution.

III. *Stock Market Equilibrium*

Let us now consider a competitive economy with the same technology as above. The initial conditions are the ownership of the supplies of input and the shares of stock of the firms. Let w_i be the supply of input and w_{ij} the fraction of the j th firm owned by the i th consumer. Simultaneously trading occurs to reach an equilibrium in the factor market, the stock market, and a bond market, not yet introduced. At the completion of trading, each firm produces with the factors hired under whatever state of nature occurs. Factors are then paid their wages (the wage contract, although fulfilled after production, is set in real terms independent of the state of nature). Let r be the payment per unit for the factor. The remaining profits, which if state θ has occurred, are

$$(14) \quad \pi_j(\theta) = f^j(\theta, k_j) - rk_j,$$

are then distributed to the owners in proportion to their ownership of stock.

Denoting the value of the i th individual's equilibrium holdings of the stock of the j th firm by s_{ij} ,¹⁰ the total stock market value of the j th firm, M_j , can be written

$$(15) \quad M_j = \sum_{i=1}^m s_{ij}.$$

The fraction of the firm owned by the i th consumer is then s_{ij}/M_j and the consumption goods he receives from the j th firm are

$$(16) \quad s_{ij} M_j^{-1} \pi_j(\theta).$$

Thus, s_{ij}/M_j is the equilibrium fraction of the firm owned, while w_{ij} was the initial fraction. With this framework, stockholders need to know

¹⁰ It is assumed that the constraint $s_{ij} \geq 0$ is not binding (i.e., everyone owns stock in each firm). This constraint, and the corresponding one for the planned economy can be dropped without altering the basic optimality results, although the analysis becomes more complicated. However, the Modigliani-Miller results may be affected by binding constraints on financial behavior.

the relationship of θ to profits although only entrepreneurs need to know the relationship between inputs and output which determines this relationship. In a certainty model firm owners know the level of profits, again without needing to know the combination of inputs and outputs resulting in the profit. This increase in information required for the result, while a natural extension is a significant increase.

In addition to the stock market let us assume there is a bond market where individuals trade promises to pay fixed amounts of consumption, independent of the state of nature, at the completion of the production process. It is assumed that all bond commitments and commitments to the factors of production, are met (bankruptcy never occurs). For convenience let us define one unit of bond as a promise to pay r units of consumption where r is the factor wage. Then, an individual receives fixed payments for both the input he owns and the bonds he holds. Let b_i be the sum of these two elements. We can now write the expression for consumption of the i th individual as

$$(17) \quad c_i(\theta) = rb_i + \sum_{j=1}^n s_{ij}M_j^{-1}\pi_j(\theta).$$

By trading on the stock and bond markets, the consumer seeks to select b_i and s_{ij} to maximize expected utility,

$$(18) \quad \int U_i \left(rb_i + \sum_{j=1}^n s_{ij}M_j^{-1}\pi_j(\theta) \right) h_i(\theta) d\theta$$

within his budget constraint,

$$(19) \quad b_i + \sum_{j=1}^n s_{ij} = w_i + \sum_{j=1}^n w_{ij}M_j,$$

that the value of bonds purchased, $b_i - w_i$, plus stocks purchased equal the value of his initial stock holdings (the bond is employed as numeraire, making the number of bonds equal their value). The consumer acts as a competitive trader in that he views r , M_j , and $\pi_j(\theta)$ as parameters.

Substituting from the budget constraint for b_i in the expression for expected utility, we have an unconstrained maximization with respect to s_{ij} which has the first order conditions

$$(20) \quad \int U'_i(-r + M_j^{-1}\pi_j(\theta))h_i(\theta)d\theta = 0, \quad j = 1, 2, \dots, n.$$

Rearranging terms, we can express this as an equality between relative prices (recalling that the bond is numeraire, with its price equal to one)

and the marginal rate of substitution of the joint product of consumption across the states of nature obtained by buying the stock of the j th firm for the joint product obtained by buying a bond.

$$(21) \quad M_j = \frac{\int U'_i \pi_j(\theta) h_i(\theta) d\theta}{\int U'_i r h_i(\theta) d\theta} .$$

Substituting the definition of profits, equation (14), and rearranging terms we obtain a similar expression for the output pattern of a firm to that we had for its profit pattern.

$$(22) \quad M_j + k_j = \frac{\int U'_i y_j(\theta) h_i(\theta) d\theta}{\int U'_i r h_i(\theta) d\theta} .$$

The step between equations (21) and (22) is analogous to the Modigliani-Miller theorem (see [6]) that the total market value of a firm is independent of its debt-equity structure.¹¹ The interpretation of this step is that the market value of output, $M_j + k_j$, equals the market value of profits, M_j , plus the value of factor payments, k_j . Recalling the normalization of bonds in terms of factor payments we can view the factor payment obligation as an ordinary element of debt. If we consider two firms, of varying efficiency, so that they have the same output stream $y_{j_1}(\theta) = y_{j_2}(\theta)$ but different input levels, $k_{j_1} \neq k_{j_2}$, we can see from equation (22) that their output value must be the same, although stock market profit value will differ by the difference in present value of their future factor payments. Equivalently we could consider two firms with the same inputs and outputs, differing in that one was in debt. Then the value of debt plus market value for one would equal the market value of the other. Further we can see that a single firm could sell equities to purchase debt (e.g., to pay factors in the future) without altering the real equilibrium position since equilibrium is preserved if each stockholder preserves his fraction of the firm owned and goes into debt to finance his increased shareholdings. This result is a consequence of competitive equilibrium with price takers facing the same prices. The fact that the firm and all its stockholders can lend and borrow on exactly the same terms preserves this condition.

¹¹ Note that this result is independent of the fact that subjective probabilities differ among individuals. This is in contrast to Lintner [5].

IV. *Production Decisions*

Let us consider, to begin, a firm that has a decomposable production function (as in equation (2)). The fact that the market value of profits equals the market value of output less that of input payments simplifies the calculation for the price-taking firm of the market value corresponding to any level of production. If, for example, the firm is considering doubling its input, this would be calculated as doubling the value of input payments (since the firm is a price taker). The output pattern remains unchanged by the assumption of a decomposable production function, the firm's output becoming $f_j(\theta)g_j(2k_j)$ instead of $f_j(\theta)g_j(k_j)$. Acting as a price taker the firm calculates that its output value will increase in proportion to output, to

$$\frac{g_j(2k_j)}{g_j(k_j)} (M_j + k_j)$$

and thus that its stock market value would become

$$\frac{g_j(2k_j)}{g_j(k_j)} (M_j + k_j) - 2k_j.$$

In general, at an input level of \hat{k}_j with a market value of \hat{M}_j , the firm would calculate market value at an alternative input level as

$$(23) \quad M_j = \frac{g_j(k_j)}{g_j(\hat{k}_j)} (\hat{M}_j + \hat{k}_j) - k_j,$$

and would plan to carry production to the point where the derivative of M_j with respect to k_j equalled zero. In equilibrium, this derivative is calculated at the equilibrium input level ($\hat{k}_j = k_j$). Thus the equilibrium condition for production is

$$(24) \quad \frac{g'_j(k_j)}{g_j(k_j)} (M_j + k_j) = 1.$$

Substituting from equation (22) for $(M_j + k_j)$ in this equation we have

$$(25) \quad \frac{g'_j \int U_j f_j(\theta) h_i(\theta) d\theta}{\int U'_i r h_i(\theta) d\theta} = 1.$$

Comparing these equations, (22) and (25), with the allocation rules in the planned economy, equations (10) and (13), we see that they are

equivalent and subject to the same interpretations given above. Thus in the case of decomposable production functions the competitive equilibrium is a constrained Pareto optimum.

In this special case of decomposable production functions, we can consider the output pattern of each firm, suitably normalized, as a commodity. Both production and utility functions can be expressed in terms of these commodities, making this model equivalent to a general equilibrium model under certainty. It is, then, not surprising that we can obtain the standard optimality implications of a competitive equilibrium, with optimality holding relative to these composite commodities. The restriction to these commodities is, of course, the linearity constraint resulting in a constrained rather than full optimum.

Dropping the decomposability assumption, it remains true that the price-taking firm wants to carry production to the point where the derivative of output value (in the stock market) with respect to input level equals one. In the decomposable case, the marginal output pattern and the total output pattern are identical (i.e., for some α , which is a function of k ,

$$f_k^j(\theta, k) = \alpha f^j(\theta, k)$$

for all θ) and the firm can obtain the appropriate prices for its marginal calculations from its own stock value. In the absence of decomposability, this price might be found in the value of some other firm (or combination of firms) if the marginal pattern of the first firm coincided with the total pattern of the second at the equilibrium input levels. Thus if at the equilibrium values k_{j_1} and k_{j_2}

$$(26) \quad f_k^{j_1}(\theta, k_{j_1}) = \alpha f^{j_2}(\theta, k_{j_2})$$

for all θ , the equilibrium condition for firm j_1 is

$$(27) \quad \alpha(M_{j_2} + k_{j_2}) = 1.$$

Note that exactly the same patterns of output are required for this calculation. Two firms with the same expected return and the same variance (using someone's subjective probability) will not, in general, carry production to the same point.

It would be surprising if firms were capable of carrying out this calculation exactly. However, we might expect them to approximate it reasonably well if the major risks are decomposable into particular types which are fairly common. For example, a firm may find its marginal risks simply related to the weather and a random variable independent of anything else in the economy (and, in some extension to price uncer-

tainty, also to the business cycle, which is not, of course, a technological uncertainty). I have not found a rule for competitive production in the general case when the firm is unable to price its marginal output stream from the average profit streams valued in the market.¹²

V. *Implications*

It is interesting to contrast the allocation in the planned economy with that arising from the simple policy of dividing up output equally at the completion of production. By dividing up claims equally before production, and permitting trade in these claims, consumers are able to raise their expected utility levels, as they view them, by means of trade among persons of differing risk aversion or different subjective probabilities. Secondly, we note that even if the planner uses his own subjective probabilities, the presence of technological uncertainty which varies among investment opportunities requires knowledge of consumer risk aversion for production decisions.¹³ This is analogous to the certainty model where decisions about possibilities involving different goods require information about tastes for these goods. Levels of risk aversion can be learned from market information only if consumers are offered risky alternatives. A stock market is one method of acquiring this information. In the absence of contingent commodity markets, perhaps socialist economies should have stock markets (possibly with stock on a leasehold not freehold basis, consumers owning claims to output with ownership of the firm reverting to the state at set time intervals).

¹² J. A. Mirrlees has raised the issue of exact achievement of the constrained optimum by nonmarket mechanisms. One such mechanism is a stockholders meeting, run in a particular way. Let the firm ask stockholders how much they are just willing to see the firm pay for the marginal unit of input. Each stockholder will answer by calculating the change in expected utility from a change in input as a function of the wage paid the input, ρ , and then equate this with zero. The expression is

$$\int U_i s_{ij} M_j^{-1} (f'_k(\theta, k_j) - \rho) h_i(\theta) d\theta = 0$$

or, solving for ρ , the wage equals

$$\frac{\int U'_i f'_k h_i(\theta) d\theta}{\int U'_i h_i(\theta) d\theta}.$$

If production is carried to the point where the wage equals the average of these answers, with the fractions of the firm owned serving as weights in the averaging, the optimal allocation rule, equation (12), is achieved.

¹³ Note that a stock market affects the allocation of all inputs into a risky production process (not just capital) since varying output patterns arising from varying input combinations have different stock market valuations. For example, substituting labor for fertilizer will, in general, alter the pattern of output across the states of nature.

Now let us turn to the Modigliani-Miller propositions (see [6]) that firms with the same output patterns have the same expected return on total capital (i.e., the value of debt plus equity, or in this case the present value of contracted factor payments plus stock market value). In turn this rate is the appropriate expected return for the margin of investment. The first proposition holds in general (following from expected utility maximization) while the second requires the decomposability assumption (and follows, then, from market value maximization by the firm). Both conclusions hold for any probability function. The condition of identical output patterns is that as functions of θ

$$y_1(\theta) = \alpha y_2(\theta)$$

for some constant α . From the conditions for expected utility maximization, equation (22), we have

$$(28) \quad (M_1 + k_1)^{-1} \int U'_i y_1(\theta) h_i(\theta) d\theta = (M_2 + k_2)^{-1} \int U'_i y_2(\theta) h_i(\theta) d\theta$$

or, upon substitution

$$(29) \quad (M_1 + k_1)^{-1} \alpha = (M_2 + k_2)^{-1}.$$

The expected return on total capital is

$$(30) \quad (M_j + k_j)^{-1} \int y_j(\theta) h(\theta) d\theta.$$

Substituting for both returns and output, we have the equality of expected returns. Note that the same output pattern, and not just the same variance, is required for the conclusion of equal expected returns.

Similarly, the market value maximization equation, (24), implied that the expected marginal return equals the expected average return. However, this result depends on the identical pattern of total and marginal returns and does not hold without the decomposability assumption.

By means of portfolio diversification on the part of consumers, all of the economy's averaging possibilities are brought to bear on each production decision. Thus, in the model, large firms have no pooling advantages over small firms, nor does the government have an advantage over private business.¹⁴ Provided that the government does not go

¹⁴ This conclusion does not depend on the assumption that fixed interest debt obligations (or equivalently wages) are met in every state of nature. Bankruptcy for limited liability corporations still leaves well defined payment patterns for both stocks and bonds. Provided both of these are traded competitively (preserving the assumption that an internal equilibrium exists or alternatively that individuals can sell short) the basic conclusions of the model are preserved. It is true that large firms, with diversified investments, will tend to go bankrupt in fewer states of nature and so will pay a lower nominal rate for fixed interest debt. But this does not alter

outside the linearity constraints of the model, government investors should imitate private business, evaluating individual projects separately, not pooling, and looking to the stock market for the appropriate return criteria. Given market value maximization, average stock market returns reflect marginal returns to investment. Neither, in general, reflects average returns to a firm's real assets.

While some examples of government investment may fall neatly into the pattern of the model (for example, pure public goods provided equally to everyone), many of them will not. Presumably some government activity may be devoted precisely to circumventing the linearity constraint where the constraint imposes a large cost on the economy. (An analysis explaining the particular set of trade opportunities available may well relate a limit on the cost of this constraint to the costs of establishing further markets.) Also, parallel to government activity in a certainty model, some actions may be taken to correct divergences from the competitive model which interfere with the optimality properties of competitive equilibrium. Where government investment is not necessarily linked to either of these aspects it seems reasonable to expect optimal behavior to be similar to that for investment falling within the pattern of the model. For example, optimal investment with nonlinear distribution rules, unless these rules are chosen to correct limitations from linearity in the private economy, may on average involve expected returns approximating those on investments with linear distribution rules.¹⁵

The model assumed a given set of firms, chosen historically to reflect investment opportunities. Relaxing this assumption to permit the addition of new firms allows the introduction of a competitive insurance market.¹⁶ This, however, raises even more seriously the problem of the informational aspect of the model and the empirical distinction among states of nature. Nevertheless, in the context of the model, by defining a pattern of output across the states of nature, trading can occur in stocks without the necessity of production behind them. This trading is neces-

the conclusion that large firms and small firms should pursue identical investment opportunities to the same margin. Various market imperfections would naturally alter this conclusion. Taxes, transaction costs in debt issuance, and difficulty for financial investors in obtaining information about the nature of real investment opportunities, $y_i(\theta)$, are obvious candidates for this disruption.

¹⁵ The fact that benefits from government investment may not be tradable may decrease their social value.

¹⁶ Another opportunity for an increase in efficiency is by the creation of two firms dividing the profits of an existing firm nonlinearly between them. This increases the number of possible patterns available to consumers. Mutual funds, however, offer no new opportunities in a perfect knowledge, no transaction cost model.

sarily buying and short selling, where selling is a promise to pay the appropriate dividend level. For example, a pattern involving payment in case of a flood in a given area, but not otherwise, is a stock which will be bought by residents of the area and sold by nonresidents. Thus, competitive insurance markets could be introduced. In the absence of all transaction costs, this could be carried to the point where it would become possible to purchase, by some combination of stocks, a unit of output in any state of nature, i.e., the set of output patterns would span the states of nature. At this point the stock market model becomes equivalent to the contingent commodity model discussed in the Appendix and the economy achieves a full Pareto optimum.

APPENDIX: CONTINGENT COMMODITY MARKETS

As mentioned earlier, the general equilibrium model with a stock market developed above is, in many ways, extremely analogous to the general equilibrium model with contingent commodity markets. Apart from the differences induced by the different market structures, individual behavior is essentially the same in the two models. In both models all trading occurs at one time. Again, consumers maximize expected utility, in one case by purchasing the joint products of patterns of consumption across the states of nature, in the other by purchasing consumption in each state of nature separately. In both cases factors of production are paid fixed amounts and stock market value is maximized in determining the extent of employment. (As in the certainty model, in the contingent commodity model the firms maximize profits, which are determinate, not random, but the level of determinate profits is precisely the value of the firm to its owners.) The similarities of production are such that, in terms of a consumer's utility function, rules for allocation of resources among firms and evaluation of firms are the same in both models (in the case of decomposable production functions, which is the only well-defined case with the stock market economy). The differences in consumption patterns arising from the limitation on purchases in a stock market model do, however, imply different allocations (as well as the difference that the stock market economy achieves only a constrained optimum while the contingent commodity economy achieves a full optimum). We shall return to these parallels below after describing the contingent commodity model.

With a system of contingent commodity markets, goods traded are denoted not only by type and time and place of delivery but also by a state of nature, for they are delivered if and only if that state of nature occurs. But, like insurance policies, they are paid for at the time of trading independent of whether that state occurs. Since the commodities it would produce in each state of nature are all sold in this way, firm profits are determinate.

Let $p(\theta)$ be the price of a unit of consumption delivered if state θ occurs. Then the profits of the j th firm are (the factor is paid in advance)

$$(31) \quad \pi_j = \int p(\theta) f^j(\theta, k_j) d\theta - rk_j$$

where r is the rate of factor remuneration. Probabilities do not enter this expression since all possible outputs are sold with payment at the time of trading. (Probabilities will, of course, be reflected in prices.)

Similarly, the consumer purchases consumption in each state of nature separately so as to maximize his expected utility. The consumer's problem can be written

$$(32) \quad \begin{aligned} & \underset{c_i(\theta)}{\text{Maximize}} \int U_i(c_i(\theta)) h_i(\theta) d\theta \\ & \text{subject to} \int p(\theta) c_i(\theta) d\theta = rw_i + \sum_j w_{ij} \pi_j \end{aligned}$$

where w_i is his stock of input and w_{ij} the fraction of the j th firm he owns. (With just a stock market, these separate commodities, $c(\theta)$, could only be purchased in bundles, reflecting profit patterns as a function of θ .) The first order conditions for this maximization are

$$(33) \quad U'_i(c_i(\theta)) h_i(\theta) = \lambda_i p(\theta)$$

where λ_i is a Lagrangian multiplier. Differentiating this equation logarithmically with respect to θ gives a description of the pattern of consumption in terms of subjective probabilities, risk aversion, and prices.

$$(34) \quad \frac{U'_i''}{U'_i} \frac{dc_i}{d\theta} + \frac{1}{h_i} \frac{dh_i}{d\theta} = \frac{1}{p} \frac{dp}{d\theta}.$$

Thus for two individuals with the same subjective probabilities (and facing the same prices) consumption variation depends on risk aversion,¹⁷

$$(35) \quad \frac{dc_1/d\theta}{dc_2/d\theta} = \frac{U_2''/U_2'}{U_1''/U_1'}.$$

Plotting these consumption patterns, we obtain a figure which shows that the individuals have the same iso-consumption loci, i.e., $c_1(\theta_1) = c_1(\theta_2)$ implies $c_2(\theta_1) = c_2(\theta_2)$. This follows from the special form of the utility function in terms of the contingent commodities, with $U_i(c_i(\theta)) h_i(\theta) d\theta$ being additive in $c_i(\theta_1)$ and $c_i(\theta_2)$ with different individuals treating the two goods symmetrically. Thus

$$\frac{h(\theta_1) U'_1(c_1)}{h(\theta_2) U'_1(c_1)} = \frac{p(\theta_1)}{p(\theta_2)} \quad \text{implies} \quad \frac{h(\theta_1) U'_2(c_2)}{h(\theta_2) U'_2(c_2)} = \frac{p(\theta_1)}{p(\theta_2)}.$$

¹⁷ This is the index of risk aversion which appears in Arrow [3] and Pratt [7].

FIGURE 1

If everyone held the same subjective probabilities, the states of nature could be redefined so they were equally probable (i.e., so that $h_i(\theta)$ became the uniform density). Then prices would vary inversely with aggregate output, showing greater variation the more risk averse the consumers. To see this, we take the market clearance condition that total consumption equal total output in all states of nature and differentiate with respect to θ ,

$$(36) \quad \sum_i \frac{dc_i}{d\theta} = \sum_j \frac{dy_j}{d\theta}.$$

Substituting for the change in consumption from equation (34) (recalling that $dh_i/d\theta = 0$) we have

$$(37) \quad \frac{1}{p} \frac{dp}{d\theta} \sum_i \frac{U'_i}{U'_i} = \sum_j \frac{dy_j}{d\theta}.$$

With greater risk aversion, more price variance is needed to induce consumers to purchase the varying output supply.

Let us now examine the production conditions in this model to show the parallel with the allocation with a stock market. Profit maximization can be written

$$(38) \quad \begin{aligned} &\text{Maximize}_{k_j} \int p(\theta) y_j(\theta) d\theta - rk_j \\ &\text{subject to } y_j(\theta) = f^j(\theta, k). \end{aligned}$$

The first order condition for maximization is then

$$(39) \quad \int p(\theta) f_k^j(\theta, k_j) d\theta = r.$$

Substituting for the price from the first order condition for utility maximization, equation (33), we have

$$(40) \quad \lambda_i^{-1} \int U_i^j f_k^j(\theta, k_j) h_i(\theta) d\theta = r.$$

Assuming a decomposable production function this can be written

$$(41) \quad g_j^j(k_j) \int U_i^j f_j(\theta) h_i(\theta) d\theta = r \lambda_i.$$

This has the same form as equation (25).

Similarly the value of output can be written

$$(42) \quad \pi_j + r k_j = \int p(\theta) y_j(\theta) d\theta = \lambda_i^{-1} \int U_i^j y_j(\theta) h_i(\theta) d\theta.$$

This has the same form as equation (22). Thus the production aspects of the two models are the same, with the differences in market structure affecting the actual input allocation by affecting the consumption possibilities which can be purchased.

CONSERVATION RECONSIDERED

By JOHN V. KRUTILLA*

"It is the clear duty of Government, which is the trustee for unborn generations as well as for its present citizens, to watch over, and if need be, by legislative enactment, to defend, the exhaustible natural resources of the country from rash and reckless spoliation. How far it should itself, either out of taxes, or out of State loans, or by the device of guaranteed interest, press resources into undertakings from which the business community, if left to itself, would hold aloof, is a more difficult problem. Plainly, if we assume adequate competence on the part of governments, there is a valid case for *some* artificial encouragement to investment, particularly to investments the return from which will only begin to appear after the lapse of many years."

A. C. PIGOU

Conservation of natural resources has meant different things to different people. But to the economist from the time of Pigou, who first took notice of the economics of conservation [10, p. 27ff], until quite recently, the central concerns have been associated with the question of the optimal intertemporal utilization of the fixed natural resource stocks. The gnawing anxiety provoked by the Malthusian thesis of natural resource scarcity was in no way allayed by the rates of consumption of natural resource stocks during two world wars occurring between the first and fourth editions of Pigou's famous work. In the United States, a presidential commission, reviewing the materials situation following World War II, concluded that an end had come to the historic decline in the cost of natural resource commodities [12, pp. 13-14]. This conclusion reinforced the concern of many that the resource base ultimately would be depleted.

More recently, on the other hand, a systematic analysis of the trends in prices of natural resource commodities did not reveal any permanent interruption in the decline relative to commodities and services in general [11]. Moreover, a rather ambitious attempt to test rigorously the thesis of natural resource scarcity suggested instead that technological progress had compensated quite adequately for the depletion of the higher quality natural resource stocks [1]. Further, given the present state of the arts, future advances need not be fortuitous occurrences;

*The author is indebted to all of his colleagues at Resources for the Future and to Harold Barnett, Paul Davidson, Otto Davis, Chandler Morse, Peter Pearse, and Ralph Turvey for many helpful suggestions on an earlier draft of this paper.

rather the rate of advance can be influenced by investment in research and development. Indeed, those who take an optimistic view would hold that the modern industrial economy is winning its independence from the traditional natural resources sector to a remarkable degree. Ultimately, the raw material inputs to industrial production may be only mass and energy [1, p. 238].¹

While such optimistic conclusions were being reached, they were nevertheless accompanied by a caveat that, while we may expect production of goods and services to increase without interruption, the level of living may not necessarily be improved. More specifically, Barnett and Morse concluded that the quality of the physical environment—the landscape, water, and atmospheric quality—was deteriorating.

These conclusions suggest that on the one hand the traditional concerns of conservation economics—the husbanding of natural resource stocks for the use of future generations—may now be outmoded by advances in technology. On the other hand, the central issue seems to be the problem of providing for the present and future the amenities associated with unspoiled natural environments, for which the market fails to make adequate provision. While this appears to be the implication of recent research,² and is certainly consistent with recent public policy in regard to preserving natural environments, the traditional economic rationale for conservation does not address itself to this issue directly.³ The use of Pigou's social time preference may serve only to hasten the conversion of natural environments into low-yield capital investments.⁴ On what basis, then, can we make decisions when we confront a choice entailing action which will have an irreversible adverse consequence for rare phenomena of nature? I investigate this question below.

Let us consider an area with some unique attribute of nature—a geomorphologic feature such as the Grand Canyon, a threatened species, or an entire ecosystem or biotic community essential to the survival of the threatened species.⁵ Let us assume further that the area can be used

¹ The conclusions were based on data relevant to the U.S. economy. While they may be pertinent to Western Europe also, all of my subsequent observations are restricted to the United States.

² For example, see [7].

³ It must be acknowledged that with sufficient patience and perception nearly all of the argument for preserving unique phenomena of nature can be found in the classic on conservation economics by Ciriacy-Wantrup [3].

⁴ An example of this was the recent threat to the Grand Canyon by the proposed Bridge and Marble Canyon dams. Scott makes a similar point with reference to natural resource commodities [13].

⁵ Uniqueness need not be absolute for the following arguments to hold. It may be, like Dupuit's bridge, a good with no adequate substitutes in the "natural" market area of its

for certain recreation and/or scientific research activities which would be compatible with the preservation of the natural environment, or for extractive activities such as logging or hydraulic mining, which would have adverse consequences for scenic landscapes and wildlife habitat.

A private resource owner would consider the discounted net income stream from the alternative uses and select the use which would hold prospects for the highest present net value. If the use which promises the highest present net value is incompatible with preserving the environment in its natural state, does it necessarily follow that the market will allocate the resources efficiently? There are several reasons why private and social returns in this case are likely to diverge significantly.

Consider the problem first in its static aspects. By assumption, the resources used in a manner compatible with preserving the natural environment have no close substitutes; on the other hand, alternative sources of supply of natural resource commodities are available.⁶ Under the circumstances and given the practical obstacles to perfectly discriminating pricing, the private resource owner would not be able to appropriate in gate receipts the entire social value of the resources when used in a manner compatible with preserving the natural state. Thus the present values of his expected net revenues are not comparable as between the competing uses in evaluating the efficiency of the resource allocation.

Aside from the practical problem of implementing a perfectly discriminating pricing policy, it is not clear even on theoretic grounds that a comparison of the total area under the demand curve on the one hand and market receipts on the other will yield an unambiguous answer to the allocative question. When the existence of a grand scenic wonder or a unique and fragile ecosystem is involved, its preservation and continued availability are a significant part of the real income of many individuals.⁷ Under the conditions postulated, the area under the demand curve, which represents a maximum willingness to pay, may be significantly less than the minimum which would be required to compensate such individuals were they to be deprived in perpetuity of the opportunity

principal clientele, while possibly being replicated in other market areas to which the clientele in question has no access for all practical purposes.

⁶The asymmetry in the relation posited is realistic. The historic decline in cost of natural resource commodities relative to commodities in general suggests that the production and exchange of the former occur under fairly competitive conditions. On the other hand, increasing congestion at parks, such as Yellowstone, Yosemite, and Grand Canyon, suggests there are no adequate substitutes for these rare natural environments.

⁷These would be the spiritual descendants of John Muir, the present members of the Sierra Club, the Wilderness Society, National Wildlife Federation, Audubon Society and others to whom the loss of a species or the disfigurement of a scenic area causes acute distress and a sense of genuine relative impoverishment.

to continue enjoying the natural phenomenon in question. Accordingly, it is conceivable that the potential losers cannot influence the decision in their favor by their aggregate willingness to pay, yet the resource owner may not be able to compensate the losers out of the receipts from the alternative use of the resource. In such cases—and they are more likely encountered in this area—it is impossible to determine whether the market allocation is efficient or inefficient.

Another reason for questioning the allocative efficiency of the market for the case in hand has been recognized only more recently. This involves the notion of *option demand* [14]. This demand is characterized as a willingness to pay for retaining an option to use an area or facility that would be difficult or impossible to replace and for which no close substitute is available. Moreover, such a demand may exist even though there is no current intention to use the area or facility in question and the option may never be exercised. If an option value exists for rare or unique occurrences of nature, but there is no means by which a private resource owner can appropriate this value, the resulting resource allocation may be questioned.

Because options are traded on the market in connection with other economic values, one may ask why no market has developed where option value exists for the preservation of natural environments.⁸ We need to consider briefly the nature of the value in question and the marketability of the option.

From a purely scientific viewpoint, much is yet to be learned in the earth and life sciences; preservation of the objects of study may be defended on these grounds, given the serendipity value of basic research. We know also that the natural biota represents our reservoir of germ plasm, which has economic value. For example, modern agriculture in advanced countries represents cultivation figuratively in a hot-house environment in which crops are protected against disease, pests, and drought by a variety of agricultural practices. The energy released from some of the genetic characteristics no longer required for survival under cultivated conditions is redirected toward greater productivity. Yet because of the instability introduced with progressive reduction of biological diversity, a need occasionally arises for the reintroduction of some genetic characteristics lost in the past from domestic strains. It is from the natural biota that these can be obtained.

The value of botanical specimens for medicinal purposes also has been long, if not widely, recognized. Approximately half of the new drugs currently being developed are obtained from botanical specimens.⁹ There is a traffic in medicinal plants which approximates a third

⁸ For a somewhat differently developed argument, see [6].

⁹ For an interesting account of the use of plants for medicinal purposes, see [8].

of a billion dollars annually. Cortisone, digitalis, and heparin are among the better known of the myriad drugs which are derived from natural vegetation or zoological sources. Since only a relatively small part of the potential medicinal value of biological specimens has yet been realized, preserving the opportunity to examine all species among the natural biota for this purpose is a matter of considerable importance.

The option value may have only a sentimental basis in some instances. Consider the rallying to preserve the historical relic, "Old Ironsides."¹⁰ There are many persons who obtain satisfaction from mere knowledge that part of wilderness North America remains even though they would be appalled by the prospect of being exposed to it. Subscriptions to World Wildlife Fund are of the same character. The funds are employed predominantly in an effort to save exotic species in remote areas of the world which few subscribers to the Fund ever hope to see. An option demand may exist therefore not only among persons currently and prospectively active in the market for the object of the demand, but among others who place a value on the mere existence of biological and/or geomorphological variety and its widespread distribution.¹¹

If a genuine value for retaining an option in these respects exists, why has not a market developed? To some extent, and for certain purposes, it has. Where a small natural area in some locality in the United States is threatened, the property is often purchased by Nature Conservancy,¹² a private organization which raises funds through voluntary subscriptions.¹³ But this market is grossly imperfect. First, the risk for private investors associated with absence of knowledge as to whether a particular ecosystem has special characteristics not widely shared by others is enormous.¹⁴ Moreover, to the extent that the natural environment will support basic scientific research which often has unanticipated practical results, the serendipity value may not be appropriable by those paying to preserve the options. But perhaps of greatest significance is that the preservation of the grand scenic wonders, threatened species, and the like involves comparatively large land tracts which are not of merely

¹⁰ The presumption in favor of option value is applicable also to historic and cultural features; rare works of art, perhaps, being the most prominent of this class.

¹¹ The phenomenon discussed may have an exclusive sentimental basis, but if we consider the "bequest motivation" in economic behavior, discussed below, it may be explained by an interest in preserving an option for one's heirs to view or use the object in question.

¹² Not to be confused with a public agency of the same name in the United Kingdom.

¹³ Subscriptions to World Wildlife Fund, the Wilderness Society, National Parks Association, etc. may be similar, but, of course, much of the effect these organizations have on the preservation of natural areas stems not from purchasing options, but from influencing public programs.

¹⁴ The problem here is in part like a national lottery in which there exists a very small chance for a very large gain. Unlike a lottery, rather large sums at very large risk typically would be required.

local interest. Thus, all of the problems of organizing a market for public goods arise. Potential purchasers of options may be expected to bide time in the expectation that others will meet the necessary cost, thus eliminating cost to themselves. Since the mere existence or preservation of the natural environment in question satisfies the demand, those who do not subscribe cannot be excluded except by the failure to enroll sufficient subscribers for its preservation.

Perhaps of equal significance to the presumption of market failure are some dynamic characteristics of the problem suggested by recent research. First, consider the consumption aspects of the problem. Davidson, Adams, and Seneca have recently advanced some interesting notions regarding the formation of demand that may be particularly relevant to our problem [5, p. 186].

When facilities are not readily available, skills will not be developed and, consequently, there may be little desire to participate in these activities. If facilities are made available, opportunities to acquire skill increase, and user demand tends to rise rapidly over time as individuals learn to enjoy these activities. Thus, participation in and enjoyment of water recreational activities by the present generation will stimulate future demand without diminishing the supply presently available. Learning-by-doing, to the extent it increases future demand, suggests an interaction between present and future demand functions, which will result in a public good externality, as present demand enters into the utility function of future users.

While this quotation refers to water-based recreation, it is likely to be more persuasive in connection with some other resource-based recreation activity. Its relevance for wilderness preservation is obvious. When we consider the remote backcountry landscape, or the wilderness scene as the object of experience and enjoyment, we recognize that utility from the experience depends predominantly upon the prior acquisition of technical skill and specialized knowledge. This, of course, must come from experience initially with less arduous or demanding activities. The more the present population is initiated into activities requiring similar but less advanced skills (e.g., car camping), the better prepared the future population will be to participate in the more exacting activities. Given the phenomenal rise of car camping, if this activity will spawn a disproportionate number of future back-packers, canoe cruisers, cross-country skiers, etc., the greater will be the induced demand for wild, primitive, and wilderness-related opportunities for indulging such interest. Admittedly, we know little about the demand for outdoor experiences which depend on unique phenomena of nature—its formation, stability, and probable course of development. These are important questions for research, results of which will have significant policy implications.

In regard to the production aspects of the "new conservation," we need to examine the implications of technological progress a little further. Earlier I suggested that the advances of technology have compensated for the depletion of the richer mineral deposits and, in a sense, for the superior stands of timber and tracts of arable land. On the other hand, there is likely to be an asymmetry in the implications of technological progress for the production of goods and services from the natural resource base, and the production of natural phenomena which give rise to utility without undergoing fabrication or other processing.¹⁵ In fact, it is improbable that technology will advance to the point at which the grand geomorphologic wonders could be replicated, or extinct species resurrected. Nor is it obvious that fabricated replicas, were they even possible, would have a value equivalent to that of the originals. To a lesser extent, the landscape can be manufactured in a pleasing way with artistry and the larger earth-moving equipment of today's construction technology. Open pit mines may be refilled and the surroundings rehabilitated in a way to approximate the original conditions. But even here the undertaking cannot be accomplished without the cooperation of nature over a substantial period of time depending on the growth rate of the vegetal cover and the requirements of the native habitat.¹⁶ Accordingly, while the supply of fabricated goods and commercial services may be capable of continuous expansion from a given resource base by reason of scientific discovery and mastery of technique, the supply of natural phenomena is virtually inelastic. That is, we may preserve the natural environment which remains to provide amenities of this sort for the future, but there are significant limitations on reproducing it in the future should we fail to preserve it.

If we consider the asymmetric implications of technology, we can conceive of a transformation function having along its vertical axis amenities derived directly from association with the natural environment and fabricated goods along the horizontal axis. Advances in technology would stretch the transformation function's terminus along the horizontal axis but not appreciably along the vertical. Accordingly, if we simply take the effect of technological progress over time, considering tastes as constant, the marginal trade-off between manufactured and natural amenities will progressively favor the latter. Natural environments will represent irreplaceable assets of appreciating value with the passage of time.

If we consider technology as constant, but consider a change in tastes progressively favoring amenities of the natural environment due to the learn-by-doing phenomenon, natural environments will similarly for this

¹⁵ I owe this point to a related observation, to my knowledge first made by Ciriacy-Wantrup [3, p. 47].

¹⁶ That is, giving rise to option value for members of the present population.

reason represent assets of appreciating value. If both influences are operative (changes in technology with asymmetric implications, and tastes), the appreciating value of natural environments will be compounded.

This leads to a final point which, while a static consideration, tends to have its real significance in conjunction with the effects of parametric shifts in tastes and technology. We are coming to realize that consumption-saving behavior is motivated by a desire to leave one's heirs an estate as well as by the utility to be obtained from consumption.¹⁷ A bequest of maximum value would require an appropriate mix of public and private assets, and, equally, the appropriate mix of opportunities to enjoy amenities experienced directly from association with the natural environment along with readily producible goods. But the option to enjoy the grand scenic wonders for the bulk of the population depends upon their provision as public goods.

Several observations have been made which may now be summarized. The first is that, unlike resource allocation questions dealt with in conventional economic problems, there is a family of problems associated with the natural environment which involves the irreproducibility of unique phenomena of nature—or the irreversibility of some consequence inimical to human welfare. Second, it appears that the utility to individuals of direct association with natural environments may be increasing while the supply is not readily subject to enlargement by man. Third, the real cost of refraining from converting our remaining rare natural environments may not be very great. Moreover, with the continued advance in technology, more substitutes for conventional natural resources will be found for the industrial and agricultural sectors, liberating production from dependence on conventional sources of raw materials. Finally, if consumption-saving behavior is motivated also by the desire to leave an estate, some portion of the estate would need to be in assets which yield collective consumption goods of appreciating future value. For all of these reasons we are confronted with a problem not conventionally met in resource economics. The problem is of the following nature.

At any point in time characterized by a level of technology which is less advanced than at some future date, the conversion of the natural environment into industrially produced private goods has proceeded further than it would have with the more advanced future technology. Moreover, with the apparent increasing appreciation of direct contact with natural environments, the conversion will have proceeded further, for this reason as well, than it would have were the future composition of tastes to have prevailed. Given the irreversibility of converted natural

¹⁷ See [2]; also [9].

environments, however, it will not be possible to achieve a level of well-being in the future that would have been possible had the conversion of natural environments been retarded. That this should be of concern to members of the present generation may be attributable to the bequest motivation in private economic behavior as much as to a sense of public responsibility.¹⁸

Accordingly, our problem is akin to the dynamic programming problem which requires a present action (which may violate conventional benefit-cost criteria) to be compatible with the attainment of future states of affairs. But we know little about the value that the instrumental variables may take. We have virtually no knowledge about the possible magnitude of the option demand. And we still have much to learn about the determinants of the growth in demand for outdoor recreation and about the quantitative significance of the asymmetry in the implications of technological advances for producing industrial goods on the one hand and natural environments on the other. Obviously, a great deal of research in these areas is necessary before we can hope to apply formal decision criteria comparable to current benefit-cost criteria. Fully useful results may be very long in coming; what then is a sensible way to proceed in the interim?

First, we need to consider what we need as a minimum reserve to avoid potentially grossly adverse consequences for human welfare. We may regard this as our scientific preserve of research materials required for advances in the life and earth sciences. While no careful evaluation of the size of this reserve has been undertaken by scientists, an educated guess has put the need in connection with terrestrial communities at about ten million acres for North America [4, p. 128]. Reservation of this amount of land—but a small fraction of one per cent of the total relevant area—is not likely to affect appreciably the supply or costs of material inputs to the manufacturing or agricultural sectors.

The size of the scientific preserve required for aquatic environments is still unknown. Only after there is developed an adequate system of classification of aquatic communities will it be possible to identify distinct environments, recognize the needed reservations, and, then, estimate the opportunity costs. Classification and identification of aquatic environments demand early research attention by natural scientists.

Finally, one might hope that the reservations for scientific purposes would also support the bulk of the outdoor recreation demands, or that substantial additional reservations for recreational purposes could be

¹⁸ The rationale above differs from that of Stephen Marglin which is perhaps the most rigorous one relying on a sense of public responsibility and externalities to justify explicit provision for future generations. In this case also, my concern is with providing *collective consumption goods for the present and future*, whereas the traditional concern in conservation economics has been with provision of *private intermediate goods for the future*.

justified by the demand and implicit opportunity costs. Reservations for recreation, as well as for biotic communities, should include special or rare environments which can support esoteric tastes as well as the more common ones. This is a matter of some importance because outdoor recreation opportunities will be provided in large part by public bodies, and within the public sector there is a tendency to provide a homogenized recreation commodity oriented toward a common denominator. There is need to recognize, and make provision for, the widest range of outdoor recreation tastes, just as a well-functioning market would do. We need a policy and a mechanism to ensure that all natural areas peculiarly suited for specialized recreation uses receive consideration for such uses. A policy of this kind would be consistent both with maintaining the greatest biological diversity for scientific research and educational purposes and with providing the widest choice for consumers of outdoor recreation.

A NOTION OF EQUILIBRIUM AND ITS POSSIBILITY UNDER MAJORITY RULE

By CHARLES R. PLOTT*

Consider a committee that is faced with the task of deciding on how to change the magnitude of several variables. It is assumed that agreement is defined by majority rule. The decision-making body could be a board of directors attempting to decide on the magnitude of several investment projects, or a group of individuals deciding upon the allocation of a budget among several public goods. The setting makes no difference as long as the variables could conceivably be changed by any amount. If a change in the variables is proposed and the change does not receive a majority vote, then the "existing state" of the variables remains. If no possible change in the variables could receive a majority vote, then the "existing state" of the variables is an "equilibrium."¹

The purpose of this paper is to make clear such a notion of equilibrium and to investigate the possibility of its existence. Section I sets forth the general setting, definitions, and assumptions. Section II pertains to situations where there is no constraint on the possible magnitude of the variables. Section III pertains to situations where there is one constraint (such as a fixed amount that the committee may spend). Section IV contains some general observations, possible applications, and questions brought forth by the procedure. An appendix contains an outline to the proofs of the propositions in the text.

Before continuing, it may be best to indicate some of the things *not* considered except by way of observation in the final section, if at all. Only "local" equilibriums are considered. Of course, "global" equilibriums must be special cases of these. There is no real theory of the path to equilibrium or even, for that matter, a convincing assurance that an equilibrium, if it exists, will be attained. Strategic considerations are ignored as are all second order conditions. These omissions are especially important in light of the results.

I. *The Basic Model*

Assume there are m individuals $(1, 2, \dots, i, \dots, m)$ who are attempting to decide on the magnitude of n variables $(x_1, x_2, \dots, x_j,$

* The author is assistant professor of economics at Purdue University. He wishes to thank James M. Buchanan of the University of Virginia and James Quirk of the University of Kansas for their helpful comments and criticisms. Financial support was provided in part from a National Science Foundation grant under the general supervision of Gordon Tullock and from a research grant provided by the Krannert Graduate School of Industrial Administration.

¹ This notion of equilibrium was first examined by Duncan Black and R. A. Newing. Special cases of some of the theorems are implied by the diagrams in [1, pp. 19-28] and [2, pp. 137-39].

$\dots, x_n)$. Each individual is assumed to have a differentiable utility function $U^i = U^i(x_1, x_2, \dots, x_n)$ defined on the n variables.²

Consider now a specific, small change in the variables (dx_1^* , dx_2^* , \dots , dx_n^*) from some "existing situation" (say \bar{X} in Euclidean n -space, E_n). This change in the variables shall be called a "motion."³ Individual i would "vote for" the motion over the existing situation \bar{X} if

$$\frac{\partial U^i}{\partial x_1} dx_1^* + \frac{\partial U^i}{\partial x_2} dx_2^* + \dots + \frac{\partial U^i}{\partial x_n} dx_n^* > 0.$$

That is, he favors the motion if it would increase his utility. Adopting the notation to be used, we can say that he "votes for" the motion b_k if

$$\nabla U^i b_k > 0$$

where

$$\nabla U^i = \left(\frac{\partial U^i}{\partial x_1}, \frac{\partial U^i}{\partial x_2}, \dots, \frac{\partial U^i}{\partial x_n} \right)$$

is the gradient vector of individual i 's utility function, b_k is some particular "motion" (dx_1^* , dx_2^* , \dots , dx_n^*) from the infinite set of "small moves away from \bar{X} ."⁴ Further, if $\nabla U^i b_k < 0$, we say he is "indifferent." It shall be assumed that indifferent individuals behave in the same specified manner, i.e., always "vote for," always "vote against," or "never vote" as the case may be.

Graphically the situation is represented by Figure 1. The curve I is an indifference curve or level surface of the utility function. Suppose \bar{X} represents the "existing state." This individual would "vote for" a proposed move from \bar{X} such as b_f , vote "against" a motion such as b_a , and be indifferent toward a proposal such as b_i .

Consider now a group of individuals $(1, 2, \dots, m)$ and the associated gradient vectors $\nabla U^i = (a_{i1}, a_{i2}, \dots, a_{in})$. Ignoring problems of strategic behavior, all individuals would "vote for" any proposal, b , which satisfies⁵

$$(1) \quad Ab > 0$$

² The variables are such that they behave as "collective goods." See [5].

³ We shall assume the "motion" vector is normalized, i.e., where $(dx_1^*, \dots, dx_n^*) = b^*$, then $|b^*| = 1$. For notational purposes, some particular motion, say j , will be denoted as b_j and the components will be denoted as $(b_{j1}, b_{j2}, \dots, b_{jn})$.

⁴ He votes for any motion for which the directional derivative, in that direction, is positive. ab , where a and b are vectors, denotes an inner product.

⁵ The problem of finding such "acceptable proposals" is simply a linear programming problem. See [4].

FIGURE 1

where

$$A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ \vdots & & & \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}.$$

It is well known that this system of inequalities has a solution, b , if and only if the system

$$(2) \quad yA = 0 \quad y = (y_1, \dots, y_m) \text{ and } y_i \geq 0 \text{ not all } = 0$$

has no semipositive solution y (see appendix).

Suppose the committee was operating under unanimity. Suppose further that an individual will vote "against" a motion that does not increase his utility (indifferent people vote "no"). Then any point in the space where (2) is satisfied would be an "equilibrium point." There would not exist a "motion" that could receive the required vote because, for any of the infinite possible motions, at least one person would vote "no."⁶

Suppose the committee was operating under majority rule. The committee would be at an equilibrium if and only if there does not exist a "motion" that could receive a favorable vote from a majority. This notion of equilibrium seems to accord well with the usual meanings of

⁶ If it is supposed that individuals would "permit" a motion to which they are indifferent, an equilibrium point must be one where (2) has a strictly positive solution y . Every "motion" would either decrease the utility of at least one individual or leave everyone indifferent.

equilibriums. Certainly if the magnitude of the variables was such that some change in them could receive the required vote there is no a priori reason to suppose that the variables would not be so changed.

II. *Equilibrium: No Constraint*

The conditions for majority rule equilibrium when there exists no constraint on permissible motions will be given. Such a constraint is added in the following section. It will be assumed that there are m (an odd number) decision makers. Simple modifications can be made to account for situations where the number of people is even.

A. Existence of an unconstrained equilibrium requires that indifferent individuals do not vote "yes."

If individuals who are indifferent are assumed to abstain from voting, such activities cannot be considered as "yes" votes. Otherwise, an equilibrium cannot exist. To prove this point, let M be an $(m+1)/2 \times n$ matrix, the rows of which come from the rows of A . Since indifferent people vote "yes," equilibrium must be a situation where $Mb < 0^7$ for all possible M that can be formed from the rows of A and all possible b . Pick an M and b that satisfy this equilibrium condition (say M_i and b_i). Then, where $b_k = -b$, $M_i b_k > 0$. The motion b_k would receive a majority contrary to the assumption of equilibrium. Indifferent people cannot vote "yes."

The remaining equilibrium conditions must be satisfied by the gradient vectors. The proofs are in the appendix.

B. Any equilibrium must be a point of maximum utility for at least one individual.

If the point is a maximum for one and only one individual,⁸ the gradients of the remaining individuals must satisfy C.

C. The remaining (even number of) rows of A can be divided into pairs for which there exists a strictly positive solution to

$$(3) \quad \begin{bmatrix} y_i \\ y_j \end{bmatrix} \begin{bmatrix} a_{i1} & a_{i2} & \cdots & a_{in} \\ a_{j1} & a_{j2} & \cdots & a_{jn} \end{bmatrix} = 0 \quad y_i, y_j > 0.$$

The last condition means that all individuals for which the point is not a maximum can be divided into pairs whose interests are diametrically opposed. The situation is shown diagrammatically by Figure 2. Points 1, 2, 3, 4, and 5 are the points of maximum utility for individuals 1, 2, 3, 4, and 5 respectively. The lines connecting the points are those

⁷ The notation $Mb > 0$ means that the inner product of b with each row of M is strictly positive.

⁸ The conditions can be modified to account for the point being a maximum for more than one individual.

FIGURE 2

points for which (3) is satisfied—the “contract curves” as traditionally termed in economics. The only point which is an equilibrium point is \bar{X} , the point corresponding to the maximum of individual 3. At any other point there exists a motion which would receive a majority vote. For example, consider \bar{Y} . The motion b_y would receive the “yes” votes of individuals 2, 3, and 5.

The above conditions, as qualified, are both necessary and sufficient for a point to be an equilibrium.

Notice that any majority rule equilibrium is obviously Pareto Optimal (almost by definition). But, certainly not all Pareto Optimals are majority rule equilibriums. The condition for Pareto Optimality is simply condition (2), or the condition described in footnote number 6, depending upon how you choose to define Pareto Optimality.

The most important point is that there is certainly nothing inherent

FIGURE 3

FIGURE 4

in utility theory which would assure the existence of an equilibrium. In fact, it would only be an accident (and a highly improbable one) if an equilibrium exists at all. For example, in Figures 3 and 4 there exists no equilibrium. And, it will be shown below that the addition of a constraint does little to relieve the situation if there are more than two variables to be determined.

III. *Equilibrium: One Constraint*

Suppose the committee was operating under a single constraint such as a budget constraint. Each of the variables has an associated price

and the committee has only a fixed amount (I) to spend. The constraint is of the form

$$(4) \quad \sum_{i=1}^n P_i x_i \leq I.$$

If the committee is at a point such that

$$\sum_{i=1}^n P_i x_i < I$$

the constraint does not alter the range of possible motions and an equilibrium must satisfy the conditions A, B, and C above. Therefore, only points such that

$$\sum_{i=1}^n P_i x_i = I$$

are of interest.

The constraint can be treated as an individual who has veto power. Where the price vector, or the gradient of the constraint is denoted as P , the only admissible (or feasible) motions are those in a set β where

$$\beta = \{b \in E_n \mid Pb \leq 0\}.$$

The problem of finding majority rule equilibrium conditions is simply one of finding conditions on the gradients of the individuals such that

$$Mb \leq 0$$

for all M and all $b \in \beta$ where M again ranges over all $(m+1)/2 \times n$ matrices that can be formed from the rows of A , the matrix of all gradient vectors.

Again, just as in the unconstrained case, it is assumed that all indifferent individuals behave in the same manner. This assumption gives rise to the following behavioral condition.

D. If a constrained equilibrium exists, people cannot "vote for" a motion to which they are indifferent.⁹

Again the remaining conditions are on the gradient vectors of the individuals.

E. For a point to be an equilibrium, the gradient of at least one individual must satisfy

$$(5) \quad \begin{bmatrix} y_1 \\ y_p \end{bmatrix} \begin{bmatrix} a_{i1} & a_{i2} & \dots & a_{in} \\ -P_1 & -P_2 & \dots & -P_n \end{bmatrix} = 0 \quad y_i > 0 \quad y_p \geq 0.$$

⁹ The proof is analogous to the proof of A above. The only difference is that rather than *any* b , one must be chosen from the set β' where $\beta' = \{b \in E_n \mid Pb = 0\}$.

FIGURE 5

This says that the point is either a constrained maximum or a maximum for at least one individual. We shall assume for the following conditions that this is true for one and only one individual. Again, the conditions can easily be modified to account for other cases.

E. For a point to be an equilibrium point, those gradients (even in number) for which D does not hold can be divided into pairs such that there exists a solution to

$$(6) \quad \begin{bmatrix} y_i \\ y_j \\ y_p \end{bmatrix} \begin{bmatrix} a_{i1} & a_{i2} & \cdots & a_{in} \\ a_{j1} & a_{j2} & \cdots & a_{jn} \\ -P_1 & -P_2 & \cdots & -P_n \end{bmatrix} = 0 \quad \begin{matrix} y_i, y_j > 0 \\ y_p \geq 0. \end{matrix}$$

In words this means that the individuals can be divided into pairs such that they are either diametrically opposed or at least opposed on every motion in the set β' defined in footnote 9. On Figure 5, the vectors P and ∇U^1 are parallel and lie in the same direction thus satisfying (5). P can be found as a positive combination of ∇U^2 and ∇U^3 thus satisfying (6).

It is certainly no trick to find a situation where there is no equilibrium at all. For example, there is no equilibrium on Figure 6, where points 1, 2, and 3 are points of constrained maximum for individuals 1, 2, and 3 respectively. Again there is nothing in utility theory that would guarantee the existence of an equilibrium. And again, if an equilibrium exists, it would be purely accidental. This result leads, at this stage of analysis, to rather pessimistic conclusions about the allocation of public goods. Samuelson [5] has demonstrated that the equilibrium attained by a market mechanism for public goods will, in general, fail to be an optimum. The analysis here implies that a majority rule political process

FIGURE 6

will fail to reach an equilibrium at all. Thus, in the case of public goods, society can count upon neither the market nor a majority rule political process to be a desirable allocative device.

IV. *Observations and Conjectures*

The results thus far seem rather negative in that equilibrium under majority rule would seem to be an almost nonexistent phenomenon. In view of this, a review of the concept of equilibrium used, and an inquiry into whether or not any important ingredients were left out should be useful.

Of great importance is the process by which motions are proposed. The decision process *itself* may dictate that some motions cannot be proposed. Often, before a motion can be voted on by a decision body, it must pass through a subcommittee. Unless proposals and amendments can be made from the floor, the subcommittee determines what motions can be voted on. In such cases, the equilibrium conditions would apply only to members of this committee. When the members of such a committee are in equilibrium, the complete voting body is in equilibrium regardless of the preferences of those not on the subcommittee.

This brings up an additional observation on coalitions. Where there exists a majority coalition which, itself, operates under a rule of unanimity, condition (2), when satisfied for the members of this coalition, defines the equilibrium points. If there exists a constraint, the traditional requirements on utility functions are sufficient to assure the existence of an equilibrium in such cases.

A third observation pertains to the role of time in the analysis. Certainly there may be great costs of indecision—if nothing else, simply sitting. As time passes, the utility functions as reflected in the com-

modity space may tend to "flatten." That is, with time, the marginal utility associated with an additional unit of a variable may tend to diminish. The points of maximum may extend to a neighborhood around the original maximum and the "contract curves" may tend to become "broad" as the time taken to reach a decision increases. This type of phenomenon would certainly tend to increase the possibility of the existence of an equilibrium.

Associated with the possibility of a change in evaluations through time is the possibility of a change in preference due to the decision process itself. The exchange of information associated with any decision process may serve actually to change the utility functions. A "persuasive" individual may be successful in changing the utility functions of others so that all of the orderings, in the end, resemble his. Or, the process may tend to cause all utility functions to change to a "similar" ordering but one which is not "similar" to any of the original functions.

The model outlined here lends itself to the possible testing of all of these speculations. If the original utility functions are known, the contract curves can be described as a system of equations and solved (at least theoretically) for an equilibrium. In the absence of such detailed information one might assume that the contract curves are linear. The only information then needed would be the points of maximum for the various individuals (or constrained maximums as the case may be). The contract curves would then be the curves L of the form

$$L = tC + A \quad 0 \leq t \leq 1$$

where

$$B - A = C$$

assuming B is the maximum for individual B and A is the maximum for individual A .

Having obtained this information the experimenter can estimate the equilibrium. The decision process can then be observed. The resulting equilibrium can be compared with the "theoretical" equilibrium and the final utility functions compared with the originals. The path to equilibrium can be observed along with associated strategic behavior, etc. It may be the case that strategic considerations influence individuals to vote against some motion which would increase their utility. Such observations could, in principle, lead to the identification of variables which systematically contribute to the final outcome of group decisions.

MATHEMATICAL APPENDIX

The proofs for the various statements and conditions given in the text are presented below. The propositions given below follow in the same order as the corresponding descriptions in the text.

Definitions

A is an $m \times n$ (m, n finite and m an odd number) matrix.

(m) is the set of vectors which serve as rows of A . The elements of (m) are $(a_1, \dots, a_i, \dots, a_m)$.

M is an $(m+1)/2 \times n$ submatrix of A . (M) is the set of all M that can be formed from A .

A^* is a $r \times n$ submatrix of A ($r = m - 1$).

(r) is the set of vectors which serve as rows of A^* .

In general, except for specifically defined submatrices such as those above, if (ξ) is a set of row vectors of some matrix with ξ elements, then $[\xi]$ is the submatrix with the ξ members of (ξ) as rows.

For any matrix $[\xi]$ and vector b the notation $[\xi] b > 0$ means that the inner product of b with every row of $[\xi]$ is strictly greater than zero. The complement of a set (ξ) is denoted as $(\bar{\xi})$. E_n denotes Euclidean n -space. The notation ab represents an inner product. Define A to be an \hat{A} if and only if for any $b \in E_n \exists M \in (M)$ such that $Mb \leq 0$.

Lemma 1. A is an \hat{A} if and only if for no $M \in (M)$ there is a $b \in E_n$ such that $Mb > 0$.

Proof. Examine first the "if" part. Assume that for $M_i \exists b_i$ such that $M_i b_i > 0$. Since M_i has $(m+1)/2$ rows, there are at most $m - (m+1)/2 = (m-1)/2$ remaining rows of A for which $ab_i \leq 0$ so A cannot be \hat{A} .

Assume that for $b_i \nexists$ an $M \in (M)$ such that $Mb_i \leq 0$. At most, there could be $(m-1)/2$ rows of A such that $ab_i \leq 0$ is the case. For the remaining $(m+1)/2$ rows—call them M_i —it must be the case that $ab_i > 0$. Thus, for M_i there exists a solution to $M_i b > 0$.

Lemma 2. If A is an \hat{A} , then for every $b \in E_n \exists$ an $a \in (m)$ such that $ab = 0$.

PROOF. Assume A is an \hat{A} . Assume that for b_i there does not exist an $a \in (m)$ such that $ab_i = 0$. By the definition of $\hat{A} \exists$ some $M_j \in (M)$ such that $M_j b_i < 0$. But, by letting $b_k = -b_i$, we find $M_j b_k > 0$, thus contradicting the assumption that A is an \hat{A} .

Theorem 1. If A is an \hat{A} , then there exists at least one $a_i \in (m)$ such that $a_i = 0$.

PROOF. For any $b \in E_n$ there must exist an orthogonal row of A by Lemma 2. To prove the theorem, it is sufficient to show that if at least one row of A is not the zero vector, then there exists a solution, say b^* , to $Ab \neq 0$. This will be shown by induction.

Assume A has only one column, no element of which is zero. Then any non-zero scalar satisfies the requirements of b^* .

Assume A has n columns. Assume further that there exists a solution, say b , to

$$\sum_{j=1}^{n-1} a_{ij} b_j = \alpha_i \neq 0 \quad i = 1, \dots, m.$$

Now, if there exists b_n such that $a_{in} b_n \rightarrow -\alpha_i$ for $i = 1, \dots, m$, we are finished. Certainly such a number exists. Just choose b_n not equal to any of the numbers

$$\left(-\frac{\alpha_1}{a_{1n}}, \dots, -\frac{\alpha_n}{a_{nn}} \right).$$

By the theorem, at least one row of A must be the zero vector. The reduced matrix A^* is formed from A by the elimination of a row which is the zero vector. The remaining discussion pertains to A^* which has $r=m-1$ rows called the set (r) .

Lemma 3. The equation

$$[\xi]x > 0$$

has a solution x if and only if the equation

$$y[\xi] = 0$$

has no semipositive solution y .¹⁰

Corollary. The equation

$$[\xi]x < 0$$

has a solution, x , if and only if the equation

$$y[\xi] < 0$$

has no semipositive solution y .

Proof. It is sufficient to show that $[\xi]x < 0$ has a solution if and only if $[\xi]x > 0$ has a solution. Suppose x is a solution to $[\xi]x > 0$. Then $x' = -x$ is a solution to $[\xi]x' < 0$. If x is a solution to $[\xi]x < 0$, then $x' = -x$ is a solution to $[\xi]x' > 0$.

Lemma 4. If A is an \hat{A} then for any $b \in E_n$ such that $a_i b_i = 0$ for some non-zero $a_i \in (r)$, then there exists at least one $a_j \in (r)$, where $i \neq j$, such that $a_j b_i = 0$.

PROOF. Let A be an \hat{A} and assume that for b_i , $ab_i = 0$ for one and only one non-zero $a \in (r)$. Since A is an \hat{A} , we know the following:

$ab_i = 0$ for one and only one non-zero $a \in (r)$, by assumption. Call it a_i .

$ab_i > 0$ for $\frac{r}{2}$ rows of A^* . Call them the set (P) .

$ab_i < 0$ for $\frac{r}{2} - 1$ rows of A^* . Call them the set (D) .

The last two statements are valid because otherwise either b_i or $-b_i$ would be a solution to $Mb > 0$ contrary to the assumption that A is an \hat{A} . It makes no difference whether (P) or (D) contains $r/2$ elements since (D) becomes (P) for $-b_i$. By Lemma 3, there exists no semipositive solution to

$$y[P] = 0.$$

¹⁰ For the proof, see [3, p. 48]. "Semipositive" is taken to mean that $y_i \geq 0$ and not all $y_i = 0$.

This is forced by the definition of (P) . There also exists no semipositive solution to

$$(1) \quad y \begin{bmatrix} P \\ a_i \end{bmatrix} = 0.$$

Assume that there does exist a semipositive solution to (1). This implies that $-a_i$ can be expressed as a positive combination of some of the elements of (P) . Assume them to be the first k elements. That is

$$-a_i = \sum_{j=1}^k y_j a_j \quad \text{where } y_j > 0.$$

Multiplying by b_i , we find

$$0 = -a_i b_i = y_1 a_1 b_i + \cdots + y_k a_k b_i \quad y_i > 0.$$

But, this contradicts the fact that $a_i b_i > 0$ for all $a \in (P)$. Because (1) has no solution, by Lemma 3 there must exist a solution to

$$(2) \quad \begin{bmatrix} P \\ a_i \end{bmatrix} \quad b > 0$$

and, since there are $(m+1)/2$ rows of the matrix in (2), A cannot be an \hat{A} . The lemma is proved.

Lemma 5. If A is an \hat{A} , then for each row vector a_i of A^* there exists at least one row vector a_j , $j \neq i$, of A^* and scalars α_i and α_j (not both zero) such that $\alpha_j a_j + \alpha_i a_i = 0$.

PROOF. If some $a \in (r)$ is the zero vector, the condition of the lemma is satisfied. If no $a \in (r)$ is the zero, then any b such that $a_i b = 0$ must be orthogonal to at least one other row of A^* . The finite condition on the rows forces there to be at least one row, say a_j , which is orthogonal to every vector b which is orthogonal to a_i . This means a_i and a_j are parallel and the lemma is proved. The formal proof follows closely the proof of Theorem 1.

Theorem 2. If one and only one row of A is the zero vector, then A is an \hat{A} if and only if the rows of A^* can be partitioned into two element sets such that there exists a solution to

$$y_i a_i + y_j a_j = 0 \quad y_i, y_j > 0.$$

PROOF. By Lemma 5, if A is an \hat{A} , then the rows of A^* can be divided into sets which are parallel. It will be shown that each such set contains an even number of vectors and that half lie in one direction and the other half lie in the opposite direction. This is simply another way of stating the theorem.

Choose any row of A^* , say a_i , and divide all rows of A^* into the sets with respect to a_i as defined below.

s = the number of vectors in a set (s) where $(s) = \{a_j \in (r) \mid \alpha_i a_i + \alpha_j a_j = 0$

has a solution α_i and α_j . Note that (s) contains a_i . Recall also that by assumption, (r) contains no zero.

q = the number of vectors in a set (q) where $(q) = \{a_j \in (s) \mid a_j = \lambda a_i \text{ has a solution } \lambda > 0\}$. Note that (q) contains a_i .

l = the number of vectors in a set (l) where $(l) = \{a \in (s) \mid a \notin (q)\}$. Notice that $s - q = l$.

b_i = some vector in E_n such that $ab_i = 0$ for all $a \in (s)$ and $ab_i \neq 0$ for all $a \in (r) \cap (\bar{s})$.

p = the number of vectors in a set (p) where $(p) = \{a \in (r) \cap (\bar{s}) \mid ab_i > 0\}$.

d = the number of vectors in a set (d) where $(d) = \{a \in (r) \cap (\bar{s}) \mid ab_i < 0\}$.

Observe that

$$r = p + d + l + q.$$

By Lemma 3 and its corollary there exists no semipositive solution, y , to

$$y[p] = 0 \quad \text{or} \quad y[q] = 0.$$

Also, there exists no semipositive solution, y , to

$$(3) \quad y \begin{bmatrix} p \\ q \end{bmatrix} = 0.$$

A solution to (3) would imply that the negative of some member of (q) can be expressed as a positive combination of a subset of (p) or vice versa. Assume $a_q \in (q)$ can be expressed as a positive combination of the first k elements of (p) , i.e.,

$$-a_q = y_1 a_1 + \cdots + y_k a_k \quad y_i > 0.$$

Multiply by b_i and obtain

$$0 = -a_q b_i = y_1 a_1 b_i + \cdots + y_k a_k b_i \quad y_i > 0.$$

But, by the definition of (p) , all members on the right of the equation are positive thus establishing a contradiction. Since there is no semi-positive solution to (3), there must exist a solution to

$$(4) \quad \begin{bmatrix} p \\ q \end{bmatrix} b > 0.$$

If A is to be an \hat{A} , (4) dictates that

$$(5) \quad p + q \leq \frac{r}{2}.$$

Otherwise, $\begin{bmatrix} p \\ q \end{bmatrix}$ would be an M for which there is a solution to $Mb > 0$

thus violating Lemma 1. By the same reasoning, we know that

$$(6) \quad p + l \leq \frac{r}{2}$$

and, since (d) becomes (p) for $-b_i$, the same argument gives

$$(7) \quad d + l \leq \frac{r}{2}$$

$$(8) \quad d + q \leq \frac{r}{2}.$$

Recalling that $r = p + d + l + q$ and solving equations 5 through 8, one can derive

$$(9) \quad q \leq l \quad \text{and}$$

$$(10) \quad l \leq q.$$

Therefore, $l = q$ and the "only if" part of the theorem is proved.

Now the "if" part. Assume the conditions of the theorem are satisfied. Choose any $b_i \in E_n$ such that $ab_i = 0$ for the zero vector. For every $a \in A$ such that $ab_i > 0$, there is an $a \in A$ such that $ab_i \leq 0$. Therefore $ab_i \leq 0$ for $(m+1)/2$ elements of (m) and A is an \hat{A} .

The theorems below are related to the discussion contained in Section Three of the text. Recall that the discussion there is about majority decisions which must satisfy a single constraint such as

$$\sum_{i=1}^n p_i x_i \leq I.$$

It is assumed that the "existing position" is one which satisfies

$$\sum_{i=1}^k p_i x_i = I.^{11}$$

The following definitions are needed.

Let C be a specific, non-zero vector (the negative of the gradient of the constraint).

$$G = \{b \in E_n \mid b \in J \cup K\}$$

$$J = \{b \in E_n \mid Cb > 0\}$$

$$K = \{b \in E_n \mid Cb = 0\}.$$

Let A be an \hat{A} if and only if for every $b \in G$ there exists an $M \in (M)$ such that $Mb \leq 0$.

¹¹ See the discussion in the text.

Lemma 6. A is an \hat{A} if and only if for no $M \in (M)$ does there exist a $b \in G$ which is a solution to $Mb > 0$. (proof omitted)

Lemma 7. If A is an \hat{A} , then there must exist some $a \in (m)$ and a set of scalars (α_i, a_o) with at least one $\alpha \neq 0$ such that

$$\alpha_i a + \alpha_o C = 0.$$

PROOF. Assume no $a \in (m)$ satisfies the conditions of Lemma 7. Then there exists $b_i \in K$ such that $ab_i = 0$ for no $a \in (m)$. The elements of (m) can be partitioned into two sets according to whether $ab_i > 0$ or $ab_i < 0$. One of these sets must contain at least $(m+1)/2$ elements. Since these sets reverse positions for $-b_i$, A cannot be an \hat{A} by Lemma 6.

Theorem 3. If A is an \hat{A} , then there exists some $a \in (m)$ such that a solution exists to

$$y_i a + y_o C = 0 \quad y_i > 0, y_o \geq 0.$$

PROOF. The following definitions are needed.

H = the number of elements in the set (H) where $(H) = \{a \in (m) \mid \alpha_i a + \alpha_o C = 0 \text{ not all } \alpha = 0\}$.

By Lemma 7, the set (H) is not empty. If a member of (H) is the zero vector, it also satisfies the conditions of the theorem. So only the case where (H) contains no zero vector need be examined.

Assume A to be an \hat{A} and assume that no member of (H) satisfies the condition of the theorem.

b_i = some $b \in K$ such that $ab_i \neq 0$ for all $a \in (\bar{H})$.

P = the number of elements in (P) where $(P) = \{a \in (\bar{H}) \mid ab_i > 0\}$.

D = the number of elements in (D) where $(D) = \{a \in (\bar{H}) \mid ab_i < 0\}$. Note that $P + D + H = m$.

If A is an \hat{A} , then

$$P < \frac{m+1}{2} \quad \text{and} \quad D < \frac{m+1}{2}.$$

Otherwise either $[P]b$ or $[D](-b)$ would satisfy $Mb > 0$ contrary to Lemma 6.

Now, there can exist no semipositive solution to

$$y \begin{bmatrix} P \\ H \\ C \end{bmatrix} = 0.$$

A solution to this implies that any $a_k \in (H) \cup C$ with $y_k \neq 0$ can be expressed as

$$\sum y_j a_j = -a_k \quad y_j \geq 0.$$

Multiply this equation by b_i and observe

$$\sum_{j=1}^P y_j a_j b_i = -a_i b_i = 0 \quad y_j \geq 0$$

which contradicts the fact that $a_j b_i > 0$ for $j=1, \dots, P$.

So, by Lemma 3, there does exist a solution to

$$\begin{bmatrix} P \\ H \\ C \end{bmatrix} \quad b > 0.$$

The same argument shows there is a solution to

$$\begin{bmatrix} D \\ H \\ C \end{bmatrix} \quad b > 0.$$

But, since $P+D+H=m$, either $P+H \geq (m+1)/2$ or $D+H \geq (m+1)/2$ so either one or the other satisfies $Mb > 0$. By Lemma 6, A cannot be an \hat{A} .

If A is an \hat{A} at least one element of (m) must satisfy the condition of Theorem 3. Elimination of this element yields a set called (r) with $r=m-1$ elements.

Lemma 8. If A is an \hat{A} and if the condition of Theorem 3 is satisfied by one and only one row of A , then for every $a_i \in (r)$ there exists at least one $a_j \in (r)$, $i \neq j$, such that a solution exists to

$$\alpha_i a_i + \alpha_j a_j + \alpha_c C = 0 \quad \alpha_i, \alpha_j \neq 0.$$

PROOF. It can be shown that if the condition of this Lemma is *not* satisfied for some row, say a_i , then there exists a $b \in K$ such that $a_i b = 0$ and $a_j b \neq 0$ for all $j \in (r)$, $j \neq i$.¹²

Assume A is an \hat{A} , no $a \in (r)$ satisfies the condition of Theorem 3, and that for a_i there exists a $b \in K$, say b_i , such that $a_i b_i = 0$ and $a_j b_i \neq 0$ for all $a_j \in (r)$, $i \neq j$. We let

P = the number of elements in a set (P) where $(P) = \{a \in (r) \mid a b_i > 0\}$

D = the number of elements in a set (D) where $(D) = \{a \in (r) \mid a b_i < 0\}$.

If A is an \hat{A} then one set contains $r/2$ elements and the other contains $r/2-1$. Otherwise, either b_i or $-b_i$ would be a solution to $Mb > 0$. Assume $P=r/2$. By the same argument used previously there exists no semipositive solution to

$$y \begin{bmatrix} P \\ a_i \\ C \end{bmatrix} = 0.$$

¹² Use corollary to Theorem 2.3 in [3, p. 37].

Thus, by Lemma 3, there exists a solution to

$$\begin{bmatrix} P \\ a_i \\ C \end{bmatrix} \quad b > 0.$$

But the set $(P) \cup a_i$ contains $(m+1)/2$ elements and is therefore an M . So A cannot be an \hat{A} . Recalling that (D) becomes (P) for $-b_i$ proves the Lemma.

Lemma 9. If A is an \hat{A} and if the condition of Theorem 3 is satisfied by one and only one row of A , then the elements of (r) can be partitioned into mutually exclusive sets each containing two elements such that there exists a solution to

$$\alpha_i a_i + \alpha_j a_j + \alpha_c C = 0 \quad \alpha_i, \alpha_j \neq 0.$$

PROOF. Assume A is an \hat{A} and that the condition of Theorem 3 is satisfied by one and only one row of A . Choose any member of (r) , say a_i , and partition the members of (r) with respect to a_i as follows.

H = the number of elements in a set (H) where $(H) = \{a_j \in (r) \mid \text{a solution exists to } \alpha_i a_i + \alpha_j a_j + \alpha_c C = 0, \alpha_i, \alpha_j \neq 0\}$. Notice that $a_i \in (H)$ and by Lemma 8, (H) contains more than one element.

$b_i = \{\text{some } b \in K \mid \text{for all } a \in (H), ab_i = 0 \text{ and for all } a \in (r) \cap (\overline{H}), ab_i \neq 0\}$.

$b_j = \{\text{some } b \in K \mid \text{for all } a \in (H), ab_j \neq 0\}$.¹³

P = the number of elements in a set (P) where $(P) = \{a \in (r) \cap (\overline{H}) \mid ab_i > 0\}$.

D = the number of elements in a set (D) where $(D) = \{a \in (r) \cap (\overline{H}) \mid ab_i < 0\}$.

Q = the number of elements in a set (Q) where $(Q) = \{a \in (H) \mid ab_j > 0\}$.

L = the number of elements in a set (L) where $(L) = \{a \in (H) \mid ab_j < 0\}$.

Observe that

$$r = Q + L + P + D.$$

By arguments used previously, there exists no semipositive solution to

$$y \begin{bmatrix} P \\ Q \\ C \end{bmatrix} = 0.$$

So, if A is to be an \hat{A}

$$(11) \quad P + Q \leq \frac{r}{2}.$$

¹³ The existence of such a b_j involves an assumption that $\alpha_i a_i + \alpha_c C = 0$ has no solution for any $a \in (H)$. No confusion should result since a_i could be so chosen.

The same argument gives

$$(12) \quad P + L \leq \frac{r}{2}.$$

Since (D) becomes (P) for $-b_i$, we have

$$(13) \quad D + L \leq \frac{r}{2}$$

$$(14) \quad D + Q \leq \frac{r}{2}.$$

Recalling that $r = Q + L + P + D$, it can be shown that

$$(15) \quad L = Q.$$

Since $L + Q = H$, the lemma is proved.

Theorem 4. If the condition of Theorem 3 is satisfied by one and only one row of A , A is an \hat{A} if and only if the elements of (r) can be partitioned into pairs such that there exists a solution to

$$y_i a_i + y_j a_j + y_c C = 0 \quad \begin{array}{l} y_i, y_j > 0 \\ y_c \geq 0. \end{array}$$

PROOF. Choose some element of (r) , say a_k . The elements of (r) can be partitioned with respect to a_k as follows.

H = the number of elements in a set $(H) = \{a_i \in (r) \mid \text{a solution exists to } \alpha_i a_i + \alpha_k a_k + \alpha_c C = 0, \alpha_i, \alpha_k \neq 0\}$.

By Lemma 8 and Lemma 9, the number of elements in (H) is greater than zero and even. Notice that $a_k \in (H)$.

Now partition (H) into pairs such that for the maximum possible number of pairs a solution exists to

$$y_i a_i + y_j a_j + y_c C = 0 \quad y_i, y_j > 0, y_c \geq 0.$$

Call the set of pairs for which this condition is satisfied $(H_p) \cdot (H_p)$ is a subset of (H) and contains H_p (an even number) elements.

H_n = the (even) number of elements in (H_n) where $(H_n) = (H) \cap (\overline{H_p})$.

b_i = $\{ \text{some } b \in K \mid ab_i = 0 \text{ for all } a \in H \text{ and } ab_i \neq 0 \text{ for all } a \in (r) \cap (\overline{H}) \}$.

P = the number of elements in a set (P) where $(P) = \{a \in (r) \cap (\overline{H}) \mid ab_i > 0\}$.

D = the number of elements in a set (D) where $(D) = \{a \in (r) \cap (\overline{H}) \mid ab_i < 0\}$.

There exists no semipositive solution to $y \begin{bmatrix} P \\ H_n \\ C \end{bmatrix} = 0$. This can be shown

by the method used previously. By eliminating the proper elements ($H_p/2$ in number) from (H_p) a set (H'_p) containing $H_p/2$ elements can be formed such that there exists no semipositive solution to

$$y \begin{bmatrix} P \\ H_n \\ H'_p \\ C \end{bmatrix} = 0.$$

Therefore, if A is an \hat{A}

$$P + \frac{H_p}{2} + H_n \leq \frac{r}{2}.$$

The same argument gives

$$D + \frac{H_p}{2} + H_n \leq \frac{r}{2}.$$

By noting that $r = P + D + H_p + H_n$, it can be shown that

$$H_n \leq 0.$$

The "only if" part is proved. Proof of the "if" is omitted.

ON LOGNORMALITY AS A SUMMARY MEASURE OF CONCENTRATION

By IRWIN H. SILBERMAN*

Discussions in the recent literature [3] [5] [6] [8] [12] [13] [14] of industrial organization have focused on the problem of determining an appropriate theoretical distribution to describe the actual array of business firms and establishments, in the economy as a whole, and in particular industries. Pragmatically, the advantage of using a simple and well-known probability distribution is immense, because we can summarize the entire array of business units by the parameters of that distribution. More specifically, a particular interest has centered around the use of the lognormal distribution. If the distribution in question is lognormal, it is possible to subject its parameters to standard classical tests of significance. Thus, for the first time, we will be able to make direct statistical comparisons of the size distributions of business units, both over time and among markets.

Studies of the usefulness of particular probability distributions as summary measures of concentration have generally had two objectives: (a) development of statistical techniques to determine the goodness of fit of the distribution in question, and (b) examination of how well the growth patterns of firms conform to the stochastic processes known to generate these distributions.

Unfortunately, the results reported thus far, both as they apply to the techniques of fitting and the applicability of the stochastic processes to particular industries, are of limited assistance to the specialist in industrial organization. If a particular distribution is to be useful in the study of concentration, the statistical test of goodness of fit employed must "make do" with the sparsity of data generally available for most industries. Further, the data being fitted must be economically relevant. Finally, it must be shown that the distribution in question is appropriate over the broad array of industries to be described, or at least, that the distribution is appropriate for industries with certain readily identifiable attributes. The latter finding might allow us to gain some insights regarding the stochastic process or processes which generate the distribution in particular cases.

* The author is associate professor of banking at New York University. He wishes to thank M. A. Adelman, Albert Ando, Gerald Glasser, Bernard Kemp, Ernest Kurnow, Ralph L. Nelson, and Edward Robinson for their advice and assistance. The project was financed by grants from the National Science Foundation and the Office of Research, Schools of Business, New York University.

As an illustration of the problems involved in satisfying these criteria, we briefly refer to a series of recent methodological papers by R. E. Quandt [11] [12], who proposes a new method of fitting, and applies the technique to several firm size distributions. Application of Quandt's technique requires data on the size of individual firms and plants operating in an industry. But across a large number of industries, such data are generally not available. In fact, Quandt draws his sample of firms in particular industries from the Dun and Bradstreet *Million Dollar Directory*, and obtains asset figures from *Moody's Manuals*. The resulting sample is biased in two respects. First, small firms will systematically be excluded because of the arbitrary cutoff. And an undetermined number of large firms will be omitted because *Moody's* does not necessarily include all such firms in an industry. Second, the general quality of the financial data supplied, together with the inclusion of all the operations of multi-product firms and the lack of uniformity in the treatment of corporate interrelationships, distort the measure of size employed.

To avoid the problems of data collection for particular industries, P. E. Hart and S. J. Prais [3, p. 151] chose as their sample "those firms which have shares quoted on the London Exchange." However, the economic meaning of the size distribution of firms in the economy as a whole is open to serious question, even if the sample were representative of the firms in the entire economy (which it was not). That is to say, pricing and output decisions are determined within particular market contexts, and it is the size distributions of sellers within these markets which should be analyzed for a meaningful study of concentration.

This paper reports the results of an attempt to comprehensively describe the seller size distributions of firms and establishments in 90 four-digit S.I.C. industries by the two-parameter lognormal function. In doing so we try to avoid the major data pitfalls encountered by other investigators. The study is based upon data collected by the Census of Manufactures, which provides the best available enumeration of companies and establishments in manufacturing. Further, we employ a statistical technique for fitting which does not require knowledge of the operations of individual business units. The only data necessary are concentration ratios generally available from published sources, and the mean and the variance of the logarithms of company and establishment size for each industry, which have been computed for us by the Census Bureau¹ without disclosing individual operations.

Section I describes the statistical test to determine the goodness of fit of the lognormal distribution, essentially by comparing observed and theoretical values along the Lorenz curve. Though the test places pri-

¹ The Census Bureau has a running computer program written by Nelson [9] to compute the required statistics.

mary emphasis upon the extreme upper tail of the distribution, where the difference between the lognormal and other highly skewed distributions is most pronounced, it can also successfully discriminate at lower-size classes of firms and establishments.

Section II discusses the data which we use to test the lognormal hypothesis. In Section III, we analyze our results and attempt to ascertain whether lognormality is systematically related to particular characteristics of the distributions. We conclude by arguing that though the lognormal hypothesis cannot be rejected for specific industries, it is inappropriate to consider the function as a generalized statistical summary measure of the industry size distributions in manufacturing.

I. *The Test for Lognormality*

We propose to determine the goodness of fit of the two-parameter lognormal distribution, and in particular, of the extreme upper tail of that distribution, by testing the difference between *actual* concentration ratios, e.g., the market shares of the top 4, 8, 20, and 50 business units, and *expected* concentration ratios, based on the assumption that the observed distribution of the size of business units can be described by the lognormal. In other words, we compute the mean and the variance of the logarithms of size of the actual distribution, and assume that they are the parameters of a lognormal distribution. We then compute the hypothetical concentration ratios implied by this assumed lognormal distribution, and compare them with the actual concentration ratios. If they are not significantly different, we infer that the upper tail of the actual distribution approximates the lognormal.²

² The essential elements of the mathematical derivation of the hypothetical concentration ratio for the lognormal distribution were presented in a 1954 paper by J. Aitchison and J. A. C. Brown [1]. In essence, the aim of that paper was to show the relationship which exists between the variance of the logarithms of the variates in a lognormal distribution and the Lorenz and Gini coefficients of concentration. Derivation of the Lorenz and Gini coefficients, however, requires knowledge of all the points on the Lorenz curve, and each point is given by what Aitchison and Brown call the first moment distribution, $F_1(x)$. The first moment distribution represents the proportion of total income accruing to persons with incomes not greater than x . But each point on the Lorenz curve is nothing more than what is in the literature referred to as a "relative" concentration ratio, i.e., the proportion of total income, assets, shipments, or employment accounted for by a given *proportion* of persons or business units.

Though our method requires the calculation of "absolute" concentration ratios, i.e., the share of total income or shipments accounted for by a given *number* of persons or business units, these can be directly obtained from the relative concentration ratios, so long as the number of firms is known. Consequently, our technique for deriving the hypothetical concentration ratios is essentially no different from the technique proposed by Aitchison and Brown, and as a result, $F_1(x)$ is equivalent to our $[m'(x_0)/m']$ (hypothetical concentration ratio based on the assumption that the distribution is lognormal).

In addition, there is presented in Aitchison and Brown [2, App. Table A1], for various values of σ^2 (variance of logarithms) the corresponding Lorenz coefficients, given that the distribution is lognormal. From these coefficients the points on the Lorenz curve (and hence the

The proposed method is flexible in that it can be used to test the share of the total market accounted for by the top 2, 3, or 4 business units, or the share of the top 20, 50, or 100 units, or of any other number of business units. There is nothing sacred about our use in this paper of the top 4, 8, 20, and 50 business units, but we employ them here because such information is generally available in government published statistics.

Glossary of Terms

The following notation appears in our technical description of the test.

$p(x_0)$ is equal to q/n , where $q=4, 8, 20$, and 50 , and n is equal to the total number of firms in the industry. Thus, in an industry having 100 firms, $p(x_0)$ will take on the values .04, .08, .20, and .50. Further, x_0 is the size associated with the q^{th} firm. Thus $p(x_0)$ may also be viewed as the proportion of total firms in the industry having a size equal to and greater than x_0 .

$m(x_0)$ is technically known as the incomplete first moment. It is equal to the sum of the firm sizes of the top q firms, divided by n , or the sum of firm sizes equal to and greater than x_0 , divided by n . Hence:

$$(1) \quad m(x_0) = \frac{\sum_{i=n-(q-1)}^n x_i}{n}.$$

m is the mean size of firm in the industry and is defined as:

$$(2) \quad m = \frac{\sum_{i=1}^n x_i}{n}.$$

$\frac{m(x_0)}{m}$ is then very simply:

hypothetical concentration ratios) may be determined.

Further, in a paper published in 1957, Hart [4] calculated, based on the relations presented in [1], the hypothetical top 3 and top 10 concentration ratios for the British brewing industry for a few selected years, and compared them with the actual ratios. The calculations were performed using the Prais slide rule. (This technique is mentioned in [3, p. 160] but its exact nature is not clear.) Hart, however, presents no statistical technique for determining whether the observed differences between the actual and hypothetical ratios are significant.

The method as utilized in this paper, although based on essentially the same theoretical considerations, has the advantage that once the number of business units, and the mean and the variance of the logarithms of size are given, the hypothetical concentration ratios can be computed directly. Consequently, it was possible to develop a computer program which could perform this process and facilitate the handling of large quantities of data.

$$(3) \quad \frac{\sum_{i=n-(q-1)}^n x_i}{\sum_{i=1}^n x_i} .$$

It will be noticed that the quantity $[m(x_0)/m]$ is the top q concentration ratio, or alternatively, it is the market share of firms having size greater than and equal to x_0 .

$m'(x_0)$ is the incomplete first moment of the lognormal distribution.

m' is the mean of a lognormal distribution, equal to $e^{(M+1/2V^2)}$ where M and V^2 are respectively, the mean and the variance of the logarithms of firm size.

$\frac{m'(x_0)}{m'}$ is then the top q concentration ratio, based on the assumption that the x_i 's are lognormally distributed.

The Test for the Lognormal Distribution

Let x equal the size variable under consideration. The size distribution of business units can then be summarized by a relative frequency function $f(x)$, with the mean of x denoted by m , and the variance of x denoted by v^2 .

The proportion, p , of business units in the top bracket, i.e., above size x_0 is given by:

$$(4) \quad p(x_0) = \int_{x_0}^{\infty} f(x) dx.$$

Define the incomplete first moment, $m(x_0)$, by

$$(5) \quad m(x_0) = \int_{x_0}^{\infty} xf(x) dx.$$

Then, the proportion of total industry size accounted for by the business units in the bracket p is given by $[m(x_0)/m]$, i.e.,

$$(6) \quad \frac{m(x_0)}{m} = \frac{\int_{x_0}^{\infty} xf(x) dx}{\int_0^{\infty} xf(x) dx} .$$

Though the development up to this point suggests that we are computing a "relative" concentration ratio, i.e., the share of total industry size accounted for by $p(x_0)$, the *proportion of firms* or establishments having

size greater than x_0 , we are in fact also computing an "absolute" concentration ratio, i.e., the market share of the 4, 8, 20, or 50 *largest firms* or establishments. This equivalence results from our fixing the fraction $p(x_0)$ to take on the values $4/n$, $8/n$, $20/n$, or $50/n$, where n is the total number of firms or establishments in the industry. For example, in an industry with 200 firms, the top four concentration ratio is obtained by setting $p(x_0)$ equal to .02. With 400 firms, $p(x_0)$ would be fixed at .01. Since concentration ratios are generally available only for the largest firms, we shall in the empirical sections below allow $p(x_0)$ to vary among industries, and deal with the top 4, 8, 20, and 50 concentration ratios.

Let us now denote $\ln x = X$. If $f(x)$ is a lognormal distribution, then X is normally distributed, with

$$(7) \quad \text{mean} = M = \ln(m) - \frac{1}{2}V^2,$$

and

$$(8) \quad \text{variance} = V^2 = \ln\left(1 + \frac{v^2}{m^2}\right).$$

Equation (4) can therefore be expressed as

$$(9) \quad p(X_0) = \int_{x_0}^{\infty} N(X | M, V^2) dX.$$

Since we know the values of M , V^2 , and $p(X_0)$, we can compute X_0 from equation (9) and a table of the normal distribution. We can then compute x_0 from the relation $X_0 = \ln x_0$.

The incomplete first moment of $f(x)$, when $f(x)$ is known to be lognormal [7, p. 158, equation 7.8a] can be expressed as:

$$(10) \quad m' - m'(x_0) = \int_0^{x_0} xf(x) dx = e^{(M+\frac{1}{2}V)} F_{N*}[k(x_0)]$$

where $F_{N*}[k(x_0)]$ is the standardized normal distribution function valued at $k(x_0)$, and

$$(11) \quad k(x_0) = \frac{(X_0 - M)}{V} - V.$$

Then, under the assumption of lognormality, the theoretical value which corresponds to $[m(x_0)/m]$ in equation (6) is given by

$$(12) \quad \frac{m'(x_0)}{m'} = 1 - \frac{e^{(M+\frac{1}{2}V)} F_{N*}[k(x_0)]}{e^{(M+\frac{1}{2}V^2)}} \\ = 1 - F_{N*}[k(x_0)].$$

If the assumption of lognormality is satisfied, $[m(x_0)/m] - [m'(x_0)/m']$ should not be significantly different from zero. Hence the difference between $[m(x_0)/m]$ and $[m'(x_0)/m']$ can be considered an indication of the goodness of the lognormal assumption.

We employ a test of significance based on the assumption that $[m(x_0)/m]$ is normally³ distributed. Since we treat $[m'(x_0)/m']$ as a constant (it is computed through the use of equation (12) above), $\sigma^2_{[m'(x_0)/m']} = 0$. Hence the variance of $[m(x_0)/m] - [m'(x_0)/m']$ is simply the variance of $[m(x_0)/m]$.

To obtain an estimate of the variance of $[m(x_0)/m]$, we simulate, assuming that firm sizes are lognormally distributed, with population parameters M (mean of logarithms of firm size) and V^2 (variance of logarithms of firm size).

The Simulation in Theory

The distribution of the concentration ratios from a specified lognormal population (M and V^2 given) can be easily simulated [2, pp. 28-29]. Suppose that we wish to construct a sample of size n from a lognormal population with parameters M and V^2 . To do so, we use a table of random normal deviates. If we denote by U_i ($i = 1, \dots, n$) consecutive values from the table, then the transformation $x_i = e^{M+VU_i}$ gives a sample of size n from a lognormal population with parameters M and V^2 . After ranking from largest to smallest, the sums of the top 4, 8, 20, and 50 simulated establishment and company sizes can be easily obtained. We now sum all the x_i to obtain the simulated total industry size, and divide it into the top 4, 8, 20, and 50 sums, obtaining the

³ In addition to the normal approximation, we alternatively considered a distribution-free test of significance. As described in the next section, for each observed concentration ratio, we have simulated a sample distribution, computed from $L=100$ samples of size n drawn from a lognormal population with parameters M and V^2 . At the 5 per cent level, a two-tailed distribution-free test of significance would take the following form:

$$\begin{aligned} C_* &= (L+1) \frac{\alpha}{2} \\ &= (101) \frac{.05}{2} \\ C_* &= 2.525. \end{aligned}$$

Thus, we reject the null hypothesis that the observed ratio is from a lognormal distribution if there are fewer than 2.525 simulated values which exceed the *observed* concentration ratio. We also reject the null hypothesis if there are fewer than 2.525 simulated values less than the observed ratio.

This alternative test was performed on eighty-two 1958 value of shipments-company size distributions, and the results were compared with those obtained using the normal approximation. The comparison yielded a net change in the classifications of three industries from not lognormal to lognormal. No modification of the conclusions of this paper is indicated as a consequence of these reclassifications.

required concentration ratios. If we repeat the above experiment L times, this procedure will yield a sample distribution of the various concentration ratios. The standard errors of the ratios can then be directly computed.

Hence, the test will take the form:

$$(13) \quad |z| = \frac{\frac{m(x_0)}{m} - \frac{m'(x_0)}{m'}}{\sigma[m(x_0)/m]}.$$

Example Calculation

Given the values in Table 1 below, the calculations to determine the goodness of fit of the lognormal distribution are straightforward.

TABLE 1—STATISTICS OF THE DISTRIBUTION OF 1,999 COMPANIES, 1947,
SIZE BY VALUE OF SHIPMENTS

| | | |
|--|--------------------|---------|
| Variance of the logarithms of company size | V^2 | 3.61428 |
| Standard deviation of the logarithms of company size | V | 1.90113 |
| Mean of logarithms of company size | M | 6.02630 |
| Actual top four concentration ratio | $[m(x_0)/m]$ | .471 |
| Standard error of concentration ratio (simulated) | $\sigma[m(x_0)/m]$ | .0710 |

We have said that $F_{N^*}[k(x_0)]$ is the standardized normal distribution function valued at $k(x_0)$, and that $k(x_0)$ is equal to $[(X_0 - M)/V] - V$. Considering the share of the top four companies in the industry, we know the value of $p(x_0) = 4/1999 = .0020$. Substituting this value of $p(x_0)$ into equation (9), i.e.,

$$.0020 = \int_{x_0}^{\infty} N(X|M, V^2) dX,$$

and solving for X_0 using the table of the cumulative normal distribution, we find that $k(x_0) = .979$. Therefore,

$$F_{N^*} [.979] = .8365.$$

Subtracting from 1.0, we find the hypothetical concentration ratio, based on the assumption of lognormality, equal to .1635. To test our two ratios for a significant difference, we evaluate (13):

$$|z| = \left| \frac{.4710 - .1635}{.0710} \right| = 4.327.$$

Using a two-tailed test, at the 5 per cent level of significance, we find that the difference between the two ratios is significantly different from zero, and we conclude that the distribution in question is not lognormal.

This is so because our criteria for accepting or rejecting the null hypothesis will be the following: We first examine the distribution in the extreme upper tail. If it provides an acceptable fit in this extreme region, we then successively examine larger portions of the distribution. If the theoretical distribution does not provide an acceptable fit in the extreme upper tail, for our purposes, we reject the null hypothesis.

II. *The Data*

For the Census years 1947 and 1958, we analyze, for a sample of 90 four-digit manufacturing industries (old⁴ Standard Industrial Classification) the size distributions of establishments and companies, size measured by value of shipments and unadjusted value added.

The S.I.C., which the Census Bureau employs to classify its data, was not designed to aid in measuring market structure, and its shortcomings are well known. However, we shall here employ the classification system because it does provide us with the only available across-the-board data on manufacturing with which to test the lognormal hypothesis.

A few additional caveats and explanations are in order. First, 1947 and 1958 were years of expansion and deflation, respectively, and as a result, establishments and companies may appear either larger or smaller than they really are in any permanent sense. Second, our initial measure of size is value of shipments. However, when value of shipments is totaled for all establishments, industry by industry, the sums will contain some duplication, since the value of manufactured products includes the value of the manufactured materials from which they were made. Hence, as our second measure of size, we consider value added, which is a "net" concept and is additive without duplication. Though Census began publishing adjusted value added in 1958, we study the *unadjusted* data to maintain consistency between 1947 and 1958.⁵

Finally, Census definitions of establishments and companies are not at all clear. For example, an establishment is not necessarily identical with a plant. If a single plant engages in distinctly separate lines of activity, it must submit a separate report for each activity, and each

⁴ The industry classifications used in this study are based on the 1945 S.I.C. code, as amended. A revised edition of the S.I.C. *Manual* was issued in 1957, and the final reports and volumes of the 1958 *Census of Manufactures* are based upon this new classification system. The preliminary reports of the 1958 Census were, however, tabulated on the 1945 code. In order to maintain consistency in the classifications between 1947 and 1958, we decided to base our work on the old code.

⁵ Unadjusted value added is computed by subtracting from value of shipments the actual cost of materials consumed, assuming all products produced in a given year are sold in that year. Adjusted value added takes into account both the trade operations of manufacturing concerns and the change in work-in-process and finished goods inventories between the beginning and end of the year.

^a 1947 only.

activity will then be treated by Census as a specific establishment. On the other hand, two plants belonging to the same company may be considered as one establishment by Census if they are, say, located in the same county. A company, on the other hand, is defined as all the establishments which enjoy common ownership or control, and which are classified in the same four-digit industry. Thus, one would expect to find a multiplant firm classified in as many industries as it has establishments operating in diverse four-digit categories. The substance of Census treatment, however, is that establishments are grouped together into companies on the initiative of the reporting companies, i.e., based on the affiliations admitted by respondents. To the extent that companies do not report corporate interrelationships, there is an overstatement in the number of companies, and an understatement in their sizes.

Analysis of the Sample

The 90⁶ four-digit Census industries studied in this paper are drawn exclusively from the list of 142 industries selected for analysis by R. L. Nelson [9] in his monograph on industrial concentration,⁷ and were

⁶ Ninety industries for 1958; ninety-one for 1947.

⁷ The reader is referred to Chapter II of Nelson's monograph for a detailed discussion of the selection criteria, as well as for discussions regarding reconstruction of the basic data files, preparation of the input tapes, the computer program, etc.

Our original plan was to select a random sample of industries for analysis. We found, how-

TABLE 3—DISTRIBUTION AMONG TWO-DIGIT GROUPS OF NINETY^a INDUSTRY SAMPLE IN 1958

^a Industry 3661 included in 1947 only.

^b Calculated from [16, Pt. I, Table 2].

^c [16, Pt. II, Table 8] lists the total number of industries as 443. Discussions with the Census Bureau confirmed, however, that industry 2443, Cigar Boxes, was inappropriately omitted.

selected from that list on the basis of comparability of the classifications between 1947 and 1958.

Table 2 presents a list of the 91 four-digit industry classifications in the sample. Table 3 describes our sample for 1958 in terms of two-digit major industry categories. Included in our sample are 20.2 per cent of the 444 four-digit S.I.C. industries in manufacturing (excluding the 19 group). The coverage among industries is not uniform, ranging from none at all in major groups 23 and 27, to 52.4 per cent of the industries in major group 36.

Though the sample contains only 20.3 per cent of the four-digit industries in 1958, it does contain 27.2 per cent of total unadjusted value

ever, that the cost of reconstructing original data files, recoding, and of preparing input tapes was prohibitive. But these tasks had previously been performed for the Nelson sample of industries. Further, Nelson, whose computer program we used, had in his work already computed the mean and the variance of the logarithms of the 1947 value of shipments establishment and company distributions. It was therefore decided to draw exclusively upon the Nelson sample.

added in manufacturing. Reference to Table 4 illustrates the large variation for particular two-digit groups, ranging from no coverage in major groups 23 and 27 to 91.2 per cent in group 29.

The sample coverage ranges from 11.4 per cent of those industries which have more than 1,000 companies, to 30.8 per cent of those industries which have less than 20 companies (see Table 5). The pattern for establishments is similar. At the 5 per cent level, a Chi-square test indicates that there is no significant difference in the coverage of industries in the various company and establishment size classes.

Finally, we find a bias of the company sample (Table 6) toward industries which are both larger (measured by value of shipments), and more highly concentrated (measured by the top four company ratio⁸ for the industry).

⁸ There is a systematic downward bias in the concentration ratios. This bias was created by the computer program not rounding the industry shares of individual companies, but simply dropping the last digit. The bias appears most strongly when a number of shares are cumulated to get the top 20 or 50 concentration ratios. We made no adjustment to correct for rounding.

III. Results of the Test for Lognormality

We now present the results of our test for lognormality of the size distributions of establishments and companies for 1947 and 1958.

Classification of the Results

As has been indicated, the distinction between the lognormal distribution and other members of the lognormal family is most pronounced in the extreme upper tail of the distribution, and it is therefore this region that is important when testing for lognormality. If the extreme upper tail of the distribution is not lognormal, then for our purposes, the distribution is not lognormal.

We establish the following criteria to evaluate the results of our lognormal test.

1. Our primary interest is in the extreme upper tail of the distribution, i.e., whether there is a significant difference between the actual and hypothetical concentration ratios at the top four level.

2. If there is a significant difference between the hypothetical and actual concentration ratios at the top four level, we immediately reject the null hypothesis that the distribution is lognormally distributed. If there is no significant difference at the top four level, we continue to test by examining the difference between successively larger concentration ratios, i.e., top 8, 20, and 50. If we find a significant difference at any of these levels, even though the extreme upper tail shows no significant difference, we again reject the null hypothesis that the distribution is lognormal.

3. We eliminate from the statistical analysis those industries which had twenty or fewer firms or establishments, since a determination of lognormality would have to be based, at a maximum, on the comparison of only two concentration ratios (top four and top eight). We consider this little information as insufficient to make a determination of the shape of the distribution.

Based upon these criteria, the following categories of results were established.

Category 1. The upper tail of the distribution is lognormal. If the actual top 4 concentration ratio is not significantly different from the hypothetical top 4 concentration ratio and, in addition, the top 8, 20, and 50 ratios are also not significantly different, we *do not reject* the null hypothesis that the extreme upper tail of the distribution is lognormal.

Category 2. The upper tail of the distribution is lognormal, but we are unable to test successively higher ratios. In this category, we include those industries where we found no significant difference between the actual and hypothetical top 4 concentration ratios, but Census disclosure of information prohibits us from testing at successively higher ratios. In later analysis this category will be excluded.⁹

Category 3A. The upper tail of the distribution is lognormal, but we find a significant difference when we test successively higher ratios. In this category we include those industries for which we found no significant difference between the actual and hypothetical top 4 concentration ratios, but for which we did find significant differences when we tested at the top 8, 20, or 50 levels. We consider this finding as sufficient to *reject* the lognormal hypothesis.

Category 3B. Disclosure prohibits testing for lognormality at the top four concentration ratio, but we find significant differences at successively higher ratios. We are unable to test the actual and hypothetical top four concentration ratios for a significant difference because of Census disclosure, but we do find significant differences at higher levels, e.g., top

⁹ For the 1947 value of shipments-establishment distributions, where the number of such cases is large, we alternatively consider them as "lognormal."

TABLE 7—SUMMARY OF ACTUAL PATTERNS OF RESULTS OF LOGNORMAL TEST ON CENSUS DATA, BY CATEGORY

| Category | Concentration Ratio, Top | Actual Pattern Exhibited ^a |
|---|--------------------------|---------------------------------------|
| 1. Upper tail of distribution is lognormal | 4 | YY |
| | 8 | YY |
| | 20 | YY |
| | 50 | Y- |
| 2. Upper tail is lognormal, but we are unable to test successively higher ratios | 4 | YYYYYY |

| | 50 | NNN-YN-YNYNNN |
| 3B. Disclosure at top 4 ratio but we find significant differences at higher ratios | 4 | DDDDDDDDDDDDDDDD |
| | 8 | YDNNNNNNDDYDYN |
| | 20 | NYDYNDNYDNYNNND |
| | 50 | NN--NNYNNNN--N |
| 4. Upper tail is <i>not</i> lognormal | 4 | NNNNNNNNNNNNNNNN |
| | 8 | YNNNDDNDNDNNYDDYY |
| | 20 | YYNNYYYYYNNNDDYDDNY |
| | 50 | YYYN-Y-N--N-NN-N-- |
| 5. We are unable to determine the lognormality of the extreme upper tail | 4 | DDDDDDDDDD |
| | 8 | DDDDYYYYD |
| | 20 | DYDYDYDYDD |
| | 50 | D-YY--YY- |
| 6. No analysis performed (20 or fewer establishments or companies) | 4 | |
| | 8 | |
| | 20 | |
| | 50 | |

^a Notes: Y—No significant difference between hypothetical and actual concentration ratios.

N—Significant difference between hypothetical and actual concentration ratios.

D—Disclosure.

--Less than specified number of establishments or companies in the industry.

8, 20, or 50. Again we consider this pattern as sufficient to *reject* the lognormal hypothesis.

Category 4. The extreme upper tail is not lognormal. We find a significant difference between actual and hypothetical top 4 concentration ratios. This finding leads us to *reject* the null hypothesis that the upper tail is lognormal.

Category 5. We are unable to determine the lognormality of the extreme upper tail. Disclosure at the top four level prevents our testing for a

TABLE 8—DISTRIBUTION OF EIGHT SAMPLES BY CATEGORY OF RESULT

| | Category | | | | | | | Total Number of Industries |
|--|----------|----|----|----|----|----|---|-------------------------------|
| | 1 | 2 | 3A | 3B | 4 | 5 | 6 | |
| 1958 Value of shipments—companies | 42 | | 31 | | 9 | | 8 | 90 |
| 1958 Value of shipments—establishments | 14 | 3 | 13 | 32 | 17 | 8 | 3 | 90 |
| 1958 Value added—companies | 41 | 2 | 27 | | 12 | | 8 | 90 |
| 1958 Value added—establishments | 15 | 3 | 13 | 23 | 26 | 7 | 3 | 90 |
| 1947 Value of shipments—companies | 36 | 1 | 28 | | 16 | 2 | 8 | 91 |
| 1947 Value of shipments—establishments | 7 | 10 | 19 | 16 | 24 | 13 | 2 | 91 |
| 1947 Value added—companies | 30 | | 31 | | 20 | 2 | 8 | 91 |
| 1947 Value added—establishments | 14 | 1 | 20 | 10 | 40 | 4 | 2 | 91 |

significant difference between the concentration ratios. Further, we have no evidence which would lead us to reject the lognormal hypothesis at the top 8, 20, and 50 levels. This category of result is therefore excluded from the analysis.

Category 6. No analysis performed. As stated above, we exclude from analysis all industries which had twenty or fewer establishments or companies.

Given the categories detailed above, we present in Table 7 the various patterns of results obtained in our tests of Census data, and their appropriate classification into one of the seven categories discussed above.

In Table 8 we present the distribution of our eight samples, by category of result of the lognormal test. Thus, we find for the 1958 value of shipments-company distributions, the extreme upper tails of 42 of our sample of 90 industries are lognormally distributed (i.e., classified in category 1). On the other hand, a total of 40 industries are classified as "not lognormal" (31 in category 3A, none in category 3B, and nine in category 4). It should be noted that the four "company" samples contain the highest proportion of industries classified as lognormal. The important point, however, is *that the lognormal distribution does not provide us with a universal description of the size distributions of sellers.*

TABLE 9—DIVERGENCE AMONG DISTRIBUTIONS BASED ON VALUE OF SHIPMENTS AND VALUE ADDED: INDUSTRIES CATEGORIZED "LOGNORMAL"

| | 1958 Companies | 1958 Establish- ments | 1947 Companies | 1947 Establish- ments |
|---|-------------------|-----------------------------|-------------------|-----------------------------|
| Number of industries in sample classified as "lognormal" when size measure is value of shipments | 42 | 14 | 36 | 7 |
| Number of industries in sample classified as "lognormal" when size measure is <i>both</i> value of shipments and value added | 36 | 10 | 28 | 4 |
| Number of industries in sample classified as "lognormal" when size is value of shipments, but <i>not</i> categorized as "lognormal" when value added is measure of size | 6 | 4 | 8 | 3 |

| Category 5 | — | 2 | — | 5 |
| Category 6 | — | — | — | — |

Size Measures

There is a clear indication that value of shipments and value added, when employed as alternative measures of the size of companies and establishments, are highly (though not perfectly) related. Such correspondence is well illustrated by reference to the 1958 company distributions. (See Tables 9 and 10.) Here we find 36 industries, or 45 per cent of those in the sample (excluding industries with less than 20 companies) are classified lognormal when size is *both* value of shipments and value added. Only in five industries is the value added classification log-

TABLE 10—DIVERGENCE AMONG DISTRIBUTIONS BASED ON VALUE OF SHIPMENTS AND VALUE ADDED: INDUSTRIES CATEGORIZED "NOT LOGNORMAL"

| | 1958 Companies | 1958 Establish- ments | 1947 Companies | 1947 Establish- ments |
|---|-------------------|-----------------------------|-------------------|-----------------------------|
| Number of industries in sample "not lognormal" when size measure is value of shipments | 40 | 62 | 44 | 59 |
| Number of industries in sample classified as "not lognormal" when size measure is <i>both</i> value of shipments and value added | 33 | 60 | 42 | 59 |
| Number of industries in sample classified "not lognormal" when size is value of shipments but <i>not</i> categorized "not lognormal" when value added is measure of size | 7 | 2 | 2 | 0 |
| <i>Value Added Categorization</i> | | | | |
| Category 1 | 5 | 1 | 2 | — |
| Category 2 | 2 | — | — | — |
| Category 5 | — | 1 | — | — |
| Category 6 | — | — | — | — |
| Number of industries in sample "not lognormal" when size measure is value added | 39 | 62 | 51 | 70 |
| Number of industries in sample classified as "not lognormal" when size measure is <i>both</i> value of shipments and value added | 33 | 60 | 42 | 59 |
| Number of industries in sample classified as "not lognormal" when size is value added, but <i>not</i> categorized as "not lognormal" when value of shipments is measure of size | 6 | 2 | 9 | 11 |
| <i>Value of Shipments Categorization</i> | | | | |
| Category 1 | 6 | — | 8 | 3 |
| Category 2 | — | — | 1 | 4 |
| Category 5 | — | 2 | — | 4 |
| Category 6 | — | — | — | — |

normal when the value of shipments classification is not lognormal. Further, 33 industries or 40 per cent of those in the sample were identically found not lognormal when both measures of size are employed. In only about half a dozen industries is there a divergence in results between the value of shipments and value added measures.

We can conceive of two hypotheses to explain the regularity exhibited by the two alternative measures of size. The first is that the same factors making for lognormality of the size distributions operate on both value of shipments and value added. Unfortunately, the individual firm and establishment size data necessary to test this hypothesis are not available from the Census Bureau.

TABLE 11—COMPARISON OF RESULTS BETWEEN 1947 AND 1958 VALUE OF SHIPMENTS-COMPANY DISTRIBUTIONS

| 1947 Category \ 1958 Category | 1 | 2 | 3A | 3B | 4 | 5 | 6 | Total |
|-------------------------------------|----|---|----|----|---|---|---|-------|
| 1 | 28 | | 7 | | | | | 35 |
| 2 | | | | | | | 1 | 1 |
| 3A | 7 | | 16 | | 4 | | 1 | 28 |
| 3B | | | | | | | | 0 |
| 4 | 5 | | 6 | | 5 | | | 16 |
| 5 | 1 | | 1 | | | | | 2 |
| 6 | 1 | | 1 | | | | 6 | 8 |
| Total | 42 | | 31 | | 9 | | 8 | 90 |

Second, value added is derived (or estimated) from value of shipments. It may indeed be that the procedures employed are biased in such a way as to yield identically shaped distributions. In any case, one fact is clear. In the analyses which follow, we expect little or no divergence in conclusions on account of our measure of size.

Divergence in Results: 1947 and 1958

The finding of correspondence between our alternative size measures is closely paralleled when we compare the 1947 and 1958 results. Table 11 presents, for the value of shipments-company distributions, a comparison of results by year. Due to space considerations, we omit comparable tables for the other samples. Forty-two industries were classified as lognormal in 1958, while 35 were so classified for 1947. Interestingly, 28 industries were identically classified in both years. Further, 31 industries were identically classified as not lognormal in both years. Thus, a total of 59 industries or 72 per cent of the sample (excluding those industries with less than 20 firms) were identically classified in both 1947 and 1958. Based on these limited data, we conclude that the applicability of the lognormal function as a descriptive device is more or less uniform for the two years under investigation. That is to say, if an industry was lognormal in 1947, there is a high probability that it will be so classified in 1958. Conversely, if the business units in an industry were not lognormally distributed in 1947, the probability of their having been lognormally distributed in 1958 is small.¹⁰

¹⁰ This statement implies nothing about the shapes of the distributions in the intervening years.

TABLE 12—SUMMARY RESULTS OF CHI-SQUARE TESTS TO DETERMINE THE RELATIONSHIP OF LOGNORMALITY TO SIZE OF CLASSIFICATION

| Group | Degrees of Freedom | χ^2 | $\chi^2_{.05}$ | Results |
|--|--------------------|--------------------------------|----------------|---------------------------|
| 1947 Value of shipments—companies | 4 | 13.216 | 9.488 | significant difference |
| 1947 Value of shipments—establishments | 2 | No Test Performed ^a | | no significant difference |
| 1947 Value of shipments—establishments (Category 2 considered "lognormal") | | 0.042 | 5.991 | |
| 1947 Value added—companies | 3 | 1.966 | 7.815 | no significant difference |
| 1947 Value added—establishments | 1 | 0.0 | 3.841 | no significant difference |

| 1958 Value added—companies | 4 | 3.658 | 9.488 | no significant difference |
| 1958 Value added—establishments | 2 | 2.909 | 5.991 | no significant difference |

^a Only seven industries classified in Category 1, lognormal tail.

Relationship of Lognormality to Particular Industry Characteristics

We have thus far found that the lognormal distribution is inappropriate as a generalized summary measure of concentration. The distribution may still be useful, however, if it can be shown that lognormality is related to specific characteristics of particular industries. In that case, we might at least be able to use the function as descriptive of that class of industries. Further, we might gain some insights regarding the stochastic process or processes which generate the distribution in particular cases.

The characteristics to be studied are industry size (total industry value of shipments and value added), the number of establishments and companies classified in the industry, and the degree of top-four concentration in the industry. In order to determine whether lognormality is significantly related to any of these characteristics, we constructed three contingency tables for each of the eight samples of industries, and used the Chi-square test to test the null hypothesis of independence.¹¹ It should be noted, however, that in each case the number of degrees of freedom for Chi-square is limited.

At the 5 per cent level of significance, we are unable to find a con-

¹¹ Category 2 results (upper tail is lognormal, but we are unable to test the top 8, 20, and 50 ratios) are generally excluded from the analysis. However, in the case of the 1947 value of shipments-establishment distributions, where the number of category 2 results is large, we performed an alternative test considering both category 1 and 2 as lognormal.

TABLE 13—SUMMARY RESULTS OF CHI-SQUARE TESTS TO DETERMINE THE RELATIONSHIP OF LOGNORMALITY TO NUMBER OF BUSINESS UNITS

| Group | Degrees of Freedom | χ^2 | $\chi^2_{.05}$ | Results |
|--|--------------------|--------------------------------|----------------|---------------------------|
| 1947 Value of shipments—companies | 4 | 20.935 | 9.488 | significant difference |
| 1947 Value of shipments—establishments | | No Test Performed ^a | | |
| 1947 Value of shipments—establishments (Category 2 considered "lognormal") | 1 | 5.845 ^b | 3.841 | significant difference |
| 1947 Value added—companies | 4 | 14.523 | 9.488 | significant difference |
| 1947 Value added—establishments | 1 | 1.150 ^b | 3.841 | no significant difference |
| 1958 Value of shipments—companies | 4 | 32.804 | 9.488 | significant difference |
| 1958 Value of shipments—establishments | 1 | 3.817 ^b | 3.841 | no significant difference |
| 1958 Value added—companies | 4 | 22.214 | 9.488 | significant difference |
| 1958 Value added—establishments | 2 | 13.053 | 5.991 | significant difference |

^a Only seven industries classified in Category 1, lognormal tail.

^b Yates correction for continuity applied.

sistent relationship between lognormality and industry size.¹² Actual and critical values of Chi-square are presented in Table 12.

There does, however, appear to be a relationship between the occurrence of lognormality and the number of establishments and companies which comprise particular industries (see Table 13). For each sample but two, the computed value of Chi-square exceeded the critical (5 per cent level of significance). More specifically, lognormality occurs with greater relative frequency among those industries which have a large number of firms and/or establishments. The cutoff point seems to be between 100–200 business units. Conversely, nonlognormality describes a higher proportion of the industry size distributions which have, in general, less than 100 companies or plants.

It is known [10] that there exists a clear and consistent correspondence between the fewness of companies and establishments classified in an industry, and the magnitude of the top-four concentration ratio for the industry. This being the case, and given that we have found a positive relationship between lognormality and large numbers of firms and establishments, we should a priori expect to find a corresponding

¹² In only one case did we find a Chi-square which exceeded the critical value, indicating the existence of a pattern. Here, actual lognormal frequencies were greater than the hypothetical in the large value of shipments size classes, implying a possible relationship between lognormality and "large" industries.

TABLE 14—SUMMARY RESULTS OF CHI-SQUARE TESTS TO DETERMINE THE RELATIONSHIP OF LOGNORMALITY TO TOP-FOUR CONCENTRATION RATIOS

| Group | Degrees of Freedom | χ^2 | $\chi^2_{.05}$ | Results |
|--|--------------------------------|--------------------|----------------|---------------------------|

relationship of lognormality with low industry concentration. Surprisingly, Table 14 does not confirm the existence of such a pattern. Rather, we find no relationship between lognormality and the magnitude of the top-four concentration ratio in an industry.

There are clearly several possible reasons for our discovering this seeming anomaly. Thus, though we find a positive relation between the manyness of firms and establishments and lognormality, the correspondence is by no means perfect. Or, manyness of business units may in fact be related to some additional unknown variable or variables, which in turn may be related to lognormality. Other hypotheses are equally compatible with the results. In any case existing available data will not support tests of the alternatives.

Divergence Between Company and Establishment Distributions

Before concluding, we investigate the observed differences between the size distributions of establishments and companies, and attempt to explain them in terms of a simple process for generating the lognormal distribution, i.e., the "law of proportionate effect."

From Table 15 we see, for the 1958 value of shipments distributions, 22 industries classified as not lognormal by establishments, were lognormal when companies were analyzed. On the other hand, there were only two instances where the establishment distribution was lognormal,

TABLE 15—NUMBER OF INDUSTRIES CLASSIFIED "NOT LOGNORMAL": ESTABLISHMENTS AND COMPANIES COMPARED

| Distribution | 1958 Value of Shipments | 1958 Value Added | 1947 Value of Shipments | 1947 Value Added |
|---|-------------------------------|------------------------|-------------------------------|------------------------|
| (a) Number of company distributions "not lognormal" | 40 | 39 | 44 | 51 |
| (b) Number of establishment distributions "not lognormal" | 62 | 62 | 59 | 70 |
| (c) Number of industries classified in <i>both</i> (a) and (b) above | 36 | 37 | 37 | 46 |
| Establishment distribution classified as "not lognormal," but company distribution classified as below: | <u>26</u> | <u>25</u> | <u>22</u> | <u>24</u> |
| Category 1 (lognormal) | 22 | 19 | 16 | 17 |
| 2 | — | 1 | 1 | — |
| 5 | — | — | 1 | 1 |
| 6 | 4 | 5 | 4 | 6 |

and the company distribution was not. Similar patterns exist for the other samples.

These findings suggest the following hypothesis. The simple law of proportionate effect states that the chance of a given proportionate increase in size is the same for business units of all sizes. However, though the law may appear reasonable for companies because of the various paths of growth possible, e.g., addition of plants, diversification, and vertical integration, it would not, a priori, necessarily appear to hold for establishments, whose growth is more narrowly limited by increasing production or transport costs, or other physical and market constraints. If this is so, it is oftentimes only the company which can maintain the necessary growth consistent with the law of proportionate effect.

Consequently, in those industries where the establishment distributions are not lognormal, while the company distributions are, the difference between the top-four company and establishment concentration ratios should be greater than the difference between the ratios when both the establishment and company distributions for an industry are lognormal. This excess should exist because in the former case, constraints on the growth of large establishments prevent their achieving the large size consistent with the law of proportionate effect. That is to say, the greater the difference in the concentration ratios, the greater the size of the largest companies relative to the size of the largest establishments.

Table 16 presents the results of the test. For each of our four groups (1958 value of shipments, 1958 value added, 1947 value of shipments,

TABLE 16—COMPARISON OF MEAN DIFFERENCES IN TOP-FOUR COMPANY AND ESTABLISHMENT CONCENTRATION RATIOS^a

| Group | Establishment and Company Distributions —Both “Lognormal” | Establishment Distributions “Not Lognormal” —Company Distributions “Lognormal” |
|--|---|---|
| <i>1958 Value of Shipments</i> | | |
| Mean difference in top-four concentration ratios | .099 | .152 |
| Number of industries | (14) | (15) |
| <i>1958 Value Added</i> | | |
| Mean difference in top-four concentration ratios | .074 | .224 |
| Number of industries | (15) | (14) |
| <i>1947 Value of Shipments</i> | | |
| Mean difference in top-four concentration ratios | .139 | .221 |
| Number of industries | (7) | (15) |
| <i>1947 Value Added</i> | | |
| Mean difference in top-four concentration ratios | .108 | .150 |
| Number of industries | (14) | (17) |

^a Number of industries may be less than or equal to those previously reported, depending on top-four concentration ratio disclosures.

1947 value added) the mean difference in the top-four concentration ratio is larger (and substantially so) for those industries where the establishment distribution is not lognormal and the company distribution is, as opposed to those industries where both distributions are lognormal. Thus, the crude data which we are able to examine support the hypothesis of constrained establishment growth, and provide one explanation to account for the differences in the size distributions of establishments and companies.

IV. *Summary and Implications for Industrial Organization*

In recent years there has been substantial controversy regarding the usefulness of probability models to explain observed business size distributions. Some of the views advanced are extreme, and range from a call for re-evaluation of public policy decisions in the light of our knowledge of stochastic processes [14], to the belief that the models provide no promise toward understanding and describing concentration [13].

Our evidence suggests an intermediate position. We have found that the lognormal distribution does not provide a summary description of the size distributions of sellers over the broad array of industries in manufacturing. In none of our eight samples did the function describe more than 50 per cent of the size distributions studied. Yet its use does

not appear inappropriate for specific industries, especially when the company distributions are considered. However, we were unable to discover a consistent relationship between the occurrence of lognormality and specified attributes of the industries which were well described. This was true despite our finding that if an industry was lognormal, it was generally so regardless of the year considered or the measure of size employed.

CONSUMER DEMAND IN THE UNITED STATES

*A Review Article*¹

By GEORGE L. PERRY*

Attempts to improve the specification and measurement of consumption functions continue to be a major object of empirical analysis in economics. In *Consumer Demand in the United States*, H. S. Houthakker and Lester D. Taylor add both to our stock of quantitative information about the demand for consumer goods and to our array of tools for analyzing consumer demand.

This book originated as a study for projecting the components of personal consumption expenditures for the government's Interagency Growth Study. Specifically, the research was designed to estimate a system of demand functions, based on time series data, for an 83 commodity breakdown of total consumption expenditures, and to use these demand functions for projecting the detailed components of personal consumption expenditures in a postulated 1970 economy. Reporting the results of this central task occupies roughly half of the 200-odd pages of the book.

In the other half, Houthakker and Taylor treat us to a range of interesting discussions arising from problems they had to solve along the way to estimating their demand equations and from off-shoots and extensions suggested by their main line of inquiry. We get some purely econometric material on problems of estimation and projection, including a discussion of the three-pass least squares method of estimation developed by Taylor and Wilson [10] which is used extensively in estimating the demand equations of the book. And we get a detailed development of a dynamic model of consumption demand applied both to durable goods and other components of consumption and to total consumption and saving. The H-T model is flexible and can accommodate a range of specific hypotheses about consumer behavior. For many readers these will be the most rewarding parts of the book; and it is a rewarding book.

It may be best to sketch what is in each of the seven chapters as the authors do in their introduction. Chapter 1 sets out the basic dynamic model of demand together with various special cases of the basic model. It is the one indispensable chapter even if one wishes to pick and choose from the rest in pursuit of some specialized interest. Chapter 2 discusses the variables and data that are used. Chapter 3 is the main chapter on econometric problems. It has sections on the projecting variance of estimated models, auto-

* The author is associate professor of economics at the University of Minnesota. He would like to thank Leonid Hurwicz for his comments and help. This paper was prepared while the author was supported by a Ford Foundation Faculty Research Fellowship.

correlation problems, the three-pass estimating method, the problem of adding-up individual demand equations to get total consumption demand, and the results of Monte Carlo experiments for testing alternative forecasting methods. Chapters 4 and 5 present the main results of the study, the estimated demand equations and the projections to 1970, together with some tentative conclusions drawn from the results and some comparisons with results of others for six European countries. Chapter 6 switches to estimating aggregate consumption and saving functions and exploring further the dynamic model and some of its variations. This and Chapter 1 comprise material of considerable interest to students of the consumption function and to anyone interested in how to do useful empirical investigations generally. Indeed the last comment characterizes the book as a whole. Finally, Chapter 7 evaluates all the results and presents a principal-component analysis of the variables in the individual demand equations. It, in addition to Chapter 3, should be of particular interest to the applied econometrician.

I

The authors' basic dynamic model is central to the book and can be described briefly. In continuous time, expenditures at a given moment are made to depend on current income and a "state variable" representing the influence of past expenditures on the present. In the case of durables, this state variable may be concretely thought of as the stock of the good remaining from past expenditures; in the case of some other commodities and services, and possibly durables as well, the state variable is interpreted to measure "habit formation" or the "psychological stock of habits" for the good in question. Formally, either interpretation is expressed by the same form of equation: $q(t) = \alpha + \beta s(t) + \gamma x(t)$ [(2) on p. 9], where $x(t)$ is the rate of income at time t , $q(t)$ is the rate of expenditures, and $s(t)$ is the relevant stock. (Other explanatory variables, such as relative prices, are introduced in a manner parallel to income.) Where the durable inventory effect predominates, β will be negative; where the habit formation effect predominates, β will be positive. Now by assuming the change in the stock is given by $\dot{s}(t) = q(t) - \delta s(t)$ [(5) on p. 10], where δ is the depreciation rate, the stock variable can be eliminated to produce an equation in terms of observable variables. To do this, solve the first equation, (2), for $s(t)$ to eliminate it from the second equation, (5). Then differentiate the first equation with respect to time and substitute for \dot{s} the new form of the second equation, which now expresses \dot{s} in terms of q and x . The result is $\dot{q}(t) = \delta + (\beta - \delta)q(t) + \gamma \dot{x}(t) + \gamma \delta x(t)$, equation (8) on page 10. This is the basic equation of the model, expressed in continuous time and treating all equations as holding exactly. Following a careful translation of the model into discrete time, which itself is worth reading by anyone fitting data to a model, the authors derive the corresponding estimating equation (apart from estimating errors) of the form $q_t = A_0 + A_1 q_{t-1} + A_2 \Delta x_t + A_3 x_{t-1}$ [(37) on p. 14]. Thus the effects of stocks are incorporated without introducing them as a separate explanatory variable.

For most values of the coefficients, the values of the original parameters can be derived from the A 's (pp. 14 and 15) and estimates are thus obtained of the stock effect (β) and the short-run (γ) and long-run ($\gamma\delta/\delta-\beta$) marginal propensities to consume. (When additional explanatory variables are introduced, some parameter values become overidentified and the authors estimate using an identifying restriction technique which they discuss.) Since $\delta > 0$, for commodities whose consumption is dominated by habit formation ($\beta > 0$), the short-run MPC will be lower than the long-run, the effect of habit formation being to dampen short-run responses to income changes. For commodities dominated by physical stock adjustment ($\beta < 0$), the opposite is true. For either type of commodity, under steady linear growth (a constant absolute increase in x each period) it is easy to show that the marginal propensity to consume in each period is a constant equal to the long-run MPC. However there is no such simple relation under exponential growth at a constant rate.

II

Despite the many interesting and valuable side-aspects of the book the authors emphasize that the core of their work is in Chapter 4, where individual demand equations for 83 commodity groups are presented and their implications discussed; and they say it is mostly by this material their work should be judged. These results are based on annual data going back to 1929. Although history may form a judgment on the accuracy of the individual projections they present, I am not sure how to judge this body of material for this review. It is certainly the most carefully done estimation and projection of such a detailed breakdown of total consumption spending that I know of. By comparison, for instance, the vast Brookings-SSRC model [8, Ch. 7] estimates only five major categories of consumption rather than the 83 categories of this book. Yet their working over such a wide front did not keep Houthakker and Taylor from treating each category independently. They have tried a range of alternative specifications for each demand relation, including both linear and nonlinear static models in addition to the basic dynamic model and some variations on it. And they have tried variables for income distribution, age distribution, and some commodity stocks where these seemed appropriate. In short, they have explored a good deal before choosing any best equation for a particular commodity, at bottom relying on common sense and judgment about what is reasonable to guide them. I think this approach is the right one, contrasted, say, with a commitment to one functional form for all commodities or one mechanistic criterion for choosing among alternatives; and what they have done with such a mass of material is impressive. If I have one over-all misgiving it is with their use of total consumption expenditures (rather than income) as the main explanatory variable in all equations, but more on this below.

Having said I admire their general procedure and being unable to judge the predictive ability of their results, let me at least note a few of their findings. The dynamic equation turns out to be very useful. It is the preferred form for 72 of the 83 categories for which equations are estimated. Habit

formation ($\beta > 0$) turns out to characterize 50 of the commodities, accounting for 58 per cent of total 1961 consumption expenditures. Inventory adjustment ($\beta < 0$) characterizes 18 commodities, accounting for 28 per cent of total 1961 consumption expenditures. Total expenditure was excluded or had a negative sign in only five minor categories out of the total of 83: perhaps inferior goods (other fuel and ice, railway commuting) or changing tastes; and perhaps bad data or specification (toilet preparations). But prices came out much worse, appearing in only 45 of the final equations and frequently only at the borderline of significance.

This result of persistent price inelasticity will disturb many readers. Supply functions could not be specified; in the dynamic model, prices were constrained to act with the same lag structure as income; and relative prices did not change much for most commodities. Perhaps there is just a statistical problem in isolating the effects of prices on demand. It is interesting that 29 of the 45 commodities for which price variables were significant are services, the group with the largest relative price movement. But the authors accept their findings on prices and offer the interesting conjecture that prices become less important at high levels of income, in part because habit formation becomes more important. This is consistent with their finding that habit formation predominates in U.S. consumption (and is much less important in a study by Taylor [9] for Sweden, which they cite, where incomes are lower). In any case, whether the authors have captured the effect of relative prices successfully is not necessarily crucial for their estimates of the effect of income on demand or for the projections of future demands that they are after. Income coefficients would be more biased the greater the correlation of income to relative prices; if the correlation is low, the bias may be negligible (although other characteristics of the estimates will be affected). And if there were bias introduced by the failure to capture price effects, the importance for projecting into the future would depend on whether the past relation of income to relative prices were expected to continue; if it were, consumption projections would not be biased even if income coefficients were.

The authors get a few results that I found curiously satisfying. The stock of television sets has a strong negative effect on the demand for newspapers and magazines and on the demand for motion pictures; the stock of automobiles has a negative effect on the demand for shoes; the stock of washing machines has a negative effect on the demand for cleaning and laundering services. And, justifying one of the relations many of us try to establish for short-term forecasting, the authors find residential construction activity helps explain purchases of some categories of furnishings and household durables. But I should add that the results just cited generally came out of static forms of the demand equations which are frequently rejected in favor of the authors' preferred dynamic model.

The authors justify their use of consumption as the independent variable rather than income with three remarks: the study was designed to allocate a projected 1970 consumption total among its components; there is precedent from other studies, done where income data were unavailable; and

total expenditure is a better measure of "true" income because, in the short run, consumers have more control over expenditure than income. Certainly the first reason could have been circumvented and the second is irrelevant. The third is puzzling; perhaps I do not understand it, but if it means that some kinds of consumption are not sensitive to short-run changes in income, this is something most analysts would be anxious to measure and quantify. There are no doubt lags; indeed, the authors' own estimates on aggregate consumption as explained by income point them up. As it is, we cannot safely translate the dynamic characteristics observed with total consumption as independent variable, such as the preponderance of habit formation, to what they would be with income in its place. And it is certainly roundabout, and no doubt full of room for error, to use the aggregate consumption equation and then the individual commodity equations as a second step. Since aggregate consumption is generally more stable than income, for most commodities the dampening effect observed as habit formation might be more prominent with income as the independent variable. It is harder to speculate on what effect the change would have on the equations for individual durable goods. The equations given are appropriate to the narrow object of the study: allocating a given consumption total. But my guess is that most readers would have found equations based on income more valuable.

III

When they move to their analysis of total saving and consumption, Houthakker and Taylor change to disposable income as the main explanatory variable, and make use of quarterly as well as annual data. Their results are of considerable interest to anyone working with aggregate consumption functions. The authors note the similarity of their dynamic equation, featuring habit formation, to the early consumption theories of Duesenberry [3] and Modigliani [6]. These explained differences between the long-run and short-run marginal propensities to consume in terms of behavioral motives of just this sort. The H-T formulation, however, is more flexible and offers more scope for testing and refining. They let the data set the impact of habit on present consumption rather than having to choose approximations such as previous peak income. What is more, special cases of the general model can fit other explanations of behavior: a hypothesis based on the nature of saving and the motive to save turns out to work best, as discussed below. Another point to note is that, by starting from a continuous time model, they can account for apparent differences in the marginal propensity to consume when it is estimated from quarterly rather than annual data; and they make use of their model's ability to reconcile the two in evaluating several variations of their equation.

The most useful variation turns out to be an interpretation of saving as the accumulation of a nondepreciating asset, a view the authors associate with the early work of Tobin [11] who stressed the importance of assets in permitting dissaving, and of Zellner [12] who did some of the early empirical verification of the importance of assets in explaining consumption. The

Ando-Modigliani model [1] elaborating the implications for growth and fluctuations of the Modigliani-Brumberg life-cycle hypothesis [7] is also closely related, as is the parallel work done by Arena [2].

When savings are treated as assets with zero depreciation and saving is made the dependent variable in the H-T model, the basic estimating equation reduces to $y_t = B_1 y_{t-1} + B_2 \Delta x_t$ [(31) on p. 183], where y is saving and x is disposable income (in per capita terms, as most frequently used throughout the book, or in absolute terms). There is a good discussion of this model and some of its implications, although the authors mistakenly assert that the absence of a separate x_{t-1} term in this saving equation implies its absence in the corresponding equation for consumption (p. 185). Making use of the identity $x_t = q_t + y_t$ where q is consumption, this saving equation actually implies the consumption function $q_t = B_1 q_{t-1} + (1 - B_2) \Delta x_t + (1 - B_1) x_{t-1}$. What is readily apparent from this way of writing it is that in the long run static equilibrium of the model, all income is consumed, as we would expect from the treatment of accumulated saving as an asset with infinite life.

Ando-Modigliani [1] estimated consumption functions of the form $\Delta q_t = \alpha_1 \Delta x_t + \alpha_2 \Delta w_t$, where x is now labor income, q is now consumption excluding the purchases of durables but including the use of their services, and w is the net value of all assets owned by consumers. Arena [2] estimated a similar function, though with capital gains on assets treated as a separate variable and using disposable income rather than labor income. Ignoring capital gains, if we define w_t as assets held at the start of period t , the relation $y_{t-1} = \Delta w_t$ yields $\Delta q_t = (1 - B_2) \Delta x_t + (1 - B_1) \Delta w_t$ from the H-T consumption equation given above. Except for the different definition of variables and the treatment of capital gains, this special case of the H-T model is thus an alternative way to express the Ando-Modigliani and Arena models.

Against the conceptual advantage of recognizing capital gains when assets appear as a separate variable, the H-T equation offers a way of avoiding any explicit estimate of assets altogether. Theory favors excluding durable goods purchases, though a correct treatment would have to account for the whole spectrum of average lines involved; but forecasts or projections do require that we explain purchases. The H-T approach for individual durable commodities is based on the negative impact of stocks on purchases; thus it indirectly recognizes that the flow of services is what counts, while avoiding the need to measure stocks directly. What, if anything, is lost when durables are aggregated with other consumer demands in the total consumption model is hard to say.

There are some serious problems with the short, but rather conspicuous, section of the book aimed at applying Milton Friedman's permanent income hypothesis (pp. 179-82). The authors interpret the hypothesis to yield a relation $\dot{y}_p(t) = \beta y(t)$ when income grows exponentially, where \dot{y}_p is the time derivative of permanent income and y is measured income. They get this by differentiating the expression

$$y_p(T) = \beta \int_{-\infty}^T e^{(\beta-\alpha)(t-T)} y(t) dt$$

in Friedman's *Theory of the Consumption Function* [4, p. 144]. Actually, differentiating this expression yields $\dot{y}_p(t) = \beta y(t) + (\alpha - \beta)y_p(t)$; to get their expression requires the further assumption $\alpha = \beta$, an assumption I could find no way to justify. In fact, if we accept $\alpha = \beta$, the expression above for $y_p(T)$ shows y_p to be infinite for all finite T (unless $\beta = 0$, a case with equally implausible implications).

Even aside from this unhappy specification of Friedman's hypothesis, the authors' subsequent procedure is inappropriate. They are led to an equation in the second derivative of consumption and income [(18) on p. 181] which they estimate in its discrete form approximation [(19) on p. 181] as a test of Friedman's hypothesis. But their own model [(8) on p. 10] would yield exactly the same second-derivative equation. Thus the authors' version of Friedman is not distinguishable from their own dynamic model on the basis of (18). Both models imply this equation and neither is identifiable from it. The different characteristics they note in the estimates based on (18) and on first-derivative forms of their own model are not a comparison of the permanent-income hypothesis against the authors' dynamic model, but rather a reflection of the statistical rather than exact nature of the equations. I am in complete sympathy with the authors' protestation that the permanent-income hypothesis is hard to translate into operationally testable form. But it would have been better to let it go at that.

IV

The authors' preferred saving equation for projections is based on aggregate saving and income and quarterly data from 1953 to 1962. The estimates are $y_t = .960y_{t-1} + .380\Delta x_t$ [(51) on p. 189], where both coefficients are significant at the 1 per cent level. This equation yields an estimate of the short-run MPC of 0.61, compared with the long-run value of 1.00. The long-run value is reached when income stays indefinitely at the same level; continual growth, as assumed in the 1970 projections, yields a value between these two, the value being lower the faster the growth of income.

If there is something that leaves this reader uneasy it is the major conclusion of the aggregate projections that under reasonable growth rates to 1970, the saving rate rises sharply. Using (51), a 1970 range of 7.7 per cent to 11.5 per cent saving rates is given under various assumptions; with the old GNP data, the 1960-1962 average was 7.1 per cent. Consumer satiation seems to be just around the corner. The situation becomes even more alarming if we put this projected rise of, say, 2 percentage points in the saving rate together with the decline in the business investment share of GNP projected by Hickman [5] in his comparably detailed study. Unless easier monetary conditions expanded demand in other sectors, such as housing, substantially above its historical relation to GNP, then striking a full-employment saving-investment balance shows the federal government would need to run persistent full-employment deficits of over \$20 billion by 1970 with such projections.²

² This statement should be qualified in many ways. It rules out conceivable, though vast

Because the National Income Accounts data were changed rather drastically since the authors' regressions were run, I estimated the preferred aggregate equation with the revised data for the quarters from 1953 to 1962. The new estimates are $y_t = .909y_{t-1} + .478\Delta x_t$, with coefficients again significant at the 1 per cent level. Now the short-run MPC is 0.47. But projected saving rates seem more reasonable. With 4 per cent exponential growth, the saving rate is 5.0 per cent; with 5 per cent exponential growth, the saving rate is 6.1 per cent. Using these for a 1970 projection would compare very well with the average saving rate of 5.4 per cent for 1960-1962 in the revised data. However, treating the 6.8 per cent actual average annual growth rate of income between 1961 and 1966 as a constant rate, the equation would have predicted an 8.0 per cent saving rate for 1966, compared with the 5.3 per cent rate that occurred. The problem of projecting far ahead with this kind of aggregate equation does not seem easily solved.

There seems to me a strong presumption, based on our postwar performance, for an unchanged saving rate over any longer-run projection period without abrupt income changes. To be convincing, arguments to the contrary should be quite explicit about what is happening to change this. A well-documented argument based on demographic factors is the kind of thing I have in mind; but I know of none. The present model is explicit in the role it assigns to assets; but their quantitative impact on consumption is not well established. In particular, the different coefficient estimates reported when different time periods are used in estimation [(48) to (51) on pp. 188, 189] suggest the equation may be capturing cyclical effects on saving but at the expense of longer-run effects that are needed for projection. Some modification in the form of the equation may be necessary in order to capture both the short- and long-run influences on consumption. Where projected saving rates are sensitive to variations in the form of the equations and the time periods chosen for estimation as they are here, it might have been preferable to constrain the model to yield a constant saving rate in the long run, making adjustments for postwar shortages, if needed, in estimating. Under steady growth, the present model yields a saving rate proportional to the growth rate of income (p. 184), and the relation is sensitive enough to yield the range of projections discussed above.

If I seem to be raising rather a lot of questions, let me hasten to say my overall judgment of H-T's work is decidedly enthusiastic. In an already long review, I have only touched on much of the interesting and useful material they present. The book is a good example of how to do and present empirical work. The dynamic model is a genuine contribution to the study of consumer demand. This will be a valuable book to a wide range of readers.

and unrealistic, changes in the mix of taxes, the level of expenditures or other serious alterations in the current composition of either side of the budget which, through effects such as the balanced-budget multiplier and different spending propensities by different classes of taxpayers might invalidate this rough way of estimating potential total demand from the potential budget surplus. It also accepts the inelasticities with respect to monetary conditions of the projections cited.

Cross-Section Studies of the Consumption of Automobiles in the United States

This is a study of the consumption of automobiles in the United States during the period 1955-57. Depreciation is used as the primary measure of consumption in order to determine how well demand measured in this way can be explained by income and other social and demographic variables. Depreciation is defined as the change in wholesale price for each car owned by the household during each year of study.

This study differs from earlier work in three respects: (1) the limited dependent variable model developed by Tobin is used in order to handle correctly the problem of zero expenditure households. These families represent a significant fraction (25 per cent) of all households in the United States in recent years. (2) The data used are drawn from the Surveys of Consumer Finances for the years 1955, 1956, and 1957. The estimates for each of the years are compared and appear to be reasonably consistent. (3) A repair cost based on the age of each car is included in the total cost incurred by the household.

The conclusions are that (1) household consumption rises with income, but rises less sharply at higher than at lower incomes, (2) expenditure decreases as the head of the household approaches retirement age, (3) expenditure increases as the number of adults in the spending unit increases, (4) expenditure decreases as the number of children increases, (5) after adjustment for other factors, spending units living in New York and Chicago show lower than average, and those living in rural areas show higher than average consumption, (6) nonwhite spending units consume cars at a lower level than white.

The Measurement of Consumption

The model used to estimate the consumption of automobiles is as follows:

$$(1) \quad C = a_0 + a_1Y + a_2Y^2 + a_3A_1 + a_4A_2 + a_5A_3 + a_6A_4 + a_7A_5 \\ + a_8N_a + a_9N_c + a_{10}N_i + a_{11}L_1 + a_{12}L_2 + a_{13}R,$$

where C is the expenditure on automobiles, Y is income, A_1 - A_5 are age brackets for the head of the spending unit, N_a , N_c , N_i are the numbers of adults, children, and income earners respectively in the spending unit, L_1 and L_2 are location variables, and R is the race of the spending unit. The independent variables were chosen from the sample data¹ on the basis of their

¹ Except for the automobile price and repair cost data described below, the data originate from the Surveys of Consumer Finances collected by the Survey Research Center at the University of Michigan. Each of the independent variables in equation (1) originates from the survey data and is measured for the entire spending unit.

plausible association with the consumption of automobiles. Each of these variables requires a few explanatory remarks.

Consumption (C). Consumption expenditure is the imputed depreciation cost of each car owned by the spending unit plus an estimated repair cost. The survey data provided the year and make of each car owned plus the price paid for each car acquired during the year of study. It was necessary to construct average wholesale values for each year and make of car.

The expected value of a given year and make of automobile was computed in the following way. Let the index, i , indicate the body style, i.e. station wagon, j , indicate the model, i.e. "Fairlane," and k , indicate the year and make, i.e. 1955 Ford. The average wholesale price of the k th year and make is

$$(2) \quad P_k = \sum_i \sum_j x_i x_{jk} P_{ijk},$$

where x_i is the relative frequency of the i th body style, x_{jk} is the relative frequency of the j th model, and P_{ijk} is the individual wholesale price.²

The depreciation expense was based on the average rate of depreciation for each make. The relation between wholesale price and age was found to fit equation (3) closely using least squares techniques.

$$(3) \quad V_{kt} = A_k e^{-\alpha_k t},$$

where V_{kt} is the ratio of the wholesale price of the k th make of car of age t to its new price, A_k is the constant term, and α_k is the rate of depreciation for the k th car. Data on the price of one- to eight-year old models of each make were drawn over several years in order to average together the effects of variations in used car prices. The estimates, α_k (which varied from 25 per cent per year for Fords to 40 per cent per year for Packards), were all twenty standard deviations from zero. The depreciation expense for each car owned is computed by multiplying the average price, P_k , from equation (2) by the rate of depreciation, α_k , from equation (3).

In addition to the depreciation cost, a repair cost was estimated for each car held by the spending unit. A rough estimate of the cost of owning cars of different ages was obtained by assuming that repair cost is a linear function of age:

$$(4) \quad r_t = bt,$$

where r_t is the repair cost of a t year old car. Using the age distribution of cars and trucks in use and the total receipts of all automobile repair shops, b was found to be \$7.80. Thus a five-year old car would cost \$39.00 to repair. Any choice of repair costs based on such limited data is highly con-

² These data were obtained from the following sources:

1. Price data—National Automobile Dealers Association, *Official Used Car Guide*, Vols. 21–25, Jan. 1954–Jan. 1958.
2. Model frequencies—National Automobile Dealers Association.
3. Body style frequencies—American Automobile Association, *Automobile Facts and Figures*, 1955, 1960.

jectural. However, it seemed better to use some scale of costs than to ignore them altogether.

In addition to repairs there are many other costs associated with car ownership and operation. License and insurance fees, gasoline, oil, and tire costs can amount to several hundred dollars per car. In some states license fees are determined by weight. In others horsepower or age determine the cost. While some states require liability insurance, others do not. Insurance rates vary from county to county. All of these factors except gasoline, oil, and tire costs would affect higher-income families to a larger extent because these families tend to own newer cars. Since the expenditure data used in this study did not include any of these costs and since other data are not readily available if at all, there seemed to be no way to add such costs either as an independent component or as a function of the age, the make or the degree of use of the car, or some similar variable. Simply to assume that such costs are constant per automobile and to add them to other costs would not change the magnitudes of the estimates but would complicate the application of the limited dependent variable method of obtaining maximum likelihood estimates. For these reasons costs other than repair costs and depreciation are omitted from this study.

Income (Y). Income is disposable income in current dollars, i.e., personal income of all income earners in the spending unit less federal and state income taxes. About 0.5 per cent of the spending units in each sample did not disclose their incomes and these were eliminated from the study. In order to test the hypothesis that the relationship between income and expenditure was nonlinear a simple quadratic was used: that is, the independent variables in this partial relationship are income and income squared. If, as previous studies indicate, (1) the demand for cars decreases as the stock increases and (2) the demand for cars increases as income increases, then the proportion of income spent on automobiles may decrease as income increases.

Age of head of household (A). The survey data recorded age in six age brackets. Dummy variables were assigned as follows: $A_1=18-24$ years, $A_2=25-34$, $A_3=45-54$, $A_4=55-64$, and $A_5=65$ years and over. The hypothesis is that expenditures on automobiles by spending units in the age brackets denoted by A_1-A_5 differ significantly from those in the largest bracket, 34-45 years.

Number of adults (N_a). This variable represents the absolute number of persons over 18 years of age in the spending unit. The hypothesis is that families with more adults would tend to have greater demand for automobiles, other things being equal.

Number of children (N_c). This variable represents the number of persons in the spending unit under the age of 18. The hypothesis is that spending units with larger numbers of children would tend to have greater demand for automobiles.

Number of income earners (N_i). This variable represents the number of persons earning \$600 or more in the spending unit. Although the number of income earners is highly correlated with the number of adults, it is included

to determine, if possible, which of the variables, if any, is more important in explaining expenditure on automobiles.

Location (L). Suppose one were to classify regions into (1) the central metropolitan areas of the largest cities, (2) other cities and towns with population above 2,500 and suburban areas of the largest cities, and (3) rural areas, including towns with populations of 2,500 and below. The hypotheses in mind are that families living in central metropolitan areas would have less need for a car, and families in rural areas would have more need for a car, than others. Preliminary investigations have supported the latter hypothesis but not the former for metropolitan areas as defined by the Survey Research Center.³ Because of these results, I decided to restrict the number of cities to be classified as central metropolitan areas in order to see if any urban trend could be found. Only residents of New York and Chicago (about 7 per cent of the total sample) were counted as living in central metropolitan areas. The technique of dummy variables was again used.

Race (R). In order to test the hypothesis that nonwhite families have different spending habits, race was treated as a dummy variable. This category includes Negro, Puerto Rican, and other nonwhite spending units.

Two additional economic variables were recorded by the surveys which would seem to be important determinants of demand, but which were not included in the final equation estimated in this study. They are liquid assets and income changes. In early tests of this model no statistical relationship could be found between liquid assets and automobile expenditure as defined here. One reason for this result is that liquid assets and income are highly correlated. The effect of recent income changes was also examined in preliminary investigations. The survey recorded income changes in five categories: increases of more than 25 per cent and less than 25 per cent, no change in income, and decreases of less than 25 per cent and more than 25 per cent. Using dummy variables, I have been able to find no significant differences in automobile spending habits between any of the categories of income change and the category of constant income.

The statistical model is important because of the existence of a substantial number of noncar owners in the population of consumers investigated. In 1941 only 50 per cent of all spending units owned automobiles. In 1950 and 1960 the proportion of owners rose to 60 per cent and 74 per cent respectively. If the noncar owners are eliminated from a study, nothing can be said about the decision whether or not to own an automobile. If these families are treated in the same manner as families that own cars, a definite bias appears. Furthermore, a change in the values of the independent variables, such as a general rise in incomes, could produce an apparent shift in the least squares estimates when no such change in actual spending habits had taken place. Tobin [11] developed a model which eliminates both of these sources of error. His limited dependent variable model takes into account the fact that many observations may be massed as a single value of the dependent variable—possibly zero as in the present study.

³ Those cities are New York, Chicago, Los Angeles, Washington, Baltimore, Boston, Philadelphia, Pittsburgh, Cleveland, St. Louis, and San Francisco.

The Results

The major quantitative results are presented in Table 1. The estimates are obtained for each of three years, 1955, 1956, and 1957, in order to judge their stability. For each of these years, Table 1 presents (a) the coefficients of regression relating automobile expenditures and each of the independent variables and (b) the corresponding standard errors. The constant terms for the three years respectively are -140, -134, and -206.

One test of the hypotheses formulated above can be made by comparing the coefficients to their standard errors. Except for the first four age variables, the number of children, and the number of income earners, all of the hypotheses are accepted at the .01 level of significance. The effect of number of children is significant but of different sign than predicted. A stronger test is the likelihood ratio test which is performed by recomputing the likelihood function using subsets of the original variables. One such restricted model is tested below. The relationship of each of the independent variables to expenditure on automobiles is discussed in turn.

The coefficients of regression for income and income squared are both significantly larger than their standard errors; and they are relatively stable from year to year. Assigning the independent variables their respective mean values, the resulting elasticities of income were found to be 1.43, 1.45, and 1.74 for the three years of study.⁴

The age bracket for 65 years and over shows significantly lower levels of consumption than the 35-44 age bracket. Spending units in the 65 and over age bracket spend at least \$133 less on automobiles than the 35-44 age bracket. The 55-64 bracket also shows some tendency for lower spending although not markedly. The 18-24, 25-34, and 45-54 age brackets, however, show regression coefficients which are either different in sign among the three years or small relative to the standard error. The three studies taken together reject the hypothesis that the age of the head of the spending unit is related to expenditures on automobiles—at least for the younger age brackets.

Each additional adult increases total expenditure by from \$59 to \$79. At least part of the explanation here is the fact that 42 per cent of the spending units with only one adult own automobiles, whereas 85 per cent of the two-adult spending units own automobiles.

The addition of children reduces expenditure per child \$14 to \$17. Of the spending units with automobiles, 43 per cent had no children. The fact that this relationship is negative must be influenced by this large proportion of spending units with no children. These families would have more money to spend on automobiles.

The number of income earners has no significant relationship with expenditure on automobiles. The coefficients of regression are about the same as or smaller than the standard error. Almost all of the spending units—

⁴ The income and expenditure data used in this study are all in current dollars. The 1956 and 1957 data were not adjusted for price changes. The consumer price index rose about 2 per cent per annum during the three years of study.

| Location | | | | | | |
| Metropolitan area | -175.6 | 24.5 | -200.3 | 22.1 | -263.8 | 25.1 |
| Rural area | 75.0 | 15.1 | 54.3 | 12.0 | 62.0 | 14.7 |
| Race: | | | | | | |
| Nonwhite | -128.1 | 22.6 | -88.8 | 20.9 | -129.2 | 28.1 |

^a The relationship estimated for each year is equation (1): $C = a_0 + a_1Y + a_2Y^2 + a_3A_1 + a_4A_2 + a_5A_3 + a_6A_4 + a_7A_5 + a_8N_c + a_9N_c + a_{10}N_c + a_{11}L_1 + a_{12}L_2 + a_{13}R$, where C = expenditure on automobiles and the independent variables are as indicated in the left hand column of the table.

96 per cent in 1956—had either one or two income earners; and the expenditure for each of these two groups is roughly the same.

In a limited sense, the location variables support the hypothesis that population density is inversely related to the consumption of automobiles. Residents of central metropolitan areas—New York City and Chicago—spend at least \$175 less on automobiles, while residents in rural areas spend at least \$54 more than the rest of the spending units. The availability of public transportation and the lack of parking space in the city, along with the greater need for transportation and the lack of substitute services in rural areas, all serve to explain this behavior. The results are limited, however, with respect to central metropolitan areas because only New York and Chicago are included as such. Generalizations should not be made until more large cities are studied. One might expect that residents of, for example, Los Angeles, would not behave as indicated because of the better roads and the lack of public transportation in that area.

The coefficients of regression for the race variable indicate that nonwhites spend considerably and significantly less on automobiles than whites. Nonwhites spend at least \$89 less than whites. Nonwhites include Puerto Rican and other ethnic groups as well as Negroes. Negroes composed 86 per cent of the nonwhite group. These results do not agree with the common conception of spending habits on automobiles by nonwhites. Further study is needed to provide an adequate explanation of this behavior. The expenditures of whites and nonwhites should be studied on a regional basis taking into account differences, if any, in rents, credit terms, and income stability as well as the demographic factors considered in this study.

Of the independent variables studied, two yield no consistent or significant relationship: age, except for the upper age brackets, and the number of income earners. One final question, therefore, arises. Suppose the age brackets below 65 and the number of income earners are eliminated from the study. What is the effect on the other parameters and, especially, on the coefficients of regression with respect to income and their stability over time?

Table 2 presents the maximum likelihood estimates of the model with the four age variables A_1 , A_2 , A_3 , A_4 , and the number of income earners, N_i , omitted. While most of the coefficients are similar to those in Table 1, the coefficients for the number of adults and the number of children are not as stable as in the previous model.

In order to examine the stability of the elasticities of income in Table 2 the elasticities were computed for this restricted model. The elasticities are 1.60, 1.53, and 1.67 for the years 1955, 1956, and 1957 respectively. These elasticities are all within the range of elasticities found for the original model, 1.43–1.74.

Likelihood ratio tests were performed for each of the three years of study. The hypothesis tested was that the subset of coefficients for the variables A_1 , A_2 , A_3 , A_4 , and N_i , are all equal to zero. The statistic which is tested is $-2 \log \lambda$ which is chi squared distributed with five degrees of freedom. λ is

| Race: | | | | | | |
| Nonwhite | —113. | 17.2 | —90.9 | 21.0 | —132. | 23.8 |

^a The relationship estimated for each year is as follows: $C = a_0 + a_1Y + a_2Y^2 + a_3A_6 + a_4A_5 + a_5N_c + a_6N_c + a_7L_1 + a_8L_2 + a_9R$, where C = expenditure on automobiles and the independent variables are as indicated in the left hand column of the table.

the ratio of the value of likelihood function at its maximum for the restricted model to the corresponding maximum value for the unrestricted model. This hypothesis was rejected at the .01 level of significance for all three years of study. On the basis of this test alone it must be concluded that some or all of the variables omitted did contribute to some extent to the explanation of the variation in automobile expenditures. Table 1 shows that the coefficients of the age variables 45-54 and 55-64 for the 1955 data were significantly different from zero. These two variables for the 1956 data were barely significant and for the 1957 data the age variable 55-64 and the number of income earners have coefficients slightly larger than their standard errors. The omission of these variables from the restricted model could have produced the negative results obtained from the likelihood ratio tests and some of the instability in the coefficients of the family size variables. Likelihood ratio tests on other subsets of the original variables were not performed.

The principal conclusions of this study of the demand for automobiles in the United States are as follows:

1. There appears to be a strong and relatively stable relationship between the consumption of automobiles as defined in this study and the disposable income of the spending unit. This relationship yields an elasticity of expenditure with respect to income which is somewhat higher than the two other studies which were based on cross-section data.
2. The age of the head of the spending unit is not related to expenditure for most age brackets. When the head of the spending unit reaches the age of 55 a negative relationship between age and consumption does appear and especially so in the age bracket of 65 and over.
3. The location of the spending unit does affect consumption. Spending units living in rural areas spend more on automobiles, and residents of the central metropolitan areas of New York and Chicago spend less than others.
4. When the spending unit has more than one adult, automobile expenditures increase; and when children are present in the spending unit, expenditures seem to decrease. The number of income earners when used with the two variables just mentioned does not contribute to the explanation of the demand for automobiles.
5. Nonwhite families spend much less on automobiles than white families with similar incomes, locations, and family composition.
6. In a restricted form of the model in which the age and number of income-earners variables which were not significant were omitted, most of the remaining relationships appeared to be consistent with the original model. Some variation appeared in the variables representing the number of adults and the number of children. The income elasticities computed from the restricted model supported the conclusion that the income elasticity over the three years of study was fairly stable.

Some Evidence on the Interest Elasticity of Consumption

Although there has existed a theoretical tradition concerned with the relationship between consumption (saving) and the rate of interest, which is acceptable in its elementary form to many economists, the related empirical issues remain not only unsolved, but essentially unexamined [5]. This paper reports upon one attempt to estimate the compensated interest elasticity of consumption by introducing an interest variable into a consumption function which is quite similar to Friedman's "Permanent Income Hypothesis" [4] and the "Life Cycle Hypothesis" developed in a series of articles by Modigliani, Brumberg, and Ando [1] [6]. In the two sections of this paper we shall derive the consumption function appropriate for estimating the substitution effect of a change in the rate of interest and report on some regressions obtained from testing the resulting model.

I

If an individual has a planning horizon n periods in length for which he plans the level of his consumption and the value of his desired net worth at the end of his planning horizon, his utility function may be expressed as

$$(1) \quad U(C_0, \dots, C_n, W_n)$$

where C_i denotes planned real consumption in period i and W_n the value of his desired real net worth. Denoting expected real labor income in the i th period as Y_i^e and net worth at the beginning of the planning period as W_0 , which for economy of notation is defined to include interest income accrued over period minus one but payable on the first day of period zero, the budget constraint for such an individual can be written as

$$(2) \quad W_0 + \sum_{i=0}^n \frac{Y_i^e}{(1+r)^i} - \sum_{i=0}^n \frac{C_i}{(1+r)^i} - \frac{W_n}{(1+r)^n}$$

where r denotes the rate of return available on the individual's saving.

Defining a rational consumer as one who acts as though he maximized (1) subject to (2), we execute this constrained maximization problem to obtain the necessary conditions for a maximum. These conditions may then be differentiated totally and solved for the differential of present consumption which is

$$(3) \quad dC_0 = V_{0,n+1} \left[dW_0 + \sum_{i=0}^n \frac{dY_i^e}{(1+r)^i} + \left(\sum_{i=1}^n \frac{i(C_i - Y_i^e)}{(1+r)^{i+1}} + \frac{W_n}{(1+r)^{n+1}} \right) dr \right] - \sum_{i=0}^n \frac{V_{0i}}{(1+r)^{i+1}} (dr)$$

where V_{ij} denotes the ratio of the ij th cofactor and the determinant of the bordered Hessian arising from the second order conditions of the maximization process.

It is now convenient to assume that (3) can be approximated by a differential equation having locally constant coefficients the solution of which, upon substituting standard notation, is

$$(4) \quad C = \alpha_0 + \alpha_1 PW_0 + \alpha_2 r$$

where α_0 is the constant of integration and

$$(5) \quad PW_0 = W_0 + \sum_{i=0}^n \frac{Y_i^e}{(1+r)^i} + \left(\sum_{i=1}^n \frac{W_{0+i}}{(1+r)^i} \right) r.$$

PW_0 contains current net worth (W_0), the present value of expected labor income

$$\left(\sum_{i=0}^n \frac{Y_i^e}{(1+r)^i} \right),$$

the present value of property or interest income

$$\left(\sum_{i=1}^n \frac{W_{0+i}}{(1+r)^i} r \right),$$

and is defined as the present worth of the consumer in period zero.

An understanding of the last term in PW_0 is important for an appreciation of the analysis to follow and therefore requires special comment. W_{0+i} denotes the net worth held during the i th period, the value of which is determined by the initial level of net worth and the optimal consumption plan of the individual. The product of this term and the rate of return on saving is the interest income which will be forthcoming in the $i+1$ th period. Consequently, the last term in PW_0 denotes the present value of all future interest income and represents the income effect of a change in the rate of interest. For a proof of this see [8].

Having expressed present consumption as a function of an interest variable and present worth, where the coefficient of the interest variable is interpreted as the substitution effect only, our task is now to relate the unobservable present worth to observable variables. One way of doing this is to use estimates of net worth and total income which have been used in previously fitted consumption functions. Since our income variable must be a surrogate for current and expected future total income, we may invoke a variant of Friedman's hypothesis and use an exponentially weighted average of current and past total income which we shall refer to as "normal" income and define as

$$(6) \quad Y_t^* = B \sum_{i=0}^{\infty} (1-B+\alpha)^i Y_{t-i}$$

where Y_t is total income in period t , B the coefficient of adjustment in an adaptive expectations model, and α a growth factor to account for the trend in measured or observed income. Alternatively, we may express (6) as

$$(7) \quad Y_t^* = B Y_t + (1-B+\alpha) Y_{t-1}^*$$

which reveals more readily the necessity of making certain computational decisions the nature of which are discussed below.

Denoting the available estimates of current net worth as W , we substitute Y^* and W for PW_0 and express the consumption function as

$$(8) \quad C = b_0 + b_1 Y^* + b_2 W + b_3 r + u$$

where u denotes the error term.

It is now necessary to make two final assumptions. First, although we have derived a consumption function for the individual, we assume it to be applicable to aggregate per capita consumption functions also. This requires that several problems be ignored, but we do so with precedent. Secondly, we note that individuals plan their consumption levels based upon the level of the net of tax variables. This implies that our income variables be interpreted as disposable income and the interest variable as a net rate of return.

Data on disposable income are readily available but such is not the case for the interest variable. The existence of a progressive tax structure over the period examined in the regressions requires that we construct an average marginal tax rate for the economy by which to adjust the published gross interest rates. (For a detailed account of how the tax rate was computed see [8].) Adjustments of the theory to take these considerations into account are slight, amounting to little more than a change in notation. Therefore, it will be assumed that the above notation refers to net of tax concepts wherever applicable.

II

The data used in estimating equation (8), the results of which are displayed in Table 1, can be conveniently labeled according to the source from which the income and consumption data were obtained. Such labels will be the "Goldsmith data" referring to R. W. Goldsmith's *A Study of Saving in the United States* [3], and the "MBA data" referring to the data used by Modigliani and Ando in their "The 'Life Cycle' Hypothesis of Saving" article [1], [2]. Several interest rates were used but only the results from using the net yield on corporate Aaa bonds are displayed in Table 1 [9].

TABLE 1—RESULTS OF FITTING THE GOLDSMITH AND MBA DATA TO THE EQUATION

$$C = A_0 + A_1 Y^* + A_2 W + A_3 r + U$$

(Numbers in parentheses are *t*-values)

| Constant | Normal Income | B^a | Net Worth | Interest | R^2 | D.W. | N_{σ}^b |
|------------------|------------------|-------|-----------------|--------------------|--------|------|----------------|
| GOLDSMITH | | | | | | | |
| 393.02 (5.15) | .4210 (5.82) | .90 | .0323 (2.25) | -2372.0 (-2.15) | .96369 | 1.64 | -.026 |
| MBA | | | | | | | |
| 192.24 (8.43) | .4425 (14.62) | .65 | .067 (11.36) | -2210.4 (-4.51) | .99902 | 1.60 | -.022 |

^a B is the coefficient of adjustment in the adaptive expectations model.

^b (The elasticity estimates were computed using the 1949 values of the relevant variables.)

The Goldsmith data cover the period 1897–1949, excluding the war years, while the MBA data cover the period 1929–1959 and also exclude the war years. In constructing Y^* it is, of course, necessary, as can be seen from equation (7), to begin with an initial Y_{t-1}^* which is not generated by a formula such as (6) or (7). In the Goldsmith data, the first observation on Y_{t-1}^* was taken to be the observed Y_t in 1897. Starting with this as a base, subsequent series in Y_t^* were generated using (7). For the empirical work reported in Table I, the initial year appearing in the regression was 1905; thus the initial value of Y_t^* actually used was an estimate based on eight previous years of observed values of Y_t . In the case of the MBA data, the available series was judged to be too short to warrant the loss of a number

of observations, hence, the initial value of Y_t^* was taken to be the first value of Y_t .

In both samples the interest variable enters with significantly negative coefficients which are similar in magnitude and are consistent with the theory that the substitution effect is negative. The low values observed for the MPC out of normal income stem from the fact that current net worth is also present in the regressions. These marginal propensities can be converted into magnitudes that are comparable to those derived from other studies in which no wealth variable appeared, by assuming a given relationship of wealth to income. If the average values of W/Y^* over the period of observation are used for this purpose, the "comparable" marginal propensity to consume out of income is $(b_1 + b_2 W/Y^*)$. The figures thus computed for the two regressions are in the neighborhood of .75, an order of magnitude which is not surprising in comparison with other estimates of marginal propensities to consume.

Both equations show little indication of serial correlation, the Durbin-Watson statistic being conclusive at the 2.5 per cent level of significance. Moreover, even though substantial correlation existed among the regressors, each variable has a significant t -value, thus alleviating any concern over multicollinearity.

The results obtained from using net of tax corporate bond yields in a consumption function containing income and wealth offer convincing evidence that consumption is responsive to changes in the rate of interest. With the interest elasticity of saving related to the interest elasticity of consumption in the following manner:

$$N_{sr} = - N_{sr} \frac{C}{S},$$

a range of estimates for N_{sr} would be .19 to .24 when computed from the elasticity estimates in Table 1 and the average value for C/S . Such elasticity estimates are much larger than those assumed to exist by many economists who feel that saving is unresponsive to changes in the rate of interest [7, p. 40]. Evidence for such a conclusion is often sought in the constancy of the savings-income ratio during periods when the interest rate fluctuated considerably. It must be recognized, however, that income effects were present when interest rates were changing and that the constancy of the savings-income ratio may have been the consequence of an offsetting substitution effect. The evidence in Table 1 indicates that a substantial substitution effect did in fact exist.

Bank Adjustments to Monetary Policy: Alternative Estimates of the Lag

Questions relating to the length of lags in the monetary process have an important bearing on discussions of monetary policy. Considerable attention has been given to lags between movements in key monetary variables such as the money supply or interest rates and movements in national income or selected components thereof. Empirical studies suggest that there are substantial lags between changes in such variables and changes in activity. These findings have led some to conclude that monetary policy cannot play an effective countercyclical role.

It has been shown that such a conclusion may be ill founded [6]. Nonetheless, even if it could be shown further that economic activity responds promptly to changes in key monetary variables, the effectiveness of monetary policy would still remain open to question. If the "inside lags" are too great, policy could be impaired. For example, if it could be demonstrated that the commercial banking system, the chief mechanism through which monetary impulses are transmitted, is slow to respond to disequilibrating factors, serious doubts would be justified concerning the counter-cyclical role of monetary policy. Much recent empirical research makes just such a showing.

A substantial body of evidence has accumulated suggesting that sluggish behavior pervades commercial bank adjustments. In studies of various types of portfolio adjustments, lags have been reported ranging from several months to several years [1] [2] [3] [4]. Lags such as these are descriptive of a banking system which would not be an effective conductor of counter-cyclical actions of the central bank.

Results reported in this paper show that, contrary to such studies, the time required for reserve adjustments by commercial banks is a matter of weeks rather than months or years. Such findings help restore the presumption that the banking system is capable of transmitting monetary policy actions in time for them to be pertinent to the economic environment within which they were conceived.¹ This paper also suggests that other researchers have found long lags primarily because they have tested their models with data aggregated over decision units and over time periods. Such findings have a bearing on the use of the Koyck distribution and may tend to cast some doubt on the whole range of lag estimates that have been made available to policymakers and reported by economists.

An excess reserves model is specified below. This model is then used as the prototype for the alternative lag estimates discussed in section II. Conclusions are presented in section III.

I. *An Excess Reserves Model*

In this section, a model of an individual bank's reserve adjustment process is specified. Such adjustments are the constituent elements of the inside lag between central bank actions and changes in bank credit and the money supply. Prompt bank responses to a changing monetary environment are necessary in order for monetary impulses to be transmitted quickly. Although the implications of this article relate to the lags between central bank actions and adjustments of individual banks, there is no explicit monetary policy variable—such as total reserves—from which lags are estimated. In specifying a model at the level of the decision-making unit, as in this study, it seems most meaningful to think in terms of variables that impinge in a direct way on individual commercial banks. The effects of monetary policy on individual banks appear in the guise of variables which the bank encounters in the ordinary course of its operations.

The underlying hypothesis of the model is that the individual bank takes action during a given interval to remove a discrepancy between its desired excess reserve position at the end of an interval and the position that would prevail in the absence of action. The familiar stock-adjustment model is well suited to this hypothesis. Also, in the earlier studies alluded to above, the stock-adjustment model was frequently employed. In order for results of tests of the present model to shed light on earlier findings, it seems desirable to make the models as comparable as possible. Accordingly, it is specified that

$$(1) \quad \Delta X = \lambda [\bar{X}_{t+1}^* - (X_t + \Delta X_t^A)]$$

where

ΔX = adjustments in excess reserves;

λ = adjustment coefficient;

¹ On the other hand, to the extent that the banking system makes quick adjustments in its quantities, it may imply reduced movements in interest rates, the market clearing mechanism. Thus, if monetary policy actions are specified in terms of interest rate movements, rapid adaptive behavior of the commercial banking system may slow the impact of policy changes. I am indebted to Frank de Leeuw for suggesting this point.

\bar{X}^* = desired excess reserves;
 X = actual excess reserves;
 ΔX^A = anticipated change in excess reserves; and
 t = time subscript.

The dependent variable, ΔX , consists of those changes in excess reserves which result from bank action. A bank can affect excess reserves by altering its holdings of earning assets, by changing its balance due from other banks, and by borrowing or repaying debt. These are summarized into a single variable.² The adjustment coefficient, λ , denotes the extent to which the bank removes a discrepancy between its desired reserve position at the end of a period and the reserve position which it anticipates in the absence of action. Estimates of this coefficient are of major interest in this paper; its size determines the lag—i.e., the number of periods required (approximately) to close discrepancies between desired and actual positions.

A bank's desired excess reserve position is not observable, but is specified to be a function of a vector of variables as follows³:

$$(2) \quad \bar{X}_{t+1}^* = g(r_{t+1}, L_{t+1}, B_{t+1}, S_{t+1}, T_{t+1}, RP_{t+1})$$

where

$$\begin{array}{ll} r = \text{opportunity costs;} & \frac{\partial \bar{X}^*}{\partial r} < 0. \\ L = \text{loan demand;} & \frac{\partial \bar{X}^*}{\partial L} < 0. \\ B = \text{cost of borrowing;} & \frac{\partial \bar{X}^*}{\partial B} < 0. \\ S = \text{bank size;} & \frac{\partial \bar{X}^*}{\partial S} < 0. \\ T = \text{trend;} & (\text{no presumption concerning effect}) \\ RP = \text{reserve settlement period}^{3a}; & \bar{X} \geq 0. \end{array}$$

² In the empirical work, the dependent variable and other dollar value variables are deflated by a size variable. It would be sufficient to assert that by hypothesis the demand for excess reserves is homogeneous of degree one in all dollar variables. In addition, however, there were practical computational considerations which had a bearing on the form the empirical work ultimately took.

³ Opportunity costs were proxied, alternatively, by 3-month Treasury bill rate, the federal funds rate, and the yield on long-term government bonds. Loan demand was proxied by changes in commercial and industrial loans, the Federal Reserve Board index of industrial production, and metropolitan area payroll employment. The cost of borrowing was proxied by the Federal Reserve discount rate and by the outstanding stock of borrowing at the beginning of the period.

^{3a} Some weekly reporting banks, the country banks, meet reserve requirements on a bi-weekly basis. Because penalties may be levied against banks that fail to meet reserve requirements, it is hypothesized that excess reserves will not be negative for a settlement period.

The remaining term in equation (1), ΔX^A , denotes anticipated changes in excess reserves. One may imagine that there are numerous factors which impinge exogenously on excess reserves—including manifestations of central bank actions—but that some of the factors are anticipated. For example, there may be anticipated changes in deposits based on known characteristics of depositors or on knowledge of lags between previous asset actions and current deposit experience. The approach taken in this paper was to imagine that these factors merge into seasonal loan and deposit anticipations. In an effort to measure such anticipations, what are here termed exogenous variables, ΔE ,⁴ are introduced in such a manner that a separate coefficient is estimated for each month. Based on seasonal experience regarding loan demands and deposit movements, a bank regards changes in exogenous variables that occur in January differently from those that occur in February, March, and so forth.

The equation to be estimated is specified as linear in its arguments, and parameters are estimated by ordinary least squares. The regression model is:

$$(3) \quad \Delta X_t = b_0 + b_1 r_{t+1} + b_2 L_{t+1} + b_3 B_{t+1} + b_4 S_{t+1} + b_5 RP_{t+1} + b_7 X_t \\ + b_{8-19} \Delta E_t.$$

As is well known, the coefficient relating the stock of excess reserves at the beginning of the period to the dependent variable, b_7 , is an estimate of λ , the adjustment coefficient. Alternative estimates of λ are discussed in the following section.

II. *Alternative Estimates of the Lag*

The model specified above was tested at both the micro and macro level. Macro-tests were performed both with weekly data and with data aggregated across weeks into months. The data were from 19 individual banks located in the Eighth Federal Reserve District. Observations spanned an eight-year period from the beginning of 1957 to the end of 1964. During this period, there were two recessions and two expansions; accordingly, monetary policy shifted several times.

From among numerous tests, a "basic" equation was selected.⁵ Results of tests with this equation are presented in Table I. Coefficients of determination range from .88 to .09, with a mean coefficient of .56. The column of regression coefficients listed beneath b_7 , the lagged stock of excess reserves,

⁴ The exogenous variable is here defined to consist of the sum of changes in cash items in process of collection, changes in demand and time deposits, and changes in the capital account. Where appropriate, items are adjusted for their impact on required reserves; the exogenous variables are of interest here only to the extent that they impinge on excess reserves.

⁵ Variables included in the basic equation are those which met the usual criteria: their coefficients were acceptable in terms of signs and according to standard tests of significance; they contributed sufficiently to the overall goodness of fit of the equation.

are of principal interest. These coefficients, estimates of the adjustment coefficient, are arrayed in Table II according to their implied speed of adjustment. Micro estimates are discussed below.

Micro Variables—Micro Relationships

Observations taken at the level of the individual bank were used to estimate micro relationships. First, individual bank data were used to estimate relationships for each of 19 separate commercial banks. Next, one set of relationships was estimated by "pooling" the data over the 19 banks.⁶ Thus each relationship, each regression coefficient, was averaged across 19 banks, with dummy variables used to capture differences among banks.

Estimates of λ derived from tests with data from the separate banks carried a negative sign as hypothesized and were significant in each test. The implied adjustments (i.e., to a 95 per cent closure) were quite rapid, ranging from .8 to 9.8 weeks. The average lag was 3.2 weeks (Table II). The estimate of λ from the "pooled" data was $-.690$, implying a 2.6-week lag (Table II). Such an adjustment is about one-fifth more rapid than the average adjustment of the 19 separate estimates.

Lags such as these at the individual bank level are sufficiently rapid to suggest that the commercial banking system is capable of prompt responses to countercyclical monetary policy actions. However, at this stage, such a conclusion is premature. Results reported here are particular to the banks studied. The results can be placed in juxtaposition to the long lag estimates reported in earlier studies, but unless more can be shown the matter rests here. On the other hand, if substantially longer lag estimates can be derived from tests of the model with data organized in a manner comparable to those used by other bank adjustment studies, a presumption can be created that the long lag estimates reported elsewhere may similarly reflect data organization.

Aggregated Variables—Aggregate Relationships

We might suppose that aggregating values of dependent and independent variables across decision units would tend to obscure observable empirical relationships. For, even if each bank made a prompt adjustment to a disequilibrating situation, as this study suggests, such adjustments would serve to place other banks in disequilibrium. For example, if an individual bank found that it had surplus excess reserves, it might remove such a surplus by buying earning assets. Such an adjustment would serve to shift deposits and, hence reserves, to yet another bank—and so forth. Such a process is simply the bank credit expansion or contraction mechanism described in basic money and banking texts.

In addition, the adjustment made by a decision unit is direct whereas that made by an aggregate is not. Given changes which are exogenous to a decision unit (an open system), the unit can regain equilibrium by bringing actual conditions into alignment with desired conditions. In terms of the

⁶ The data were treated as though they were from one bank for 152 years (8 years \times 19 banks).

present analysis, a bank can bring actual reserves into line with desired reserves. On the other hand, an aggregate (if it is a closed system) cannot alter conditions which are truly exogenous to it. The banking system cannot "shed" reserves. But as individual banks do so, those variables in terms of which its desired position is defined—e.g., total deposits, interest rates, etc.—change until desired reserves are brought into conformity with actual reserves.

Notwithstanding these considerations, aggregation across decision units

^a To a 95 per cent closure.

did not substantially increase the lag in bank adjustment from actual to desired reserves positions. Aggregation across banks, but not time, lowered the estimate of λ to $-.438$, implying a lag in adjustment of 5.2 weeks (Table II). While this lag is nearly twice as great as that with the micro data, it does not approach those reported in earlier studies. The aggregation of only 19 banks was insufficient to capture the blurring of empirical relationships which might occur at a higher level of aggregation. In a small open system, the adjustments of one decision unit need not impinge upon other units in the open system. It may be that longer lags would have been estimated had the system been closed.

Aggregation Across Time

The data were brought into close conformity with those used in other studies by averaging the aggregate weekly observations into months. Tests with these data yielded an estimate of λ of $-.099$, implying a 28.7-month lag (Table II). A lag of this length is comparable to those reported in earlier studies. Thus, once the data were made comparable, the lag estimates became comparable. The lengthening turns partly on the choice of period in terms of which the adjustment coefficient is specified. Thus, for example, there is no means by which quarterly observations can capture an adjustment period of one week or one month.

Beyond this, however, there was a sharp decline in the absolute value of estimated λ . Such a decline may reflect an increased prominence of specification error. Yair Mundlak has shown [5] that the determination of the period of adjustment is a crucially important ingredient in the specification of a distributed lag model. In particular, if the "true" period of adjustment is relatively short, it is inappropriate for a model aggregated over time to include a lagged stock of the dependent variable. Moreover, the statistical testing of such a misspecified model is likely to yield estimates of λ with low absolute values.

To the extent that one is inclined to accept this study's conclusion that the true period of adjustment is a matter of weeks, it follows that the specification of a monthly stock-adjustment model in this paper was inappropriate. In turn, the statistical results were likely to have resulted in an estimate of λ which was biased downward (absolute value). These observations tempt one to suggest that those studies which show that the banking system is slow to adapt—studies wherein stock-adjustment models were tested with monthly or quarterly data—may similarly reflect specification error.

III. Conclusions

Results from this study suggest that individual commercial banks respond rapidly to conditions which place them in disequilibrium. Thus, the inside lag between disequilibrating actions of the central bank—such as would be involved with an abrupt change in the rate of expansion in the reserve base—and equilibrating responses of the banking system can be relatively short. Based on individual bank observations taken at weekly intervals, this paper reports lags ranging from one to ten weeks. In earlier studies based on aggregate data organized around months or quarters, speeds or adjustment were reported ranging from several months to several years.

Why the difference? How can it be that studies of commercial bank behavior can reach results which are at such variance? One possible explanation is that their differences are a consequence of differences in the models. While such an explanation may have merit, based on this study it seems plausible to suggest that the estimates simply reflect differences in the way the data are organized. For, when data aggregated across banks and then across weeks into months were used, the lag estimate rose sharply. It rose

from weeks with micro, weekly data, to years with macro data aggregated across months.

At the very least, such results constitute evidence that estimates of structural coefficients based on aggregate data may yield very little information about the response characteristics of the institutions which make up the aggregate. A tentative but stronger conclusion is that the lag estimates of other studies reflect substantial specification error, and that these estimates are biased toward long lags. If so, policymakers have been provided with lag estimates which create an inaccurate impression of the length of the inside lag.

External Financing and the Rate of Economic Growth

This paper demonstrates that the degree of external financing of investment relative to internal financing, by business enterprises, depends on the growth rate of the economy.¹

Every growing economy has many industries, expanding or contracting at different rates. Within each, different business establishments expand or contract at rates varying from the industry average. Thus, the economy

¹ Importance of external financing is much discussed in finance books, but seemingly without reference to the general rate of economic growth. Cf. [6, pp. 338-40], [5, Ch. 16], [8, Ch. 25], [4, Ch. 15, 16].

consists of many business establishments growing or declining at a variety of rates.

Business enterprises do not have balanced portfolios of business establishments growing or declining at varying rates. Hence, firms show a variety of growth rates varying from the economy's average. Firms with high growth rates require external financing for investment since internal sources are inadequate. Firms with lower rates, thus less need for investment expenditures, do not. This note analyzes the relationship between total external finance and investment on a net basis, i.e., ignoring depreciation as a source and replacement investment (thus assumed equal to depreciation) as a use of funds.

Every Western-type economy is composed of many firms, with different rates of expansion or decline. These may be arranged, according to growth rates, in a frequency distribution, assumed normal around the economy's average growth rate.² Standard deviation σ measures the dispersion of firm growth rates.

The magnitude of σ depends on the economy's average growth rate ρ . Even if $\rho=0$, there is dispersion of firm growth rates; some firms decline, others grow, even though industry growth rates may all be zero.³ As the economy's growth rate rises, dispersion of firm growth rates around it also rises. With higher economic growth, some industries expand rapidly during earlier stages of their life cycle, others decline during later stages [3]. Hence, some firms grow rapidly; others decline. The faster economic growth, the faster is change, obsolescence, replacement of old by new [2, pp. 7-9], i.e. Schumpeterian creative destruction [7, Pt. 2, Ch. 7]. Thus the faster the growth, the greater is σ .⁴

$$(1) \quad \sigma = f(\rho), \quad \frac{d\sigma}{d\rho} > 0$$

We assume that p/k , the net rate of profit earned on capital by different firms in an economy in the same time period does not depend on their relative growth rates but is everywhere a constant, ϕ .⁵

$$(2) \quad \frac{\dot{p}}{k} = \phi$$

Every firm has some rate of growth or decline r , which equals the ratio of net investment i (increase in its capital stock) to capital stock k .⁶

² This assumption can be dropped at the expense of mathematical complexity.

³ A stationary state with all industry plus all business establishment growth rates zero may be visualized. Then business enterprise growth rates are zero.

⁴ Probably σ approaches an asymptote $\sigma(\max)$ as the rate of economic growth increases and an asymptote $\sigma(\min)$ as the rate of economic decline increases.

⁵ Alternately, the profit rate of individual firms could be an increasing function of the firm's growth rate for any given average profit rate in the economy.

⁶ Strictly speaking, eq. (3) specifies the growth rate of the firm's capital stock. It equals the growth rate of the firm's net value added when the capital/net value added ratio is constant.

$$(3) \quad \frac{i}{k} = r$$

Investment expenditures by the firm are a use of funds. The source of funds for these may be internal and/or external to the firm. Net internal sources equal net profits minus dividend payments.

The profit retention function may be described thus: firms with zero growth rates on the average have high relative dividend payments since there is no net need for internal funds for investment. With higher growth rates, firms on the average cut dividends as needs for financing investment rise [1, pp. 234-35]. When the firm's growth rate i/k equals profit rate p/k , it needs a sum equal to net profits to finance investment. This would argue for zero dividends, thus completely financing investment internally. However, it is well known that firms may pay out some dividends even when they need on balance all of internal funds generated, making up the difference through external finance. Thus we specify a dividend function such that the dividend payout ratio declines with increase in the firm's growth rate and such that a minimum payout ratio α is reached at or prior to the point when the firm must first resort to external finance. We define a critical growth rate r^* of the firm above which the firm must resort to external finance. With profits as the source of funds and both investment and dividends as the use of funds, we have at r^* ,

$$(4) \quad \frac{p}{k} - \left[r^* + \alpha \frac{p}{k} \right] = 0 \quad \text{or} \quad r^* = \frac{p}{k} (1 - \alpha)$$

and,

$$(5) \quad \rho = \frac{I}{K}$$

$$(6) \quad \rho \text{ is given exogenously.}^7$$

Figure 1 shows the frequency distribution of firm growth rates around the national rate, assumed independent of the firm's capital stock. The shaded right hand tail, beyond r^* , indicates firms needing external sources of finance due to high growth and thus high investment outlays. We recenter.

$$(7) \quad x = r - \rho$$

$$(8) \quad x^* = r^* - \rho$$

As in any normal curve,

$$(9) \quad y = \frac{1}{\sigma\sqrt{2\pi}} e^{-x^2/2\sigma^2}$$

⁷ Strictly speaking, the average growth rate of the economy's capital stock is specified exogenously. This equals the average growth rate of the economy's output when the capital/output ratio is constant. For convenience, we simply use the term "rate of growth" (for both firms and economy). Cf. footnote 6.

FIG. 1. FREQUENCY DISTRIBUTION OF GROWTH RATES OF FIRMS

Total external finance needed in the economy is derived thus: for all firms with growth rates above the critical growth rate, take the difference between sources (net profits) and uses of finance (net investment plus dividends), multiply by frequency of occurrence, and sum.⁸

$$(10) \quad E = K \int_{x=x^*}^{x=\infty} \left[\frac{i}{k} + \alpha \frac{p}{k} - \frac{p}{k} \right] y dx$$

where E is the total amount of external finance for the economy and K the total stock of capital in the economy, which is known.

$$(11) \quad K = \bar{K}$$

Combining and integrating, external finance/total investment is

$$(12) \quad \frac{E}{I} = \frac{[\rho - \phi(1 - \alpha)]Q + Z}{\rho}$$

where

$$Q = \left[\frac{\text{Normal}}{\text{Curve}} \right]_{-\infty}^{\infty} \frac{x}{\sigma} = \frac{r^* - \rho}{\sigma}$$

and

$$Z = \frac{\sigma}{\sqrt{2\pi}} e^{-(r^* - \rho)^2 / 2\sigma^2}$$

⁸ Essentially, this equation assumes that the economy is composed of a large number of small firms.

Table 1 lists calculations for percentage of total investment financed externally for a sample of values of: average growth rate; average profit rate; standard deviation of firm growth rates distribution; minimum dividend payout ratio. For example, with a 10 per cent profit rate, 4 per cent growth rate, 8 per cent standard deviation, and zero minimum payout ratio (99.74 per cent of firms in the range -20 per cent to +28 per cent growth rates), 26.25 per cent of investment is financed externally.

TABLE 1—SELECTED COMBINATIONS OF FACTORS DETERMINING EXTERNAL FINANCING

| $\rho = 4\%$ $\phi = 10\%$ | $\alpha = 0$ | $\rho = 4\%$ $\sigma = 8\%$ | $\alpha = 0$ | $\phi = 10\%$ $\sigma = 8\%$ | $\alpha = 0$ | $\rho = 4\%$ $\phi = 10\%$ | $\sigma = 8\%$ |
|-------------------------------|-------------------|--------------------------------|-------------------|---------------------------------|-------------------|-------------------------------|-------------------|
| σ | E/I (per cent) | ϕ | E/I (per cent) | ρ | E/I (per cent) | α | E/I (per cent) |

| 9 | 33.74 | 14 | 10.13 | 6 | 26.38 | | |
| 10 | 42.16 | 15 | 7.76 | 7 | 27.35 | | |

An estimate has been made for the standard deviation of the firm growth rates distribution based on 75 U.S. corporations, largely in manufacturing, for the 1959-64 period. For this sample, the standard deviation was 7.8 per cent and the average growth rate 5.8 per cent.⁹ The median rate of return on invested capital for the 500 largest U.S. corporations was 9.1 per cent in 1963; the rate of profit for all U.S. manufacturing corporations was some 10.2 per cent that year [10, Tables 678, 688].

Combining equations (1), (2), (4), and (12), it can be seen that the degree of external financing of investment relative to internal financing is a function of the rate of economic growth, when ϕ and α are given.

If we consider the degree of external financing of investment on a gross rather than a net basis, i.e., introducing differences between depreciation and replacement investment, the results of Table 1 must be modified. External finance needed to finance gross investment will then be substantially lower, since depreciation allowances exceed replacement investment for growing firms, the difference rising with the growth rate. If price changes are introduced, depreciation on original cost instead of a revalued basis di-

⁹ This sample, selected from a larger sample of 372 corporations from [9], comprised those companies which showed no mergers, acquisitions, new consolidation of subsidiaries, etc. Both standard deviation and average growth rate are unweighted averages for the companies concerned. It should be noted that the average growth rate of 5.8 per cent exceeds that for undeplicated GNP (5.4 per cent), in part because of the inclusion of one high growth company, in part due to the fact that sales of some U.S. firms include those of their foreign subsidiaries. The average growth rate of GNP in 1958 prices was 3.9 per cent during this period.

minishes the real value of depreciation when prices rise, and increases the degree of external finance.

The Neoclassical Theorem Once Again: Closed and Open Economies

In a recent note in this *Review* [2], Alvin Marty has presented a diagrammatic exposition of the neoclassical theorem (Golden Rule) that among balanced growth paths consumption per man is maximized on the balanced growth path where the marginal product of capital is equal to the natural rate of growth, or equivalently where the elasticity of output (or the share of capital under constant returns to scale and competitive distribution) equals the saving rate [3] [4]. The purpose of this note is to provide an alternative, simpler diagrammatic proof, showing that the Golden Rule is an application of the usual economic rules for optimization and to extend the Golden Rule to simple open economies.

Golden Ages and Golden Rules in a Closed Economy

Assume for the moment a one-good economy, with no technical change. Within this context the neoclassical theorem is a rule for choosing the constant saving rate, and therefore capital-to-labor ratio and balanced growth path, which will yield the maximum sustainable per capita consumption. To derive the theorem we will use Figure 1, first constructed by John Fei, and recently used by James Tobin [5]. On the horizontal axis we measure

FIGURE 1

the ratio of capital to labor (capital intensity). On the vertical axis we measure pure numbers, such as growth rates, or, as output (X) and capital (K) are measured in the same units, the ratio of output to capital.¹

The curve X/K represents the average product of capital, which falls as the capital intensity rises, due to the law of diminishing returns to a variable factor.² The height of the horizontal line, Gg , represents the growth rate of labor, g , which Harrod has christened the natural rate of growth.³

Assume that some constant saving ratio, s , prevails for all time. It is only through this saving and implied consumption behavior that demand enters the picture. Once we make this assumption the theorem becomes technological. The growth rate of capital is sX/K and we represent it on the graph by lines proportional to X/K , $s_1(X/K)$ and $s_2(X/K)$. If $s = s_1$, the system can now be seen to converge to some equilibrium, A , with a constant K/L , by the usual simple reasoning, that if capital grows faster than labor the capital to labor ratio must increase, etc. The graph thus shows us that because of the technological phenomenon of diminishing returns a constant

¹ We assume throughout only one commodity to avoid index number problems. This also means that the marginal product of capital is a pure number, which can be identified with the rate of interest.

² The lines are drawn straight only for simplicity. The average product is shown starting from some positive number greater than g and ending at zero. Of course, this is not necessarily so, for example, some C.E.S. production functions approach a positive number rather than zero asymptotically; but for a state of balanced growth to occur, it is sufficient that the average product of capital be greater than the growth rate of labor as K/L approaches zero, and less than g as K/L approaches infinity.

³ Of course, g need not be a constant; it might depend on the income per head, or the natural rate of growth might also represent the rate of growth of labor in efficiency units.

saving ratio cannot maintain anything but $\bar{k}_1 A$ (equals g) as the growth rate of capital, so that eventually capital and labor must grow at the same rate. Our choice of s determines where a point like A lies along Gg , as well as the equilibrium capital intensity, \bar{k}_1 .

The rectangle $O\bar{k}_1CD$ is $X/K \cdot K/L$ or the output per man associated with \bar{k}_1 and s_1 . Now notice that, for any balanced growth path, the growth rate of capital is always represented by OG , or $\bar{k}_1 A$. Saving per man is represented by a rectangle $O\bar{k}_1AG$. The rectangle above the population growth curve ($GACD$), obtained by subtracting saving per man from output per man, equals consumption per man; and the objective is to maximize the area of this rectangle.

Let us recall the problem of a monopoly with constant marginal costs, like Gg in Figure 1, and facing an average revenue or demand curve, like X/K . For any output the rectangle $GACD$ represents profit. Maximum profit is attained by increasing output until marginal revenue equals marginal cost. The same principle applies in the case of a neoclassical economy seeking maximum sustainable consumption per man. The marginal to the average product of capital, in the same sense that marginal revenue is marginal to the demand curve, is the marginal product of capital (f_K), that is the addition to output per man from a rise in the capital to labor ratio. The additional cost incurred by increasing the equilibrium capital to labor ratio is simply the extra saving per man which must be made in every year to keep the capital to labor ratio at this new, higher level. A small increase in the equilibrium capital to labor ratio always requires OG extra saving per man, the rest of the extra output per man goes to consumption.

Just as the profit-maximizing firm increases output until the marginal revenue on the last unit produced equals its marginal cost, so an optimizing community should increase the capital to labor ratio by varying the saving rate and capital intensity until the addition to output per man equals the extra saving per man. On all previous increases in capital intensity the increase in per capita product exceeded the increase in per capita saving, yielding additions to per capita consumption. Any further increase in capital intensity will yield a change in per capita output which is smaller than the required additional saving, and therefore per capita consumption will be reduced.

By the above reasoning an optimizing community chooses a saving rate (s_2) and capital intensity (\bar{k}_2) such that the marginal product of capital equals the growth rate of population ($f_K = g$). Since this is an equilibrium capital intensity, which will be maintained by balanced growth, the growth rate of capital also equals the growth rate of population ($s(X/K) = g$). Therefore the growth rate of capital equals the marginal product of capital, ($s(X/K) = f_K$), which implies that the saving rate must equal the elasticity of output with respect to capital, or under competitive distribution, the share of capital

$$\left(s = \frac{f_K K}{X} = \frac{f_K}{\text{Average Product of Capital}} \right).$$

Innovation

The above diagrammatic formulation is also useful because the effect of innovation on the growth path can easily be ascertained. A single once-and-for-all innovation may be classified in the Hicksian sense as capital saving, neutral, or labor saving, depending on whether the marginal product of capital increases less, the same, or more than the marginal product of labor⁴ at the existing capital to labor ratio. In a constant returns to scale production function, this is equivalent to inquiring whether the marginal product of capital increases relatively less than, the same as, or more than the average product of capital [1, pp. 212-15, 257-59]. The effect on the equilibrium of a single technological change is to leave equilibrium growth rates unchanged but to raise the optimum K/L and equilibrium consumption per man. The exact increase depends on the type and intensity of innovation, and the extent of diminishing returns as the capital-to-labor ratio increases.

When we turn to continuous innovation, the case of pure labor augmentation is easily analyzed. In this case each laborer becomes λ per cent more productive each year. We may now define the labor force in efficiency units \hat{L} , where an efficiency unit is equivalent to the productive ability of a man in the base year.

If we now interpret capital intensity on the X axis as capital per efficiency laborer, rather than the capital-to-labor ratio, then the average and marginal products remain the same for each capital intensity [6]. If we let the height of line Gg represent the growth rate of efficiency labor ($\lambda+g$), then it is easy to see that a constant saving rate again implies some stable capital intensity. The rectangle $GACD$ now represents a constant consumption per efficiency laborer, and, since the number of laborers per efficiency laborer declines at λ per cent per year, consumption per man increases at the rate of λ per cent every year. Constraining ourselves to a choice among balanced growth paths, the objective is now to maximize the consumption per efficiency laborer since that will also lead to a choice of the highest of the rising per capita consumption time paths, and therefore maximize the steadily rising per capita consumption in every period. Using the above method we find that we should again choose a saving rate s_2 and implied capital intensity K/\hat{L} such that the marginal product of capital equals the growth of efficiency labor ($f_K = \lambda+g$). Since we are choosing between balanced growth paths, the growth of capital also equals the growth of efficiency labor, ($s(X/K) = \lambda+g$), and we obtain the same result; the rate of saving should be set equal to the elasticity of output with respect to capital ($s = f_K K/X$).

Is the optimum saving rate chosen above the same as the optimum rate in an economy with no technical change? Labor augmenting technical progress means that at each interest rate the ratio of capital to efficiency labor is equal to the ratio of capital to labor in a world without technical change. This means that we can compare on one graph, using the same mar-

⁴ Although they can be easily handled, the very labor-saving and very capital-saving types of innovations are not considered.

ginal and average product schedules, two economies which differ only because one has labor-augmenting technical change, provided we write capital per efficiency laborer on the horizontal axis. In the economy with labor-augmenting technical progress, our optimum savings rule will lead us to choose a higher marginal product of capital and therefore a lower capital intensity, just as it would if, instead of technical progress, the second economy had a more rapidly growing labor force. This will mean the optimum saving rate, equal to the share of capital, will be greater, equal to, or less than the optimum saving rate in a world without technical progress, as the elasticity of substitution

$$\left(\frac{\text{percentage change in } K/L}{\text{percentage change in } \frac{\text{Wages}}{\text{Interest}}} \right)$$

is less than, equal to, or greater than one.

Golden Ages in an Open Economy

We now consider the case of the small economy in a large world which, by virtue of its relative smallness, faces an interest rate on world capital markets that is invariant to its own borrowing or lending activities.⁵ We assume that the profit-maximizing behavior of cosmopolitan capitalists insures that capital will flow into or out of this small country as domestic investment opportunities (created within its own borders) at the world rate of interest exceed or fall short of saving from national income (accruing to its citizens).⁶

With the marginal product of domestic capital held equal to the world rate of interest in this way, the question of optimal saving in the open economy is fundamentally different from that in the closed economy. As we have seen, the closed economy could adjust its equilibrium marginal product of capital (f_k) relative to its equilibrium growth rate (g) by choosing among alternative saving ratios. But the open economy, by assumption, must regard the marginal product of its capital as given, and equal to the world interest rate. Since its equilibrium growth rate is also given, exogenous forces, not social choice, determine f_k relative to g . However, by choosing among alternative saving ratios, the open economy can adjust its long-run debtor-creditor position vis-à-vis the rest of the world, seeking maximum sustainable per capita consumption.

We will find that among equilibrium growth paths, the addition to na-

⁵ In the spirit of the discussion of the closed economy we continue to assume a one-good world. This assumption totally suppresses terms-of-trade and monetary considerations which are usually entered into the analysis of capital movements. It is not, of course, necessary to consider these variables in a priori explanations of capital movements although one may wish to do so at another level of analysis.

⁶ The term "domestic" refers to the labor and capital employed in the country, and the income and product they generate. "National" refers to income accruing to citizens (or residents, in this case) of the country. National income and domestic product differ in the present model if there are international interest payments or receipts.

tional income per man from an increment of saving is equal to the world rate of interest ($=f_k$) while the extra saving per man is equal to the natural rate of growth, g . This is a familiar notion developed in the foregoing sections. However, for the open economy, each of these is invariant to saving behavior. Consequently, the country should save "as little as it can" ("as much as it can") if its natural rate of growth exceeds (falls short of) the world rate of interest.

In terms of the marginal cost—marginal revenue interpretation of golden rule saving suggested above, marginal cost and marginal revenue are, by assumption, horizontal straight lines which coincide only by accident. In analogous circumstances, the profit-maximizing firm can always increase profits (decrease losses) by expanding (contracting) production if $MR > MC$ ($MR < MC$). This implies indefinite expansion of contraction unless some constraints are imposed (e.g., production ≥ 0). We shall see that constraints are also, in general, required to limit the debtor-creditor position of the open economy seeking an optimum Golden Age. First, it is necessary to define a Golden Age for open economies and to establish existence and stability conditions.

Phelps [4, p. 794] defines a Golden-Age path as "... a growth path in which literally every variable changes (if at all) at a constant relative rate." For the closed economy, the definition implies that "... if investment is positive then output, investment and consumption must all grow at the same (constant) rate" [4, p. 794]. Here, of course, there is no distinction between domestic and national accounting variables.

For the open economy, national income exceeds (falls short of) domestic product if there are interest receipts (payments) on net foreign credit (debt). Consequently, we must extend Phelps' basic definition to require that national income and each of its components grow at the same (constant) rate as domestic product and each of its components. We shall see that a necessary condition is that the ownership of capital by residents (whether employed at home or abroad) grows at the same (constant) rate as national income (whether earned at home or abroad).

Figure 2 portrays the small, open economy. Imposing a world interest rate (the horizontal Rr line) means that international capital flows will guarantee that a particular capital-labor ratio, \bar{k} , will always prevail so long as technical progress either is absent or can be described as labor augmenting.⁷ Domestic product per worker is thus locked in at $O\bar{k}CD$. Consequently, a constant world rate of interest ensures that domestic capital and output grow at the same rate, g , as labor. In the figure, the growth rate of labor is represented by the horizontal line G_{lg} . The growth rate, g , and the interest rate coincide only by accident and each is invariant to national saving behavior.

This completes the picture of the domestic economy. We now turn to a consideration of national income variables.

National income and additions to the nationally owned stock of capital

⁷ Subsequent references to labor will assume that it is measured in efficiency units.

FIGURE 2

depend on saving behavior and we now derive conditions such that these two variables grow at the same rate. Define E as national equity, or the nationally owned stock of capital. Its analog in the closed economy is the domestic capital stock, K . The open economy is a net debtor (creditor) if E falls short of (exceeds) K . Saving is the net addition to equity:

$$\frac{dE}{dt} = S.$$

Saving is a constant proportion of national income, which is composed of wage payments to domestic labor plus interest payments on national equity whether employed at home or abroad.⁸ We assume that the same proportion of the two kinds of income is saved. Saving, by assumption, cannot be negative.

$$S = sY = swL + srE, \quad s \geq 0.$$

⁸ More conventionally, national income is domestic product minus (plus) net interest payments (receipts).

$$Y = X - rD$$

where X is domestic product and D is the net debt position,

$$D = K - E.$$

Separating X into its distributive components,

$$X = wL + rK$$

and substituting these last two expressions into the first yields:

$$Y = wL + rE.$$

Dividing through by E , letting

$$E^* = \frac{1}{E} \cdot \frac{dE}{dt} = \frac{1}{E} \cdot S \quad \text{and} \quad e = \frac{E}{L},$$

$$E^* = sr + sw(r) \cdot \frac{1}{e},$$

where w is a function of r .⁹ The growth of equity, E^* , is a declining function of the equity-labor ratio, e .

By plotting the equity-labor ratio, e , on the horizontal axis along with the capital-labor ratio, k , we can superimpose the equation just derived on the picture of the domestic economy to portray the growth of national income variables as well as those which refer to domestic product.

From our definition, a golden age exists if the E^* line intersects the labor growth line, G_1g_1 , at point H where an equilibrium equity-labor ratio is established at \bar{e}_1 . Equity, E , grows at the same rate, g_1 , as labor. It is easy to show that this guarantees that income grows at that rate, g_1 , also.¹⁰ Existence conditions for a Golden Age are consequently nothing more than intersection conditions for the E^* and the Gg lines at a value of $0 \leq e < \infty$. Algebraically, existence of a Golden Age requires that

$$g = sr + sw(r) \cdot \frac{1}{e}$$

have a solution for $0 \leq e < \infty$. Solving for e ,

$$e = \frac{sw(r)}{g - sr}$$

The necessary and sufficient condition for existence is therefore

$$g > sr$$

on the assumption that $sw(r) \geq 0$. Graphically, this condition simply ensures that the E^* line does not lie wholly above Gg . Since $E^* \rightarrow sr$ as $e \rightarrow \infty$, E^* will always exceed g if $g < sr$ for $e < \infty$. If the growth of equity, E , forever

⁹ For linear, homogeneous production functions and with competitive distribution: $w = f_L(k)$ and $r = f_K(k)$. Since r is a parameter in this case, $k = f_K^{-1}(r)$. By substitution, $w = f_L[f_K^{-1}(r)]$, or simply, $w = w(r)$.

¹⁰ Since $Y = wL + rE$, it follows that

$$\frac{1}{Y} \cdot \frac{dY}{dt} = Y^* = \frac{wL}{Y} L^* + \frac{rE}{Y} E^*,$$

or

$$Y^* = \frac{wL}{Y} g + \frac{rE}{Y} g,$$

or

$$Y^* = g.$$

exceeds the growth of labor and domestic product, Golden Age conditions are violated.¹¹

Moreover, if the condition for a Golden Age solution is satisfied, the solution is stable. Without rigorous demonstration, we offer the following intuitive proof: since the E^* line slopes downward to the right, the intersection at a point like H on the G_1g_1 line establishes an equilibrium e at e_1 , for if e is displaced, say, to the right of e_1 , labor will grow faster than equity, thereby restoring e to its original position.

Golden Rules for Open Economies

The analysis of Golden Rule saving for closed economies suggested that the growth rate (g) could be viewed as the marginal cost of additional saving and the marginal product of capital (f_k) as the associated marginal revenue.¹² In choosing among Golden Age saving ratios, the closed economy could vary the marginal product of capital (r) so that consumption was maximized where $MC=MR$, or $g=r$. For the open economy, the marginal cost of additional saving (g) equals its associated marginal revenue (r) only if g and r coincide by accident. If that should happen, however, society should be indifferent among alternate saving ratios.

More generally, $g \neq r$. If $g > r$ the MC of additional saving exceeds the associated MR so the Golden Rule of saving is to save nothing. Conversely, if $g < r$, $MC < MR$, so society should save as much as it can without violating Golden Age existence conditions.

These rules can be illustrated in Figure 2. Assume first that $g > r$ and a Golden Age is established at points H (for national income variables) and E (for domestic product variables) with $g=g_1 > r$, $e=\bar{e}_1$ and $k=\bar{k}$. In per worker terms, national income is wages, $RECD$, plus returns to equity, $O\bar{e}_1QR$.¹³ Saving is $O\bar{e}_1HG_1$.¹⁴ Consumption is national income minus saving, $(RECD + O\bar{e}_1QR - O\bar{e}_1HG_1)$, or $(RECD - RQHG_1)$. Since wages, $RECD$, are invariant to saving behavior, due to capital flows, consumption is maximized when the shaded rectangle, $RQHG_1$, is minimized. This is accomplished by choosing a Golden Age where nothing is saved. National income is then wages, $RECD$ and all wages are consumed.

Assume now that $g < r$ and a Golden Age is established at points M (for national income variables) and E (for domestic product variables) with $g=g_2 < r$, $e=\bar{e}_2$ and $k=\bar{k}$. In per worker terms, national income is wages, $RECD$, plus returns to equity, $O\bar{e}_2NR$. Saving is $O\bar{e}_2MG_2$. Consumption is

¹¹ An interesting extension of this analysis is to the unstable case where $E^* > sr > g$. In that case, national income always grows faster than domestic product and labor. The question of optimal savings in that circumstance involves a number of considerations beyond the scope of this short note.

¹² With g and r as constants, marginal costs and revenues are equal to average values.

¹³ Wages are domestic product, $O\bar{k}CD$, minus returns to domestic capital, $O\bar{k}ER$, or $RECD$. Returns to equity are equity, $O\bar{e}_1$, times the rate of interest, OR , or $O\bar{e}_1QR$.

¹⁴ $\frac{S}{L} = \frac{dE}{dt} \frac{1}{L} = \frac{dE}{dt} \frac{1}{E} \cdot \frac{E}{L} = E^* \cdot e = g \cdot e$. In this example, $\frac{S}{L}$ equals OG_1 times $O\bar{e}_1$ or $O\bar{e}_1HG_1$.

national income minus saving, $(RECD + O\bar{e}_2NR - O\bar{e}MG_2)$, or $(RECD + G_2MNR)$. Again, wages, $RECD$, are invariant to saving, so consumption is maximized when the shaded rectangle G_2MNR is maximized. This is accomplished by saving as much as possible without violating existence conditions for Golden Age growth. That is:

$$s = \frac{g}{r} - \epsilon \text{ where } \epsilon > 0 \text{ but as small as possible.}$$

For example, if the growth rate, g , equals 3 per cent and the world interest rate equals 6 per cent, the economy should save just under one-half its national income. If it were to save more, Golden Age conditions are violated. The growth of national income would forever outpace the growth of domestic product and labor. While this situation may be preferred to any Golden Age, we are not equipped to analyze it with the tools at hand.

Clearly, if $g=r$, neither of these shaded rectangles exists. Marginal cost always equals marginal revenue. Consumption is unrelated to saving. This result gives us another opportunity to contrast optimal saving in closed and open economies: in the closed economy, consumption is maximized when saving is such that $g=r$; in the open economy, consumption is invariant to saving behavior when $g=r$ (a parametric conjunction).

To put the argument another way: for the open economy, and as between equilibrium growth paths, the gross decline in consumption per worker due to an increment in saving is always the growth rate, g . This effect is countered by a concomitant rise in national income per worker, always equal to the world interest rate, r . The net effect on per worker consumption is r minus g . Consequently, if $r < g$ ($r > g$) consumption per worker is maximized when nothing ("as much as possible") is saved. If $r=g$, the net effect of changing saving on consumption is zero.

Patterns of Stability in Foreign Trade: OECD and COMECON, 1950-1963

The stability of the trade between nations is only one aspect of their economic relations—in addition to the volume and the growth of trade, the terms of trade, and the exchange rates to name a few—but it is a rather important one. The experience of the 1930s demonstrated how instabilities within countries can be transmitted to others through trade; serious concern with the problem of international economic instability continues to the present [6, pp. 406–51] [13] [20] [24] [25, pp. 93–126].

One of the advantages claimed for economic planning of the Soviet type is that it makes for stabler international trade:

In contrast to the autarky and the unpredictable conjunctural fluctuations inherent in the foreign trade of the capitalist countries, trade in the world socialist market develops in conformity with the requirements of the planned economies of the socialist-camp countries. There can be temporary disproportions in this market caused, for example, by inadequacies in coordinating the economic plans of the socialist states. But such disproportions are of a particular and temporary nature. . . . [3, pp. 44–45];

The greatest evil which always beset all underdeveloped countries on the foreign market . . . was that the cyclical factors and fluctuations inherent in the capitalist economic system led to sharp and quite sudden fluctuations in demand for their goods. Trade with the Soviet Union imparts an increasingly apparent element of stability . . . on the commodity markets [23, p. 19].

Claims such as these have been very frequent [8] [18, p. 43] [27] [50, pp. 15–17] but have not been tested by the writers although the necessary data exist. This paper reports the results of statistical investigations of imports and exports stabilities for the OECD and the COMECON blocs. The investigation covers: (1) the comparative stability of the trade of individual countries composing the blocs vis-à-vis all countries, the blocs, and the underdeveloped countries; (2) the comparative stability of total trade of each bloc, for trade within each bloc, and between each bloc and the underdeveloped countries; and (3) the behavior of trade of the two large powers, the Soviet Union and the United States.¹ Part I discusses the approach used in the study and presents the results. Part II evaluates the reliability of the findings and Part III examines the determinants of the trade stability patterns.

¹ J. D. Coppock and E. Neuberger have dealt with some aspects of the problem of comparative trade stabilities. Among other differences, Coppock used for "total Soviet trade" only the figures on trade with the non-Communist countries. These figures amounted to a small fraction of the actual total during the period under consideration [1, pp. 70–71]. Neuberger, on the other hand, limited his research to trade in primary products and considered only a few countries [20, 21].

I. *Approach and Results*

The study of trade stability can be based either on the country's aggregate trade vis-à-vis the "rest of the world" or on binary, country-pair comparisons involving a large number of trading partners for each country. This study is based on country-pair comparisons. Total trade flows are much too aggregative and can conceal important differences in stability. For example, the imports of a developed country from other developed countries might be quite stable, but imports from less developed countries might be subject to large fluctuations. Or the shift from one supplier to another will not be reflected in the totals yet both suppliers will be affected in opposite directions by the shift.

The decision to use the country-pairs in turn dictated the next choice: whether to study the stability of the physical volume of trade, the prices, or the values of imports and exports. The present study employs trade data expressed in current prices; data in constant prices were not available in sufficient detail for country-pair comparisons. The use of current values data is not necessarily a drawback. In some respects, most importantly in regard to current purchasing power of underdeveloped countries, fluctuations in value terms are as important as fluctuations in price or physical volume [37, p. 2].

Several statistical measures of instability are available. This study uses the "normalized standard error," which is defined as the standard error of estimate of the least squares fit to yearly trade data divided by the average volume of trade.² This measure eliminates from the original time series data the growth and volume components; the resulting stability indicators are pure numbers. Regressions were estimated using both the actual observations and their logarithms. The first type of estimate assumes that a constant absolute increment (or decrement) represents perfect stability, the second accepts a constant rate of increase (or decrease). The smaller of the two stability measures was chosen for each country to represent the stability of imports or exports. More complex fits were not attempted.

For each country considered in this study, two stability indicators were calculated. One is the median value of all individual country-pair stability indicators; the median is used for it does not assume either cardinality or exactness of the individual indicators. The other is an aggregate stability indicator which is derived by weighting the individual indicators by the corresponding volume of trade;³ the aggregate stability indicator represents

² The stability indicator for each import and each export flow is defined as

$$S_i = \frac{SEE_i}{A_i},$$

where SEE_i stands for the standard error of estimate and A_i stands for average volume of import or export from country i . For other possible measures of instability and their relative merits, see [1, pp. 23-26] [14, pp. 48-50] [21, pp. 23-28, 85-93].

³ The procedure is equivalent to normalizing the summation of all the standard errors of estimate by the yearly import or export volume totals. The aggregate stability indicator for

the stability of imports and exports of each country, or each bloc, vis-à-vis all other countries taken together and is thus somewhat comparable to the usual measures of stability for total imports and exports [1, pp. 49-79]. The calculations are presented in Tables 1 and 2 for a number of countries and for the OECD and COMECON blocs. They cover total trade, trade with the OECD and COMECON groups, and trade with the underdeveloped countries.

The results of the calculations can be summarized in the following way:⁴

1. The United States exhibited a surprising stability for both total imports and exports flows; these were more stable than either OECD, COMECON, or Soviet flows. U. S. imports provided about the same stability for the rest of the OECD countries as the Soviet Union provided for the rest of the COMECON countries. It offered stabler markets for the underdeveloped countries than did all the OECD countries, the Soviet Union, or all COMECON countries. U. S. exports exhibited similar stability.

2. The stability of Soviet total imports and exports was average; it was about the same as the OECD and COMECON averages. The Soviet imports from and exports to the underdeveloped countries were considerably less stable than the corresponding U. S. flows; they appear less stable than the total OECD flows, but more stable than the total COMECON flows.

3. The OECD had better stabilities of imports and exports than the whole COMECON bloc and it had more stable trade with the underdeveloped countries than did the COMECON. The OECD imports from the COMECON countries were more stable than the COMECON imports from the OECD countries.

4. The trade instabilities of both the OECD and the COMECON blocs were much higher vis-à-vis the underdeveloped countries than with their other trading partners.⁵

5. Intra-bloc trade appears to have been more stable for the COMECON countries than for the OECD bloc.

II. *Reliability of Findings*

The reliability of the results obtained can be considered in two parts: first, the adequacy of the underlying data; and second, the statistical significance of the differences in stability indicators.

Basic figures for imports and exports are available in United Nations,

each country (W_j) equals

$$W_j = \frac{\sum_{i=1}^M S_i \frac{A_i}{\sum_{i=1}^M A_i}}{\sum_{i=1}^M \frac{SEE_i}{\sum_{i=1}^M A_i}}$$

where M stands for the number of trading partners of country j .

⁴ See Table 2 for significance of differences in stability indicators.

⁵ The only exception was the U.S. exports which did not differ statistically from total U.S. exports and the Soviet imports which did not differ from total Soviet imports.

^a Number of individual imports or exports flows.^b The Mann-Whitney *U*-test:

$$z = \frac{U - \mu_U}{\sigma_U}, \quad U = n_1 n_2 + \frac{n_1(n_1 + 1)}{2} - R_1,$$

where n_1 and n_2 are the sample sizes ($n_1 > 8$, $n_2 > 8$) and the R_1 is the sum of ranks assigned to the group whose sample size is n_1 ;

$$\mu_U = \frac{n_1 n_2}{2}, \quad \sigma_U = \sqrt{\frac{n_1 n_2 (n_1 + n_2 + 1)}{12}}.$$

The null-hypothesis that the two countries (or one country and a group of countries, or two groups of countries) are equally stable should be rejected for two-tail probabilities at 5 per cent level if $z > 1.96$ (see [28, pp. 116–27]).

^c Total trade less trade with underdeveloped countries.

Source: Table 1.

comprehensive country coverage. Some minor adjustments of the basic figures were necessary to obtain continuous series. These consisted either of filling-in missing observations between two years by linear interpolation, or linking-in data from a different source at the beginning or the end of a continuous series. Such adjustments were few compared to the total number of observations and could not distort the empirical results. The reliability, comparability, and accuracy of figures obtained from official publications

were not subjected to separate scrutiny.⁷ The uncertainties connected with recording basic international trade data are well known and do not have to be reiterated here [19, pp. 137-80]. In defence of our findings, two facts should be pointed out: first, we are interested in comparing trade stability of countries, or blocs, not in the absolute stability levels; and second, the stability indicators are measured as deviations from trends. These considerations reduce both the importance of exact and comparable definitions of "imports" and "exports" and the importance of errors in basic data. If the errors of observation in the time series are consistent, that is, the figures are always too high or too low, they will not significantly affect the trend and the variations around it. And if these errors lead to consistent overestimation (or underestimation) of stability for all countries, the influence of such errors will tend to cancel out in the intercountry or interbloc comparisons of stability levels. Only in the case of errors in basic data leading to overestimation of stability of one country or bloc and underestimation in the other will the comparison be seriously distorted. There is no a priori reason to believe that such should be the case, but it is of course not possible to prove that such biases do not exist. However, most of our conclusions are not sensitive to substantial errors in stability indicators; they would hold even if we allowed for significant errors in basic observations.

Second, the empirical results which demonstrate differences in relative import and export stabilities can be tested for statistical significance. The Mann-Whitney nonparametric U-test, which is based on sum of ranks and does not assume normality, homoscedasticity, or exactness of observations, was used.⁸ The results of the tests are presented in Table 2. In most cases considered, the null-hypothesis that the trade flows of the countries or of the blocs compared were equally stable should be rejected.⁹

III. DETERMINANTS OF STABILITY PATTERNS

The relationship between the stability of export totals and various explanatory variables was investigated recently by J. D. Coppock [1]. We attempted to carry the analysis further and to explain stability of individual import and export flows of each country with its many partners. The possible explanations of these instability patterns are rather complex. They would run in terms of divergent price and income elasticities of imports and exports, growth and stability of incomes of the importing countries, the commodity composition of trade, the share of imports and exports in domestic consumption and output, commercial policies, as well as sporadic events and political preferences. We attempted to establish for each

⁷ One general comment should perhaps be made on the comparability of statistics for the two blocs. The OECD statistics are in current dollars, the COMECON statistics are expressed in the "foreign trade" currencies of the individual countries reflecting world market prices; the latter approach constant prices since they are adjusted only from time to time (see, e.g., [51, p. 71] [3, p. 59]). Since fluctuations in value tend to be larger than fluctuations in volume (see, e.g., [1, p. 4] [38, p. 39]) the use of "foreign trade" currency units for the COMECON bloc countries tends to underestimate their instability.

⁸ The test does require independence of observations. It is likely that the individual country-pair indicators of stability are not completely independent.

⁹ The parametric *t*-test yielded similar results.

country the relationship between the stability of expenditures on imports from its many trading partners and the following explanatory variables where data were available: the volume of imports; the rate of growth of imports; and the level of income of the exporting country as a surrogate of the commodity composition of imports which could influence stability.¹⁰ Similarly, we attempted to explain the stability of exports by the following: the volume of exports; the rate of growth of exports; the growth of income in the importing country; the stability of income of the importing country; and the level of income of the importing country. In addition, two classificatory variables were introduced for both import and export regressions, one indicating membership in the OECD bloc and the second indicating membership in the COMECON bloc. The regression equations took the following form for each country

$$\text{Import: } S_j = a_1 + b_1V_j + b_2G_j + b_3Y_i^L + b_4C_0 + b_5C_e$$

$$\text{Export: } S_i = a_2 + c_1V_i + c_2G_i + c_3Y_j^G + c_4Y_j^S + c_4Y_j^L + c_5C_0 + c_6C_e$$

where S stands for the stability indicator for individual imports or exports flows; V stands for the average volume and G for the rate of growth in volume of imports or exports; Y^S for stability of income, Y^G for growth of income and Y^L the level of income, with subscripts j and i for the importing and the exporting countries, respectively. C_0 and C_e are the classificatory variables for the OECD and the COMECON respectively ($b_4=1$ and $b_5=0$ for the OECD, and $b_4=0$ and $b_5=1$ for the COMECON; likewise for c_5 and c_6).

Unfortunately, the results were not satisfactory for either import or export regressions. The modest results obtained are undoubtedly due both to the omission of important explanatory variables for which no data are available, such as price and income elasticities, and to the rough nature of the data used in the regressions. The regression coefficients for import stabilities in a few countries are given in Table 3. Two numerical variables, the volume and the growth of imports,¹¹ and two classificatory variables explain at most only one-half of the stability of imports of the individual countries. The attempt to explain the export stabilities was no more successful. The most important explanatory variables were the two classificatory variables. In a stepwise regression, they appeared first in the majority of cases and their coefficients were significant in practically all cases. In the absence of additional numerical variables, membership in the two blocs appears to be the deciding factor in import and export stabilities for either the OECD or the COMECON bloc countries.

IV. *Concluding Remarks*

Empirical results of this study shed new light on the trade stability patterns of the two blocs. The economic performance with respect to the trade stability of the OECD in general and the United States in particular was

¹⁰ We assumed here that countries with low per capita incomes typically export primary products.

¹¹ The level of income of the exporting country was dropped since none of the regression coefficients was significant.

surprisingly good when compared to the Soviet Union and the COMECON countries. There is little factual basis for the charge frequently levied that the foreign trade of the free market countries of the OECD was less stable than that of integrally planned economies of the COMECON bloc; the opposite is closer to the truth. While the trade of the OECD countries with underdeveloped countries was more stable than that of the COMECON, both blocs exhibited greater instability in their trade with underdeveloped countries than in their remaining trade. Membership in the two blocs appears important in explaining the trade stability patterns.

A Note on Tariffs and Subsidies

Assume circumstances in which optimum, from the viewpoint of a single country, would be achieved by free trade. The government, however, decides to encourage an import-substituting industry to expand to a given extent. Granting this decision, the question is whether the second-best solution is the encouragement ("protection") by a tariff on competing imports or by a subsidy to home producers in the industry.

There seems to be an agreement that, disregarding fiscal aspects, subsidies have an advantage. This is based mostly on an intuitive argument

FIGURE 1

that while both tariffs and subsidies distort the production pattern, tariffs alone disrupt also the consumption pattern. The only rigorous proof of the argument, of which I am aware, has been provided by Corden.¹ The proof rests, however, on a highly restrictive assumption, which diminishes drastically its validity: "The internal distribution of income is unaffected by any changes in the model, and the device of community indifference curves can be employed" [2, p. 235]. In effect, the superiority of subsidies may be easily demonstrated without resort to this device.

The analysis will adopt the familiar model of two goods, incomplete specialization, perfect competition, perfect mobility of goods (save the contemplated interference by the government), and lack of any other conceivable distortions (such as external economies). It will also be assumed that world prices are given.²

In Figure 1, PQ is the transformation ("production-possibility") curve between goods X and Y . The slope of ww represents the transformation ratio between the two goods in the world market. With free trade, the economy's production locus will be at A ; while the consumption basket will be on ww , somewhere to the right of A —assuming that the country exports Y and imports X .

The government now decides to expand, by tariff protection, the production of X from OA_x to OB_x . This will be done by the imposition of a tariff on X which will make the domestic market-transformation ratio equal to the

¹ In [2]. See also [1] for a discussion of tariffs vs. subsidies in instances in which the economy suffers from domestic distortions.

² Without this assumption, free trade is not the optimal solution (for a single country). In other words, the choice between tariffs and subsidies will have to take into account the difference between the two in their terms-of-trade effect, from which the present analysis will abstract. See [2].

FIGURE 2

slope of rr , rather than ww . The new production locus is B . The new consumption-possibility curve, or budget restraint, is therefore $w'w'$ (having the same slope as ww). The new consumption basket, assuming that the tariff is not prohibitive, will be somewhere to the right of B —say, at C .

Now suppose that the government replaces the tariff by a subsidy of an equal rate. Suppose also that, by lump-sum transfers, everybody's income remains what it was with the tariff. This assumption leaves the income distribution unaffected by the method of (net) tax collection. The important feature of the model is, however, that a redistribution of income induced by changes in relative prices is *not* ruled out by assumption.

The domestic market-transformation line for producers remains rr ; the production locus will remain at B , and the budget-restraint line will remain $w'w'$. The substitution ratio for home consumers will, however, change. X now becomes cheaper, relative to Y . The consumption combination will thus move to the right of C —say, to D . It may now be easily shown that D is superior to C .

Figure 2 presents an individual (home) consumer, H . With the tariff, and the consumption combination for the economy of C (in Figure 1), the consumption basket of this individual is C_h . This may be viewed as his initial endowment of goods. With the shift to a subsidy, H 's budget-restraint line becomes $w_h w_h$. Assuming that the consumer reacts to relative-price changes, his consumption basket will move from C_h to D_h ³ (a move to the left of C_h would be irrational, while C_h itself is a limiting case). But since C_h is still an open possibility, D_h must be superior to it. And since no special properties have been attributed to individual H , the same conclusion must be valid for any other consumer in the economy. The subsidy position is thus superior

³ This assumption is implied in Samuelson's "revealed-preference" demonstration that an income-compensated demand curve must be negatively sloped. See [3].

to the tariff position for each and any consumer;⁴ and no attempt to offset consumer losses and gains is required in order to reach the conclusion that, for the economy as a whole, D is superior to C . Hence, subsidy is preferable to tariff.

If, on the other hand, a change in income distribution due to the form of (net) tax collection is not to be abstracted from by assumption, this proof may be understood as if it involved the use of the compensation principle. That is: it demonstrates that subsidies lead to a potential increase of welfare, since some distribution of income exists in which everybody is made better off than with tariffs (at the actual tariff-ridden income distribution).

⁴ It should be noted that the reverse exercise would not be legitimate. Take consumer H at the subsidy position D_h . Suppose, now, that the subsidy is replaced by a tariff. It would not be possible to claim that with the initial endowment D_h , the consumer should move leftward on the budget-restraint line $r'r'$ to a superior combination, for the simple reason that $r'r'$ could *not* be a budget restraint for all the economy's consumers. The only uniform ratio at which all the consumers could sell X for Y (and vice versa) is the one represented by $w_h w_h$ (or ww), that is, the transformation ratio in the world market. Each consumer will now exchange his X (by buying less of it) for Y in the world market, at the ratio indicated by $w_h w_h$ (the difference between it and the transformation ratio as he sees it being the saving of the tariff duty); and this will proceed until point C_h is reached, in which the consumer's subjective transformation ratio is equal to rr , his market-transformation rate. But C_h , as has been seen, is inferior to D_h .

"Price" vs. "Tariff" Elasticities In International Trade— A Suggested Reconciliation

Estimates of elasticities in international trade [4] have been derived by a variety of methods, one of which employs the effect of tariff changes on the volume of trade to get import-demand elasticities. A puzzling phenomenon related to this method is that the elasticities so obtained have been consistently higher—and by a wide margin—than those derived from a direct price-quantity relationship. Thus an implied "tariff elasticity" of -4.3 has been estimated for the United Kingdom for the early 1930s [8, pp. 168-69]; of -9 for Germany for the mid 1950s [9]; and of -6 for the United States

for 1955-59 [7]. In a more direct comparison Krause found the U.S. elasticity of demand for imports calculated with respect to the tariff change to be 2-3 times the elasticity calculated with respect to price [6]. This note suggests that the reason for the disparity might lie, at least partly,¹ in the difference between nominal and effective tariff rates.

While the nominal tariff refers to the rate published in the country's tariff schedule, the effective protective rate is defined as "the percentage increase in value added per unit in an economic activity which is made possible by the tariff structure relative to the situation in the absence of tariffs but with the same exchange rate" [5, p. 222]. In order to estimate the protective effect of the tariff, the rate applied to each product must be related to value added rather than to the gross value of output, allowance being made for tariffs on imported materials. For while nominal tariffs apply to the total value of imports, they protect only the portion of that value produced in the home country. At the same time, the level of protection accorded the production of a final good is also affected by the level of duty on imported inputs used in the production process.

In a simple case where commodity (j) is subject to a nominal import duty (T_j), and uses one imported input (i) on which the tariff is (T_i), the value added per unit of j in the absence of a tariff is:

$$v_j = p_j(1 - a_{ij})$$

and the value added per unit of j made possible by the tariff structure is:

$$v'_j = p_j[(1 + T_j) - a_{ij}(1 + T_i)]$$

where p_j is the price of a unit of j in the absence of tariffs and a_{ij} is the share of i in the cost of j in the absence of tariffs. The effective protective rate is:²

$$(1) \quad G_j \equiv \frac{v'_j - v_j}{v_j} = \frac{p_j[(1 + T_j) - a_{ij}(1 + T_i)] - (1 - a_{ij})p_j}{p_j(1 - a_{ij})} = \frac{T_j - a_{ij}T_i}{1 - a_{ij}}$$

Industrial countries levy higher tariffs on finished manufactures than on raw materials and intermediate goods. Correspondingly the effective rates on manufactures are considerably higher than their nominal counterparts. Indeed, for several countries or country-groups (United States, United Kingdom, European Economic Community, Sweden, and Japan) the observed differences between the two rates are often in the 50-80 per cent range [1 and 3].

In the course of successive GATT negotiations during the postwar period, tariff reductions were concentrated mainly in manufactured products (i.e., categories 5-8 SITC). Partly because finished goods were initially subject to higher nominal rates than products in earlier stages of fabrication, and partly because of the industrial countries' protective attitudes towards certain primary materials, tariffs on finished products were probably sub-

¹ For another possible reconciliation see [2].

² For the development, discussion and extension of this formula see [5].

ject to larger cuts than those on semifinished and primary commodities. In terms of the above notations: $\Delta T_j > \Delta T_i$.

How would this affect the effective protective rate? Assuming no change in a_{ij} , the "total differential" of G_j will yield the change in effective protection for any given changes in T_j and T_i :

$$(2) \quad \Delta G_j \sim \frac{1}{1 - a_{ij}} \Delta T_j - \frac{a_{ij}}{1 - a_{ij}} \Delta T_i.$$

Divide through by ΔT_j

$$\frac{\Delta G_j}{\Delta T_j} = \frac{1}{1 - a_{ij}} - \frac{a_{ij} \cdot \Delta T_i}{(1 - a_{ij}) \Delta T_j} = \frac{1}{1 - a_{ij}} \left(1 - \frac{a_{ij} \cdot \Delta T_i}{\Delta T_j} \right)$$

From this we have:

$$\frac{\Delta G_j}{\Delta T_j} \geq 1 \text{ if: } \frac{1}{1 - a_{ij}} \left(1 - \frac{a_{ij} \Delta T_i}{\Delta T_j} \right) \geq 1; \text{ or } 1 - \frac{a_{ij} \cdot \Delta T_i}{\Delta T_j} \geq 1 - a_{ij}.$$

We conclude that:

$$(3) \quad \frac{\Delta G_j}{\Delta T_j} \geq 1 \text{ if } \frac{\Delta T_j}{\Delta T_i} \geq 1.$$

In words, the change in the effective tariff on the final commodity will exceed or fall short of the change in the nominal rate applied to it, depending on whether or not the change in the nominal tariff on the final good exceeds the change in duty imposed on the imported inputs.³ Also, in order for the effective rate to remain unchanged, we must have

$$(4) \quad \frac{1}{1 - a_{ij}} \Delta T_j = \frac{a_{ij}}{1 - a_{ij}} \cdot \Delta T_i; \text{ or } \frac{\Delta T_j}{\Delta T_i} = a_{ij}.$$

Our hypothesis suggests that in most cases the changes in nominal tariff rates on finished goods exceeded those on primary and semimanufactured commodities. This is subject to empirical verification. But if true, it implies that postwar changes in effective rates exceeded the changes in nominal rates. And it is the effective rather than the nominal rate that determines the "production effect" of the tariff.

When import-demand elasticities are estimated by relating *nominal* tariff changes to changes in the volume of trade, the implied variation in relative prices is smaller than what has actually occurred. Thus, observed changes in quantity represent responses to larger price changes than are superficially apparent, and the resulting demand elasticities would be higher than elasticities obtained by other methods. Conversely, it should be recognized that when elasticities obtained by other means (i.e., without

³ In this formulation, the changes in duty are expressed in terms of percentage points rather than as percentages of the previous rates.

reference to tariff changes) are employed along with nominal tariffs, to estimate the effect of tariff policies (such as multi-lateral reductions or a free trade area in manufactures) on trade flows and welfare, they are likely to underestimate these effects. Only for an across-the-board change which applies to all commodities, will the results be conceptually accurate.

A Note on Exchange Rate Changes and Capital Flows

The purpose of this note is fourfold: (a) To analyze, under fixed and floating exchange rate systems, the behavior of the forward foreign exchange market in response to two exogenous disturbances—(1) a change in expectations about the future spot rate and (2) a change in the short-term interest differential. (b) To show that under certain conditions the "two interest rate" policy of Keynes [2] will be a failure. (c) To show again (see [3]) that even in flexible exchange rate countries domestic monetary policy is, under certain conditions, not independent of international considerations. (d) To suggest the relevance of my conclusions to the problem of empirically testing the interest rate parity theory (IRPT).

The IRPT is assumed to hold in the long run, although not necessarily in the short run. Only one maturity shall be considered (say three months).

The domestic (say U.S.) and foreign interest rates for that period are r^d and r^f . Exchange rates are quoted as the domestic price of foreign currency: S =spot rate; F =market forward rate; F^* =forward rate satisfying the IRPT, i.e.,

$$F^* = S \left[\frac{1 + r^d}{1 + r^f} \right];$$

and S^e =spot rate expected by speculators (nonhedgers). Assume that r^d is given to the foreign countries either because of the relatively large size of the United States or by U.S. monetary policy, and assume that r^f is set by the monetary authorities. Consider an initial position where $S^e = F = F^* = S$, i.e., the IRPT is satisfied and interest rates are coincident ($r^d = r^f$).

Now suppose that expectations change so that $S^e < F = F^* = S$. What will happen in the fixed exchange rate case (say the U.K.)? Speculators will sell forward pounds at F in anticipation of covering at S^e . Arbitragers (hedgers) will buy these forward pounds and cover by selling spot at the pegged rate, S . As a result, F is forced down so that $S^e \leq F < F^* = S$. The capital flow will be severe as long as the authorities support the pound at S and do not change $r^d - r^f$. If the peg is to be maintained r^f must rise—a deflationary policy must be followed—so that $S^e = F = F^* < S$. The foregoing description is a capsule summary of recent (and not so recent) British exchange rate history. British monetary policy has often and to a large extent been determined by international considerations.

In a floating rate system (say Canada, 1950–62) no domestic monetary adjustments need be made. Speculation against the Canadian dollar will merely lower the spot rate as well as F so that $S^e = F^* = F = S$ once again. If everyone's expectation changed in the same way, no capital flow is required and adjustment is rapid. For this reason the domestic economies of flexible exchange rate countries are said to be insulated from the vagaries of international trade and payments.

Consider now the other possible exogenous disturbance, a change in ($r^d - r^f$). Assume r^d rises. Since interest rates are now higher in the United States than in the United Kingdom, spot funds will flow out of the United Kingdom; and they will be covered forward at F so that F is driven up until $S^e = S < F = F^*$. The United Kingdom will be following a "two interest rate" policy first advocated by Keynes—a low rate at home to maintain aggregate demand and a high rate vis à vis foreigners (since they gain on the forward hedge when $F > S$, i.e., $r^d \approx r^f + (F - S)/S$) to maintain balance of payments. But because the spot rate cannot change and no reason exists for expectations about future spot rates to change, such a policy cannot be maintained in the long run. As speculators become more confident of the "two interest rate" policy, which implies that the subsequent spot rate is less than today's forward rate, they will sell forward sterling in increasing amounts causing a massive capital outflow which must result in devaluation or a policy of domestic inflation. Thus in response to an exogenous shift in expectations a change in the interest differential is *required*—the "two

interest rate" policy is forced on the United Kingdom. But when the United Kingdom would like, independently, to undertake such a policy, it cannot be successful.

Finally consider the response to a rise in r^d under a floating rate. The initial result will differ. Since S^e is unchanged, the burden of the initial adjustment will be on S , which in this case can move, and not on F so that $F = F^* = S^e > S$. But such a position cannot be an equilibrium position for long. If speculators expect the Canadian monetary policy to be a permanent one, they will be able to profit by selling forward exchange and covering at maturity. Such actions will cause a once and for all capital outflow and a moving equilibrium position in which ${}_{t+i}F^*_t = {}_{t+i}F_t > S_t > {}_{t+i}S_t^e = S_{t+i}$, where all rates are depreciating over time, where ${}_{t+i}S_t^e$ accurately predicts the subsequent spot rate, S_{t+i} , and where the forward rate is rather mechanically tied to the spot rate by the IRPT. Note that there is not a continuing capital outflow as in a fixed rate system. Instead the adjustment is in a steady depreciation of the exchange rate. The decline in S means, however, that Canadian exports will increase, i.e., aggregate demand will increase, and inflationary pressure will result as in a fixed exchange country unless the monetary authorities allow a rise in r^f . Thus even under a floating rate, domestic monetary policy is not independent of international disturbances. The Canadian situation in the late 1950s and early 1960s was actually the reverse of the illustration just presented. The United States in 1959 went into a recession causing r^d to fall relative to r^f . An appreciation of the exchange rate resulted and Canada also experienced a recession because the Canadian authorities refused to allow r^f to fall.

Consider now the validity of regressions to test the traditional IRPT. The IRPT states that the relation of F to S is determined solely by the interest differential

$$\left[\text{i.e., } F/S = 1 + R, \text{ where } R = \frac{r^d - r^f}{1 + r^f} \right].$$

A more sophisticated modern theory [4] would maintain that speculative expectations are also important, at least in the short run. If this is so and if expectations are omitted from the tests of the IRPT, there will be a misspecification bias in the coefficient of R which will depend on the regression between R and the omitted variable (see [1]). Since F/S is being predicted the appropriate variable (at least conceptually) to represent expectations is S^e/S . Part of the importance of the earlier analysis is that it will permit a prediction of the direction of bias. In the United Kingdom, the situation described in paragraph 3 above has been typical. Such a situation implies a positive correlation between R and S^e/S (when S^e declined, r^f was forced to increase and R also declined), and this in turn implies an upward bias in the coefficient of R . The typical Canadian situation, described above implies a negative correlation between S^e/S and R (when r^d declined and R decreased, S^e increased more than the current S because speculators expected continued tight money in Canada and thus a continued appreciation of

subsequent spot rates); and this negative correlation, in turn, implies a downward bias in the observed coefficient of the interest differential. For example I ran, using weekly data for the United States-Canada and the United States-United Kingdom, regressions on the traditional IRPT for both Canada and the United Kingdom that resulted in coefficients of .80 for the interest differential, R . Inclusion of a missing expectations variable changed Canada's coefficient to .96 (much closer to the theoretical expectation of 1.0) and changed the United Kingdom's coefficient to .60 (much farther from the theoretical expectation of 1.0).

Wages and the Guideposts

Economists seem quite unsure of whether the guideposts are working and are divided on whether they like them. Among those who don't, a further division exists between those who don't like them because they don't work and those who don't like them because they do. In any case, some facts would help everyone decide on which grounds to oppose or defend the guideposts, the facts, of course, being incapable of actually changing anyone's basic position for or against them.

One casual argument that is made is that the guideposts are no longer a factor, witness the various wage increases that have shattered them. I am prepared to argue from casual evidence, and shortly will. But some settlements, or even all settlements, being made above the Administration's central figure of 3.2 per cent show nothing. The interesting question is whether wage (and price) changes have been smaller than they would have been without the guideposts.

To test this, one needs an estimate of what they would have been; an investment in one method of making such an estimate [1] led me to look at this question. The method is to use an equation for estimating wage changes (straight time hourly earnings of production workers) in manufacturing based on postwar quarterly data. For the 1947-60 period, the equation estimated was [1, p. 50]

$$\dot{W}_t = -4.313 + 0.367\dot{C}_{t-1} + 14.711U_t^{-1} + 0.424R_{t-1} + 0.792\Delta R_t, \quad R^2 = .88,$$

(0.054) (2.188) (0.068) (0.176)

where

- \dot{W} is the percentage change in straight time hourly earnings over the past year
 \dot{C} is the percentage change in the Consumer Price Index over the year
 U^{-1} is the reciprocal of the percentage unemployment rate over the year
 R is the average profit rate in manufacturing over the year (after tax profits as a percentage of equity)
 ΔR is the quarterly first difference in R .

For the period starting with the first quarter of 1962, the differences between actual and estimated values of \dot{W} are given in the left column of Table 1 below. The right column gives the same differences based on a similar equation covering only the quarters from 1953 to 1960.¹

The pattern of forecast errors coincides so beautifully with guideposts that the burden of proof regarding their effectiveness would, at least, seem to have shifted a bit. A dummy variable would clearly be significant, more so if it reflected the increasing urgency with which the Administration has embraced guideposts as the years passed and the unemployment rate fell. The historical residuals from the wage equation give no basis for expecting this result. While residuals show some autocorrelation,² during the 1948 to 1960 period the longest run of residuals with the same sign was 6 quarters compared with the 15 successive negative quarters shown in Table 1. Furthermore, there was no suggestion of a negative trend in the wage change variable; if anything, the contrary might have been suspected. Before the run shown in Table 1, the equation had underpredicted wage changes most of the time since 1958 [1, p. 77]. The possibility of a longer trend was checked by using the equation for 1953-1960 to predict the wage changes of the preceding years, 1948 to 1953.³ The equation overpredicted wage changes by an average of 0.84 percentage points [1, p. 75]; underprediction would have been expected if the present results for recent years were the result of a long-term trend.

I find these results highly suggestive. But any good skeptic could suggest plausible reasons other than guideposts for them too. So I have looked for some further evidence from other data.

The best approach is suggested by the criticism that the guideposts are (necessarily) enforced unevenly, some industries and bargains being specially subject to their pressure because they are highly visible. Visibility enters in both because it is infeasible to police every small wage settlement

¹ In this case the equation was

$$\dot{W}_t = -4.712 + 0.680\dot{C}_{t-1} + 18.421U_t^{-1} + 0.360R_{t-1} + 1.244\Delta R_t, \quad R^2 = 0.80.$$

(0.132) (3.050) (0.120) (0.300)

² The Durbin-Watson statistic is 1.2 for the wage equation shown.

³ Such a check was suggested by the referee of this paper.

TABLE 1—ACTUAL MINUS ESTIMATED PERCENTAGE WAGE RATE CHANGES

| Year-Quarter | From 1947-60 Equation | From 1953-60 Equation |

| -3 | -2.11 | -2.35 |
| -4 | -1.61 | -1.88 |
| 1966-1 | -2.48 | -2.79 |

and because bad pattern-setting effects may be feared from visible bargains, making them even more important than their size alone would indicate. A separation into visible and invisible settlements would thus permit a rather strong test of the guideposts.

The first requirement is to separate the industries according to their visibility or susceptibility to guidepost pressures. An objective measure would be nice to have, but I did not find one. Instead, I consulted some experts who presumably have a learned opinion and asked them to separate the two-digit manufacturing industries into two groups. Where my experts disagreed or were uncertain, the industry was left out of both groups.

The next question was how to compare wage behavior in the two groups. Ideally, one would like an equation for each industry like the one above for all manufacturing. Then the pattern of recent residuals from the different industries could be compared. For various reasons, it is not as easy to get such wage equations with disaggregated data, the main problem being the irregular timing of wage changes. So I have resorted to a more casual test. I have simply taken the ratio of wage changes before guideposts to wage changes after guideposts for each industry. If the guideposts are having an impact, the ratio should be higher for the visible industries.

In order to minimize other effects, I chose periods for the ratio of wage changes that were as similar as our economic performance would allow: 1963 to 1966 and 1954 to 1957. Letting W stand for average hourly earnings of production workers and R^W stand for the ratio just described, we have

$$R^W = \left(\frac{W_t}{W_{t-1}} \right)_{1960s} \div \left(\frac{W_t}{W_{t-1}} \right)_{1950s}.$$

R_i^W stands for an individual industry's ratio; R_V^W for the mean ratio of in-

TABLE 2— R^W : RATIOS OF WAGE CHANGES IN THE 1950s TO WAGE CHANGES IN THE 1960s

^a The change from 1965 to 1966 was approximated by the change between the April-May average for each year.

dustries in the visible group; and R_I^W for the mean ratio of industries in the invisible group. The W_t/W_{t-1} terms were computed for different intervals within the basic time periods chosen, and there are thus R^W statistics based on the 1954 to 1955 wage change divided by the 1965 to 1966 wage change; the average wage change from 1954 to 1956 divided by the average wage change from 1964 to 1966; and the average wage change from 1954 to 1957 divided by the average wage change from 1963 to 1966. Again, because of the irregular timing of wage changes, the last of these, involving the ratio of average wage changes over three-year periods, was expected to give the sharpest comparisons.

Table 2 lists the industries in the visible and invisible groups together with the individual industry and group wage change ratios. With few excep-

tions, the individual R_i^W 's are higher for the visible industries. The indicated difference between R_V^W and R_I^W , the mean ratio for each group, is statistically significant at the one per cent level for the ratios using three-year wage changes and at the 5 per cent level for the others. Thus, when compared with the mid-1950s, wage changes in the mid-1960s have slowed down in the visible industries relative to the invisible ones. Indeed, in invisible industries, the average annual wage change from 1963 to 1966 was 3.8 per cent compared with 4.3 per cent from 1954 to 1957; in visible industries the comparable figures are 2.9 per cent and 5.0 per cent. The differential slowdown is 1.6 percentage points. It is stretching casual empiricism pretty far, but for the period spanned, such a difference between the visible and invisible industries looks quite consistent with the residuals for the aggregate manufacturing equation shown earlier, on the hypothesis that the invisibles were unaffected by guideposts and the visibles affected to the extent shown by the larger R^W ratios in Table 2 (or the 1.6 percentage point differential just cited).

Next, it is possible to clear up some misgivings about what else may be going on to yield these results by looking at employment data in the same way the wage data were examined. Employment changes are an imperfect substitute for detailed analysis of individual industries; but they may serve as a proxy for what one would like to know. Many views of aggregate wage determination, including the one expressed by the equation given earlier in this paper, are consistent with the view that short-run *relative* wage changes among industries can be identified with relative shifts in demand, and hence employment, among these industries. Other things being equal, the R^W ratios shown in Table 2 would be positively related to the corresponding ratios of employment changes. In particular, if higher employment-change ratios were observed for the visible industries, it would mean the invisibles experienced the relatively larger growth in labor demand in the 1960s compared with the 1950s, and this fact could explain what we have observed without recourse to guideposts.

Table 3 shows the employment-change ratios, designated by R^E , computed in the same way as the wage-change ratios of Table 2. Employment refers to production workers. For the three-year spans, the rank correlation between the R_i^W 's and R_i^E 's for individual industries in the invisible groups is 0.864, significant at the 5 per cent level. This supports the basic presumption that, in industries unaffected by guideposts, relative wage changes are positively related to relative employment changes. Within the visible industries subgroup, the rank correlation is only 0.200, an insignificant magnitude and perhaps not unexpected since the basic hypothesis calls for guideposts to interfere with wage changes here. (With ordnance and accessories removed the rank correlation becomes 0.648, significant at the 10 per cent.)

Alongside these results for individual industries, the telling comparison is between the mean wage-change and employment-change ratios for the two industry groups. While R_V^W exceeds R_I^W in each time span shown in Table 2 R_I^E exceeds R_V^E in each time span shown in Table 3. This is more support than the guidepost hypothesis needs: If R_V^E just equaled R_I^E it would sup-

port the guidepost explanation offered for the findings with wage changes alone. In fact, the indicated difference between R_V^E and R_I^E is not significant at the 10 per cent level. These results still show that relative employment changes cannot account for the differential in wage behavior that we observe between the visible and invisible industries.

The employment data can be applied to our question somewhat more formally by specifying the following model. Assume the ratio of wage changes in the i th industry to the average wage change in manufacturing is proportional to the ratio of employment change in the i th industry to the average employment change in manufacturing. That is:

$$\frac{W_{t,i}}{W_{t-1,i}} \bigg/ \frac{\bar{W}_t}{\bar{W}_{t-1}} = a_i \left[\frac{E_{t,i}}{E_{t-1,i}} \bigg/ \frac{\bar{E}_t}{\bar{E}_{t-1}} \right]$$

where a bar over a variable now indicates the manufacturing average. If nothing changed this relation between the periods we are considering, we could compute the ratios as before, eliminate the unknown a_i 's, and expect a relation of the form

$$R_i^W - \frac{\bar{R}^W}{\bar{R}^E} R_i^E = 0$$

However under the guideposts hypothesis being tested, for visible industries we would expect

$$R_i^W - \frac{\bar{R}^W}{\bar{R}^E} R_i^E = d_i > 0$$

since \bar{R}^W is increased less by guideposts than R_i^W ; and for invisible industries we would expect

$$R_i^W - \frac{\bar{R}^W}{\bar{R}^E} R_i^E = d_i < 0$$

since \bar{R}^W is increased more than R_i^W . Thus letting d_V be the expected d_i for visibles and d_I the expected d_i for invisibles, we hypothesize $d_V > d_I$ and, in the strongest form of the test, $d_V > 0$ and $d_I < 0$.

Because the total manufacturing ratios, \bar{R}^W and \bar{R}^E , are not merely averages of the R_i^W and R_i^E for the individual industries used here (and because other things may have changed in the relation besides guideposts), the strongest test, requiring both $d_V > 0$ and $d_I < 0$ may well fail for extraneous reasons.⁴ However the weaker test, $d_V > d_I$, should be met if the effectiveness of guideposts can be identified by the differential wage behavior in visible and invisible industries.

Table 4 lists the d_i 's for the individual industries and for the visible and invisible industry subgroups. The hypothesis $d_V > d_I$ is accepted with various levels of confidence for the different subperiods, the one per cent level being reached for the three-year spans if the ordnance and accessories industry is excluded. Guideposts do seem to have slowed wage changes in visible industries relative to invisible industries to a significant degree.

Many questions remain. Accepting all the above results, have guideposts been desirable on balance? Generally we dislike measures that distort relative prices; but what if visible industries in the past distorted wages as markets tightened with the balance ultimately restored at the cost of inflation? And a final caveat. We cannot prove that only guideposts could have caused the wage behavior observed. In particular, my colleague Carlos Diaz suspects that growing import competition may have been as important, an interesting conjecture but hard to test.⁵ On the present evidence, I feel one

⁴ In fact $d_V > 0$ does fail significance tests; $d_I < 0$ is significant at the 1 per cent level using the three-year spans.

⁵ In a study on the guideposts which he is preparing for the Brookings Institution, John Sheahan considers this conjecture and tentatively rejects it.

Price Elasticity and Linear Supply Curves

There is a lengthy section in almost every price theory text dealing with the behavior of price elasticity along linear demand functions. The point is to show (1) how elasticity changes along the function and (2) how these elasticities are related to total expenditures at alternative prices and quantities. Yet price elasticity behavior along positively sloped linear and other supply curves usually is treated much less fully, presumably because there is no question whether or not a price change increases or decreases sellers' total revenue. Prices and total revenues move together. About the most shown is that linear supply functions (or linear segments of other supply curves) are unit elastic if they pass through the price-quantity origin when extended, elastic if they intersect the price axis, and inelastic if they intersect the quantity axis [2, pp. 190-92] [3, pp. 100-102] [5, pp. 197-200]. However, to complete the story, instructors also might discuss the behavior of supply elasticity and total revenue *along* these linear functions. That is the purpose of this note.

This topic is a matter of some importance since linear supply curves, even though a special case, often are used in the classroom and have been employed in a multitude of empirical supply response studies. For instance, several recent studies used linear functions to estimate production response and supply elasticity for important commodities in less-developed nations [1] [4] [6] [7, pp. 65-82]. In each of these studies, policy implications might have been sharpened had price elasticity behavior along the estimated linear supply curves been considered in conjunction with the published elasticity estimates computed at mean values. It would be unusual if current prices and outputs, important for current policy decisions, coincided with mean values of historical data series. Thus we should be as aware of the analytical consequences in assuming linearity on the supply side as we are on the demand side.

To tackle the question, first consider the linear supply function

$$(1) \quad Q = a + bP \quad (b > 0)$$

where Q is the quantity supplied of some commodity, P is its price, and a and b are intercept and slope parameters respectively.¹ Figure 1 depicts this supply function at three arbitrary levels of a . For S_1 , a is less than zero; for S_2 , a is equal to zero; and for S_3 , a is greater than zero.

Now form the price elasticity of supply from equation (1)

$$(2) \quad Ep = \frac{\partial Q}{\partial P} \cdot \frac{P}{Q} = b \frac{P}{Q}$$

and using equation (1) to eliminate P

¹ The variable, P , may be some previous price, a price ratio, or a complex price expectation. In this context, it is regarded simply as the appropriate supply-inducing price variable. The intercept a can be viewed as including other supply "shifters" fixed at some level.

$$(3) \quad Ep = 1 - \frac{a}{Q}$$

Figure 2 shows how Ep varies along each of Figure 1's three supply curves: S_1^* shows elasticities along S_1 ; S_2^* is associated with S_2 ; and S_3^* is associated with S_3 . Along S_1^* , supply elasticity is infinitely large when Q is zero and then approaches $+1.0$ from above as Q increases. Along S_2^* , elasticity is always $+1.0$. Along S_3^* , elasticity is zero when Q equals a and then approaches $+1.0$ from below.

So, as others have shown, linear supply curves are unit elastic, elastic, or inelastic according to whether they intersect the origin, the price axis, or the

FIGURE 1

quantity axis. But all linear supply curves converge to an elasticity of $+1.0$ as Q (and P) increase. How fast $+1.0$ is approached depends upon a . The closer a is to zero, the faster the approach.

Along negatively sloped demand curves, total expenditures for a commodity increase, decrease, or remain constant as its price rises according to whether its demand elasticity is less than, greater than, or equal to -1.0 . This well-known relationship can be important in economic and business policy decisions. On the supply side, however, sellers' revenue always will increase as price rises along a positively sloped supply curve due to rightward shifts in the demand curve or to increases in guaranteed prices to sellers. Does the supply elasticity coefficient carry useful information other than whether quantities supplied change proportionately more or less than price? With linear supply curves, total revenue is given by the parabolic equation

$$(4) \quad R = P \cdot Q = \frac{Q^2 - aQ}{b}$$

FIGURE 2

FIGURE 3

This equation measures the size of the total revenue rectangle under the supply curve at each Q . Figure 3 shows the behavior of R for Figure 1's three supply curves, each now indicated with a double asterisk.

Since R reaches no maximum as Q (and P) increase, it may be useful to know the proportionate change in R given a one per cent increase in price

when the supply curve remains stationary. Such an expression is

$$(5) \quad E_r = \frac{\partial R}{\partial P} \cdot \frac{P}{R} = 1 + E_p$$

where E_r is the "price elasticity of total revenue," and applies to any supply function, linear or not. As E_p approaches $+1.0$, E_r nears $+2.0$. That is, when supply is unit elastic, a one per cent increase in price, given through the market by a demand increase or by government support programs, will raise sellers' total revenue by two per cent. If supply is price elastic, total revenue will increase more than two per cent for each one per cent price increase. If supply is inelastic, a one per cent price increase will raise total revenue between one and two per cent. When supply is completely inelastic, a one per cent price increase leads to a one per cent revenue increase since there is no response in quantity supplied.²

In summary, supply elasticity varies along any linear supply function which does not intersect the origin. At higher prices and outputs, the linear function's elasticity approaches $+1.0$, the speed of approach depending upon the size of the price- or quantity-axis intercept. Sellers' total revenue always increases along any positively sloped supply curve as price rises. The percentage change in total revenue associated with a one per cent price change, whether or not the curve is linear, equals $+1.0$ plus the price elasticity of supply ($1 + E_p$). Thus, with any positive price elasticity, the proportionate response in sellers' total revenue always will be greater than any given percentage price change. These relationships should be kept in mind when interpreting and using elasticity information obtained from estimated or assumed supply curves.

JAMES P. HOUCK*

² Notice that this formulation of E_r applies equally well to demand curves where E_p is negative.

Railroad Social Saving in Nineteenth Century America

The last ten years have witnessed rapid extension in the application of econometric technique to economic history, a development whose progress can be traced in past issues of this journal [3, pp. 86-98] [4, p. 128] [5, pp. 344-389]. The "new" economic history, it is claimed, unites economic history with economic theory and makes possible dramatic and precise revaluation of the significance of past events and institutions [3, pp. 92-93]. Perhaps the best known and most substantial "new" economic history project is Professor Fogel's reinterpretation of the contribution of railroads to U.S. economic development [1]. Fogel emphasizes the deficiencies in traditional, nonquantitative, railroad interpretations. These, he considers, represent "... the hero theory of history applied to things ..." [1, p. 236]. By using various econometric techniques Fogel calculated the value of railroad social saving in one year, 1890. The saving was equivalent to 6.3 per cent of gross national product [1, p. 220]. He regards this figure as a maximum measure of railroad contribution. A more realistic figure, making due allowance for economic adjustment to a nonrail situation, would be a saving of below 5 per cent of gross national product [1, p. 223].

How significant is a saving of 5 per cent of gross national product in 1890? Surprisingly, Fogel devotes scant attention to the significance of the figure he worked so hard to produce. He clearly regards 5 per cent as a good deal lower than the sort of figure that traditional nonquantitative interpretations would have led us to expect. Marc Nerlove has drawn attention to Fogel's failure to develop his conclusion. According to Nerlove, "Fogel's tacit acceptance of the triviality of the saving due to railroads is just the sort of half conscious quantification of which he accuses traditional economic historians" [2, p. 112].

Further analysis of Fogel's conclusion suggests that railroad social saving was far from trivial. The calculation represents railroad saving in one year, 1890. Fogel treats his conclusion as a measure of total railroad contribution—as if a saving of 5 per cent in 1890 implies that the gap between the actual U.S. economy and the hypothetical nonrail economy would have been 5 per cent twenty years earlier in 1870, and still 5 per cent in 1900. This assumption is unsound. It represents the extension of a snapshot analysis to a dynamic situation where the removal of any one economic variable, in this case railroads, would have a compound effect over time. Table 1 illustrates the compound effect of the loss of a railway social saving of 5 per cent, (a) for one year only, and (b) over five years. In both cases a GNP growth rate of 4 per cent per annum is assumed. Even if the economy lost its railroads for only a year, owing to a strike or similar cause, after five years the gap between the rail and nonrail economies would amount to 5.85 per cent. When the economy is deprived of its railroads permanently, the accumulated loss of railroad social saving would be much greater—in this case enough to more than offset an annual 4 per cent growth rate. After five years the margin between the rail and nonrail economies would amount to 27 per cent.

TABLE 1—INTERPRETATION OF A RAILROAD SAVING OF 5 PER CENT OF G.N.P. WHEN GROWTH RATE IS 4 PER CENT P.A.

(a) Effect of losing railroads for one year. i. Rail economy
 (b) Effect of permanent loss of railroads. ii. Nonrail economy

| | G.N.P. (a) | | (b) | |
|--------|------------|--------|--------|-------|
| | i | ii | i | ii |
| Year 1 | 100 | 95 | 100 | 95 |
| 2 | 104 | 98.8 | 104 | 93.8 |
| 3 | 108.16 | 102.75 | 108.16 | 92.55 |
| 4 | 112.48 | 106.86 | 112.48 | 91.25 |
| 5 | 116.98 | 111.13 | 116.98 | 89.9 |

The model exaggerates railroad contribution because it makes the dubious assumption that other things would remain the same. Society would have made some adjustment to the nonrail situation. The model is unrealistic to this extent, but it is much more realistic than a static interpretation. Even if we allow a generous discount for adjustment to a nonrail economy the indication is clearly that the long-term contribution of railroads was more important than Fogel implies. Traditional interpretations of railroad significance were not as far off the mark as Fogel suggests.

Market Value and the Theory of Investment of the Firm

Recent econometric studies of investment behavior have found the market value of the firm to be an unsatisfactory variable in explaining changes in the firm's desired capital stock.¹ The purpose of this paper is to

¹ See [2], [6]. For some earlier studies in which the market value variable seems to perform more satisfactorily see [3], [4].

FIGURE 1. EQUILIBRIUM PRICE-OUTPUT COMBINATIONS

argue that erratic results are not really surprising since the theory of the firm indicates that desired capital stock can not reasonably be treated as a function of either market value or profits.

Consider the case of a rationally managed firm acting to maximize the present value of its net cash flows. This action, in a certainty world, is equivalent to maximizing the market value of the firm since its securities represent the total of all claims to the cash flows [5]. We can therefore write,

$$V = \int_0^{\infty} e^{-rt} [PQ - C(Q)] dt = \frac{1}{r} [PQ - C(Q)]$$

where V is market value, r is the rate of interest, P is output price, $C(Q)$ is the total cost of producing Q units of output, and Q is related to capital stock and other productive factors by the production function. Assume that the firm faces a demand curve of the form $P = P_i(Q)$ where the subscript i acts as a "shift parameter."² V is maximized when $PQ - C(Q)$ is maximized and this occurs, referring to Figure 1, at the price-output point A for which marginal revenue equals marginal cost.³

² The model considered here is of a monopolistic firm. Some comments on the competitive case follow.

³ The linearity of the demand curve is not essential to the argument as should be clear from the discussion.

Let there be an unanticipated shift in the demand function from $P_0(Q)$ to $P_1(Q)$. Clearly, V is greater at C , the new price-output equilibrium, than it is at B . In turn, B is a more profitable price-output combination than A because output is the same at A and B but price is greater at B . In this case, therefore, the demand shift permits the firm to decrease output but increase V . If the prices of productive factors are fixed, desired capital stock will be lower at the lower output.⁴ By similar reasoning it can be shown that there are demand shifts for which both V and desired capital stock increase. It follows that desired capital stock can not be treated as a function of market value since for any given change in V , capital stock may either increase or decrease depending on the shift in demand.

The foregoing analysis has been restricted to monopoly, dominant price-leader oligopoly, and other imperfectly competitive situations where the firm faces a downward sloping demand curve. In the case of pure competition with no externalities, the number of firms in the industry will change as demand fluctuates, but each firm will maintain the same output and capital stock so that changes in V , if any, will be unrelated to the desired capital stock of any firm.⁵ If externalities are introduced, equilibrium output and capital stock positions of the firm may be greater than, equal to, or less than their position before a demand shift according to the assumptions made about external technological and pecuniary economies. In the competitive industry case, moreover, interequilibrium profits or losses will affect V while not necessarily implying anything about the movement or equilibrium position of capital stock.

The discussion so far has been cast entirely in terms of the relationship between market value and desired capital stock but, insofar as V is a generalized profits variable, the same arguments apply almost directly to the similar use of current or past profits. Actually, the relationship will be even more tenuous to the extent that past profits are not related to future profits in any very simple way. Furthermore, the analysis has dealt only with the effects of demand shifts but it is clear that there are many other sources of slippage in the chain between capital stock and market value. Two of these sources of slippage are perhaps worth explicit mention. First, capital-saving technological change may occur which will affect the links between profits and output and between output and capital stock. Second, there is the possibility of changes in investor horizons about the length of time future investment opportunities will last, affecting the link between profits and market value. Ancillary to this last point, but nonetheless important, is the fact that a given change in market value may be consistent with a change in

⁴ Assuming, of course, that capital is not an inferior input in which case the lower output would be produced with a greater capital stock. Inferiority of capital does not change the basic point of this paper, although it does change the line of analysis slightly. For a discussion of inferior inputs see [1].

⁵ In a competitive industry with no externalities where output changes because firms with identical amounts of capital stock enter and exit, it may be that there is a linear relationship between the total capital stock held by the industry and aggregate market value of all firms in the industry. However, with less restrictive assumptions that allow for differing amounts of capital stock among firms, externalities, and changing factor prices a linear model does not seem plausible even on the industry level.

profit conditions at any point in the future—not necessarily the next period. Thus, V could increase in response to a highly profitable long-range condition despite current losses in output and reductions in capital stock.

To summarize, it seems doubtful that market value or any other profits variable is a good indicator of desired capital stock or even a good control variable since it reflects such a diverse set of phenomena. Even in those cases where a good fit is obtained, we do not know why it is good or how to interpret it.

Steel Imports and Vertical Oligopoly Power: Comment

The article by W. Adams and J. B. Dirlam (hereafter referred to as A&D) in this *Review* [1] has provoked some expected comment [4] [5] to which A&D provide an interesting reply [2]. Much of this exchange concentrated upon the role of technological factors in the deterioration of the U. S. steel industry's competitive position.¹ It is the purpose of this note to show that in the case of the one major innovation A&D have chosen to support their argument, the LD process,² there is little evidence for their contention that the

¹ A&D have since elaborated their argument in a somewhat different direction, distinguishing between the propensities to innovate of large and small firms [3] and thus at least implicitly absolving U.S. industry from the wholesale condemnation pronounced in the paper here under discussion.

² The LD process, frequently referred to in this country as the BOF (basic oxygen furnace), was developed commercially in Austria in the late 'forties and early 'fifties. In this process, a charge of scrap and molten iron is placed in an open, pear-shaped, vessel. A jet of oxygen is then blown upon the surface of the charge at supersonic speed from a "lance" lowered into the vessel, bringing about a violent reaction. It is generally agreed that, except in unusual circumstances, the LD process is more economical, both in capital and operating costs per unit of output, than the open hearth method of steel-making.

United States lagged seriously behind the other major steel-manufacturing countries of the world. On the other hand, our results also cast doubt on the validity of R. E. Slesinger's statement that "by this measurement [production data for one year] U.S. producers were technologically ahead of—not behind—European producers" [5, p. 153]. In addition, our data show that A&D have little statistical support for their assertion that "... the oxygen process began to be introduced in U.S. steel mills at a significant rate only after the im-

FIGURE 1. INSTALLED LD CAPACITY, 1957-65

port threat became serious" [1, p. 647; and again 2, p. 163] and that European mills were at least five years ahead in recognizing the economic advantages of the process. As a matter of fact, the introduction of the process occurred at an almost equal rate in Western Europe and the United States. While A&D are willing to make allowances for the technological difficulties some European countries had (revolving largely around the chemical composition of available iron ore resources), they see no extenuating circumstances, in terms of technological adaptation, in the case of U.S. industry.

G. A. Hone and D. S. Schoenbrod reach a position which appears most ten-

able on the basis of the available evidence: "Adams and Dirlam are misled in their view that oxygen conversion was adopted sufficiently more quickly by competing foreign steel firms so as to give them a significant price advantage" [4, p. 159]. But even they refer to Europe only and use rather sketchy capacity data which, by themselves, tell little about the competitive impact of the new technology.

Since the controversy centers largely upon the *rate* at which the LD process was adopted in the major steel-producing areas of the world, it is surprising that all the participants in the discussion restrict themselves to citing capacity or production figures for some selected years to support their positions. It would appear that only an examination of relevant data for the whole period could give some insights into the actual changes.

As a first step in assessing the rate of adoption of the new technology, Figure 1 shows the installed LD capacity in the United States, Western Europe, and Japan, from 1957 on. Before that year, there existed only two installations of LD converters in Austria (VOEST Linz and Donawitz), one in Canada (Dominion Foundries and Steel, Ltd.), one in France (Société des Aciéries de Pompey), and one in the United States (McLouth Steel Co.). Since the first Austrian oxygen furnace went into commercial operation in 1952, one can only conclude that all countries were equally slow in availing themselves of the new technology's benefits, if indeed one assumes that a five- to eight-year lag represents "slowness" in the case of an innovation requiring major pilot testing and large financial commitments. Professor Herbert Trenkler, one of the main contributors to the development of the process, commented on the early attitude of steel manufacturers in general very much in the terms which A&D now apply to U.S. firms only: "During that period the world's experts just sat back to watch the results obtained by the first big plants" [6, p. 6].

From 1957 on, there is little difference in the growth rate of LD capacity in any of the three areas under consideration. Of course one may still argue that U.S. industry *should have been* the leader in the adoption of the new process, but there is no evidence that it lagged behind Western Europe and Japan. This point is further emphasized by the data of Table 1, which show the share of the United States in world LD capacity. We see that it was actually in the early 'sixties that this country's firms failed to keep full pace with the overall spread of the new process.

TABLE 1—U.S. LD CAPACITY AS PERCENT OF WORLD INSTALLED LD CAPACITY

A valid argument can be made that the true competitive impact of the new technology does not occur just at the margin (i.e., absolute "new" capacity figures do not measure competitive position), but should be viewed in terms of

the share of total steel output of each area produced by the LD process.³ Table 2 shows the production of steel by the oxygen process as a percentage of total steel production, for the years for which comparable data were available.

From these figures it can be seen that there was no substantial difference in the growth of LD shares in total production between the United States and Western Europe. In the case of Japan we find, not too surprisingly, that new LD capacity played a major role in the rapid growth of that country's steel industry. Whether this is sufficient "to put the issue in focus," as A&D claim [2, p. 163], must remain a value judgment. They cite no further evidence to show that the LD process per se rather than the fact that it was part of entire-

ly new integrated plants, gave the Japanese steel industry a major competitive edge. A&D are correct when they criticize Slesinger for establishing a dichotomy between the *annual* capacities of "large" open hearths and "small" oxygen converters [2, p. 161]. On the other hand, the more frequent batches of output resulting from the much shorter heat times of the LD furnace do require major modifications in the supply of hot metal as well as in the production process following the ingot stage. This is but one example of the technological adjustments required for the successful introduction of the process. One may surmise that any industry that has more than doubled its output in a six-year span would be in a better position to take advantage of the new technology's inherent economies than one that has to build the new process into an existing physical production system.

³The use of percentage-of-capacity figures as a measure of competitive strength seems difficult to support. After all, what matters is not how much capacity an industry has available in a given year, but what proportion of its actual output was produced by the newer, less costly, process. Since A&D show that there existed unused capacity in all three areas during the period under discussion [1, p. 627], production data should clearly yield a more accurate measure. It seems safe to assume that the most economical capacity was kept on stream whenever there existed a choice of leaving some equipment idle.

To sum up: There is no statistical evidence of a major lag in the construction of LD capacity in the United States, compared with Western Europe and Japan. The European and U.S. steel industries also produce approximately the same share of their total output by the new process, while Japan has based the rapid expansion of its steel production largely upon new plants built around the requirements of the oxygen furnace. If one wishes to argue that a slow rate of technological progress had contributed to the competitive difficulties of the U.S. industry, one has to do so on some basis other than the history of the LD process.

Steel Imports and Vertical Oligopoly Power: Reply

Rosegger comments on two of our recent articles—the first dealing with steel imports and vertical oligopoly power [1], the second with the inventive and innovative performance of the U.S. steel giants [3].

In the first article [1], we described the catatonic price policy of a vertical oligopoly in the face of burgeoning imports. We showed that the steel giants were so intent on preserving their vertical price structure that they preferred to abandon certain markets rather than meet the importers' price cuts. We noted that their nonprice reaction to the import threat consisted of a technological and political counterattack. Rosegger seems to forget that we treated technological innovation, i.e., the growth of oxygen steelmaking and continuous casting, as a *response* to, not as *cause* of, the competitive challenge of imports [1, pp. 646-47].

In the second article [3], we tested the "Schumpeterian" hypothesis and showed that, in introducing the oxygen converter, the U.S. steel giants lagged behind their smaller domestic rivals as well as their foreign competitors. The LD converter—the "only major breakthrough at the ingot level since before the turn of the century" [3, p. 175]—was invented by a miniscule Austrian firm in 1950, and first installed in Europe in 1952, Canada in 1953, and the

United States in 1954. The U.S. innovator was McLouth Steel, a firm which accounted for roughly one per cent of domestic steel capacity. The Big Three did not follow its lead until a decade later—U.S. Steel in December 1963, Bethlehem in 1964, and Republic in 1965. To the extent that the domestic steel industry kept pace with its foreign counterparts at all, this was largely attributable to the innovative propensity of the smaller firms. (For the distribution of oxygen steel capacity by size of U.S. producers, see [3, p. 183].) Rosegger is strangely silent on this point.

International comparisons are hardly more flattering to the giant-dominated domestic industry. ECSC-plus-Austria consistently *produced* larger absolute tonnages of oxygen steel than the United States till 1962, and larger relative tonnages until the end of 1965. Japan's oxygen steel production exceeded that of the United States in absolute terms starting in 1961, and in relative terms starting in 1958. As late as 1965, oxygen steel output in the United States was still a smaller proportion of total crude steel production than in such major producing nations as ECSC, Austria, Japan, Australia, and South Africa [4, esp. Table 1]. Evidently, the United States still had not closed the gap. As for the installation *rate* of LD *capacity*, purportedly portrayed in Rosegger's Figure 1, keep in mind that that the U.S. steel industry (in 1960) was 50 per cent larger than that of ECSC, 500 per cent larger than that of Japan, and 5,000 per cent larger than that of Austria!¹

The foregoing international comparisons, as we have repeatedly pointed out [2, p. 163; 3, p. 182; 4], are all the more remarkable because the new technology was immediately (1950) applicable to the low-phosphorus ores of North America, whereas most ECSC producers had to wait until 1957 before the LD process was modified to accommodate the high-phosphorus ores traditionally used in their steel industries.

Finally, as we have demonstrated elsewhere, [2] [4], it is doubtful whether technological feasibility of the new process was a significant bar to innovation by the steel giants, or whether it can explain their decision to install some 40 million tons of the "wrong" (i.e., open-hearth) capacity during the 1950's—capacity which was obsolete almost as soon as it was put in place [5]. That the U.S. steel giants lagged in innovation behind their smaller rivals at home and their Lilliputian competitors abroad is an indisputable fact. The explanation for this lag may be debated *ad infinitum*—unless, of course, one is prepared to accept our quite modest hypothesis that America's steel oligopolists are slothful innovators.

University of Rhode Island*

WALTER ADAMS AND JOEL B. DIRLAM

¹ It is curious that Rosegger criticizes others for using "selected years to support their positions" but does not explain his selection of 1957 as a baseline date for his international comparisons. After all, the Austrians had *installed* their first converter fully *five* years earlier.

A New Approach to International Liquidity: Comment

In a recent issue of this *Review* Professor Tibor Scitovsky proposes a "functional approach" to international finance [1]. According to this approach a country is to maintain "the kind of balance of payments that best serves its domestic goals" rather than an equilibrium in the balance of payments for its own sake. It is a credit to his ingenuity that once his scheme is adopted, the level of unemployment will decrease, international liquidity will increase, and at the same time developing countries of the world will receive unrequited assistance.

The gist of this scheme is to allow the deficit country to obtain exchange reserves from a reformed International Monetary Fund with goods and services produced in the country. The surplus country will eventually hold these newly created reserves, and developing countries will receive the additional products. A problem arises, however, as to the size of exchange reserves to be given to the deficit country in exchange for the products. Professor Scitovsky proposes that the new reserves created should be equal to the value of the products to be transferred to developing countries. It will be shown in this note that if this proposal is adopted it is most likely that the deficit country will be continuously in deficit, the creation of new reserves being always short of the deficit in the balance of payments.

Suppose a country has an initial deficit of D_t^* , where $D_t^* = M_t^* - X_t^*$, and M_t^* and X_t^* are the imports and exports of the country in period t . It is getting new reserves by producing additional output (T_t^*), which are equal to the value of this output. There is, however, an additional increase in the output of the country (ΔY_t) due to the multiplier effect of the autonomous increase in the aggregate demand by T_t^* . Then, given a positive value of the marginal propensity to import (m), the increase in imports,

$$\begin{aligned}\Delta M_t &= m \cdot \Delta Y_t, \\ &= (m \cdot \pi) \cdot T_t^*,\end{aligned}$$

where π is the income multiplier. Then, the post-transfer imports,

$$M_t = M_t^* + \Delta M_t.$$

Now, since the transfer of the output is equal to the pre-transfer deficit, D_t^* ,

there will still remain a deficit which is due to the increase in imports and which cannot be financed with the newly created reserves. That is, when the transfer has been made, the post-transfer deficit,

$$\begin{aligned} D_t &= M_t - X_t^*, \\ &= D_t^* + \Delta M_t. \end{aligned}$$

Obviously, given the value of T_t^* , the value of ΔM_t depends on $(m \cdot \pi)$.

For most countries the value of $(m \cdot \pi)$ would be greater than zero but less than one. They would, therefore, find themselves short of reserves even after the receipt of the new reserves, which are equal to D_t^* . One simple solution of this problem seems to be to give the deficit country new reserves which are greater than the transfer of the output and sufficient to cover the post-transfer deficit.

Reply

I am glad that Professor Lee caught and pointed out my omission to take into account the multiplier effects created by the deficit country's producing the goods with which it pays for its new reserves. These effects are another important reason for including the payment for the new reserves in the recipient country's government budget. The simplest case is that where the new reserves are paid for out of taxes. Then the value of the multiplier is unity, the additional repercussions on the balance of payments Lee is concerned with are absent, and my original argument is unchanged.

TIBOR SCITOVSKY

National Debt in a Neoclassical Growth Model: Comment

In a recent article in this *Review*, P. A. Diamond produced a competitive model which concluded that the utilities of some generations are altered by converting part of the national debt from internally held debt to externally held debt [2]. In Diamond's model a flotation abroad (rather than at home) of a given amount of national debt means an equivalent importation of real capital. This extra capital increases wages and decreases interest rates, thereby currently benefiting the younger, working class at the expense of the retired capitalists.

Our critique of Diamond's model of externally held debt concerns the basic

premise above—namely, that a flotation of debt abroad means an importation of real capital. Before developing the critique, we shall attempt an economic explanation of Diamond's complete set of qualitative conclusions regarding the exportation of national debt. This should illustrate that Diamond's results flow quite naturally from his basic premise and should provide an indirect check on many of the technical manipulations contained in his paper.

1. *An Economic Explanation of Diamond's Conclusions*

Diamond assumes that an export of national debt is not merely a temporary, one-period movement but continues on into the next period; therefore, the members of the current younger generation, who gain a wage increase via the current capital import, will suffer an interest rate drop in the next period when they become retired capitalists. More specifically, Diamond, who analyzes only steady states, assumes that total externally held debt expands at the same rate as the total population. Consequently, the current younger generation, during its retirement, will lose interest equal in total value to the wage bill increase it receives via the current debt exports multiplied by one plus the rate of population growth (thereby keeping wage rates constant over time). This future loss to the members of the current younger generation must be discounted (by multiplying it by the reciprocal of one plus the rate of interest) to compute its present cost to this generation. Therefore, whenever the rate of interest exceeds the rate of population growth, the debt export provides a component of net gain to the current younger generation and all future generations. The current older generation loses.

If intramarginal debt exports exist, further effects of this debt-export policy emerge. Diamond assumes in the text of his paper that the world rate of interest always adjusts to the domestic rate of interest. So an additional debt export—and therefore capital import—benefits everyone in the country via the reduction in the interest rate and therefore the taxes necessary to service the intramarginal exports of national debt. Diamond adds these positive effects of a debt export to the effects described above, so that whenever intramarginal debt exports exist, even when the rate of interest is somewhat below the rate of population growth, the existing younger generation and all future generations will gain from a debt export policy. Diamond drops his assumption that the world rate of interest adjusts to the domestic rate of interest in the first paragraph of his Appendix B. In the plausible case in which the world interest rate increases with the exportation of debt, all generations in the country *suffer* from an additional debt export through the interest increase on the intramarginal debt exports. In this case, the existing younger generation and all future generations may be hurt by the debt export even when the rate of interest exceeds the rate of population growth.

The above discussion contains all of Diamond's qualitative conclusions regarding the effects of an exportation of existing national debt. Therefore, *given* Diamond's basic assumption that an exportation of existing national debt means an equivalent importation of real capital, all of his conclusions regarding the effects of an exportation of national debt are consonant with standard economic analysis.

2. *The Critique*

If an exportation of national debt from country A to country B were to mean an increase in the real capital used in country A, there would be an *increase* in the return to capital in country B as well as a decrease in the return to capital in country A. An importation of real capital would thus disequilibrate the international market for real capital, a market which is in equilibrium only when the rates of return in the different countries bear a given relation to one another. Ignoring transportation and transaction costs, this market would re-equilibrate by an exportation of originally imported real capital, leaving the exportation of national debt with no effect whatever upon the allocation of *real* resources.

Even if transportation and transaction costs did exist (they apparently do not in Diamond's model), they could be ignored as long as the disequilibrium which would result from a movement of real capital to country A is foreseen; for then this capital import would not have occurred in the first place. The exporters of domestic national debt in country A would have preferred to take a perfect substitute such as a debt instrument rather than an imperfect substitute such as real capital whose return decreases with its importation; and the importers of foreign national debt in country B would have preferred to give up a perfect substitute such as a debt instrument rather than an imperfect substitute such as real capital whose return increases with its exportation.¹

Hence, the government's exportation of its national debt, its flotation of national debt abroad rather than at home, has *no effect* upon any equilibrium interest or wage rates and *no effect* upon the utility of any generation.

The incompleteness of Diamond's international market for real capital is the basic source of his strange mathematical result that a change in the political allegiance or location of the holders of the national debt alters the allocation of real resources in a perfectly competitive model. Diamond's model does contain a supply curve of real capital imports in his Appendix B, but it completely ignores the demand side. So the model fails to equate the quantity supplied with a quantity demanded in the market for real capital imports. The only economically logical interpretation of Diamond's model is that the demand curve for capital imports coincides with the supply curve; but this would yield an indeterminate equilibrium (and also is inconsistent with his assumption of a diminishing marginal product of capital).

Therefore, Diamond's analysis of externally held debt, an analysis based upon an international flow of real capital, is inconsistent with the existence of an equilibrating international market for real capital.

This critique is by no means a denial of the politically important classical orthodoxy that internally held debt is a debt which a country owes to itself while externally held debt is a debt which one country owes to another. The differing distribution effects of unanticipated repudiations of debt (which may

¹ Of course, the government could succeed in importing real capital by incurring transportation or transaction costs which the free market deems to be overly expensive or, more generally, by subsidizing capital imports; but then the capital import would be attributable entirely to the government's expenditure or subsidy policy, and not at all to the exportation of the country's national debt.

arise in nonperfectly competitive worlds) are of obvious political importance to a country. Nor is it a denial of the relevance of the international capital market in helping to determine the final economic effects of a change in the *total* national debt. Clearly, the smaller the elasticity of supply of external capital, the larger the change in the domestic interest rate resulting from a given expansion in the *total* national debt. But it is a denial of that part of the "new orthodoxy" which claims that the *economic* effects of externally floated debt differ from the *economic* effects of internally floated debt.²

EARL A. THOMPSON*

*The author is assistant professor of economics at the University of California, Los Angeles. He is indebted to a colleague Michael Intriligator for several helpful discussions regarding this comment.

² A critique of this part of the "new orthodoxy" for the special case in which the marginal product of the imported resources is constant has been produced by Buchanan [1].

BOOK REVIEWS

General Economics; Methodology

New Dimensions of Political Economy. By WALTER W. HELLER. Cambridge: Harvard University Press, 1966. Pp. xii, 203. \$3.50.

National Economic Policy. By JAMES TOBIN. New Haven and London: Yale University Press, 1966. Pp. x, 211. \$5.00; paper, \$1.75.

The ideas grouped together under the label of the New Economics no doubt owe much to Keynes. But there is an essential difference, rightly emphasized by Walter W. Heller in his *New Dimensions of Political Economy*, between economic ideas that make convincing reading in a principles text and ideas that "work"—gain support, get adopted, bring about results. The forging of a durable link between the doctrines of the fiscal activists of the forties and fifties and the policies advocated and put into practice by the new economists of the sixties is the great achievement of the New Economics. This achievement, described by Heller as "translation, adaptation, and innovation," is the subject of these two books.

Heller's *New Dimensions*, an expanded form of his Godkin Lectures of 1966, contains three inter-related essays. The first, "Advice and Consensus in Economic Policy Making," is devoted to the new role of economists. Heller traces out the changes in the environment of public policy making and the progress in economic thinking that together have ushered in the Age of the Economist. It is no exaggeration to say, as Heller does, that "Economics has come of age in the 1960s. Two Presidents have recognized and drawn on modern economics as a source of national strength and Presidential power. Their willingness to use, for the first time, the full range of modern economic tools underlies the unbroken U.S. expansion since 1961" (p. 1). If anything, this may be an understatement, since it neglects the increasing use of economics or in Washington parlance, Hitchcraft, in the management of the vast enterprises of federal, state, and local governments. But the increasing role of economics in the management of government enterprise only serves to reinforce Heller's argument.

Heller provides a definitive inside account of the role of the Council of Economic Advisers in the Kennedy and Johnson administrations. In the wake of the vast success of the Council under Heller's chairmanship, many proposals have been made to expand the scope of its activities. In Heller's view the strength of the Council lies in its immediate access to the President and in the absence of conflicting responsibilities. He is skeptical of most of the proposed changes, favoring informality, flexibility, and fluidity in the Council's relationships within the Executive Office.

The second essay, "The Promise of Modern Economic Policy," presents the central doctrines of the New Economics. Omitting the qualifications supplied by Heller, the basic ideas are these: The goals of economic policy are 4 per cent unemployment, a rate of growth of real output of $4\frac{1}{2}$ per cent, price stability, and balance-of-payments equilibrium. The current state of

fiscal policy is measured by the full employment surplus, the federal budgetary surplus as measured in the national income accounts that would prevail at full employment of present labor force and capacity. If actual output falls short of potential output, the full employment surplus should be decreased; if pressure on capacity becomes too great, the full employment surplus should be increased.

Up to this point the New Economics is recognizable as orthodox Keynesianism, advocated by Hansen and Keynes and taught by Samuelson. However, the concept of full employment surplus provides an essential link between theoretical and practical analysis of fiscal policy. Even a federal budget substantially in deficit at less than full employment may not provide sufficient stimulus. The degree of stimulus is measured not by the size of the current deficit but by the size of the surplus that would prevail at full employment. A second level of sophistication is introduced through the concept of fiscal drag, defined by Heller as "the automatic growth in potential revenue arising out of growth in potential GNP" (p. 181). Since tax receipts expand more than in proportion to GNP, the political economist is fighting a continuing battle with fiscal drag in the form of a \$7 to \$8 billion dollar annual increase in revenues over automatic increases in transfer payments. In designing fiscal policy provision must be made for a fiscal dividend in the amount of \$7 or \$8 billions in greater expenditures and reduced taxes each year in addition to any reduction in taxes or increase in expenditures necessary to stimulate the economy to higher levels of performance.

The theory of fiscal policy just outlined may sound like Keynes, but it will be helpful to the less than omniscient student to learn that the dynamic character of the analysis adds a new dimension to the Keynesian discussion of fiscal policy. The conventional Keynesian prescription of balance over the cycle with surpluses in good years and deficits in bad as well as the objective of orthodox fiscal policy, a balanced budget at all times, is replaced by balance at full employment, a perpetually moving target. Intellectually, this change in perspective may be translation and adaptation; it represents a remarkable innovation from the point of view of practical economic policy.

Heller documents the course of the political and practical success of the New Economics, beginning with the fight against a tax increase in 1961 during the Berlin buildup, culminating in the great tax cut of 1964, and continuing with the excise tax cuts of 1965. He answers critics on the right by pointing to five years of rapid growth without inflation. He deals with critics on the left by demonstrating that two-thirds of the fiscal dividend of \$48 billions between 1961 and 1965 was employed for increases in expenditures while only one-third took the form of tax reductions. He also reviews other aspects of Council policy, including the wage-price guideposts, and analyzes the economic policy of 1966, the first post-Heller year of the Johnson administration.

Heller's third essay, "Strengthening the Fiscal Base of Our Federalism," is devoted to the much-discussed Heller Plan for providing federal tax revenues to the states in the form of direct grants not tied to specific governmental functions. The Plan is to distribute 2 per cent of the federal personal income tax base or about 10 per cent of receipts from the personal income tax to the

states on a per capita basis. The justification for the Heller Plan is that the federal government has largely pre-empted the only tax that is growth-responsive (that has receipts increasing more rapidly than GNP), leaving the states with less responsive sales and property taxes. States on the other hand have responsibility for items of public expenditure that should be highly growth responsive, especially expenditures for health, education, and welfare. The Plan commits a sizeable portion of the annual fiscal dividend in advance, reducing the burden of fiscal drag.

James Tobin's collected essays on national economic policy, covering writing over the past fifteen years, provide an interesting perspective on the development of ideas about economic policy. Three essays written in the waning years of the Eisenhower administration, taken together with Heller's 1966 characterization of the New Economics, yield a before-and-after picture of the viewpoint of the leading new economists. Despite the rapid development of a consensus around the New Economics, important differences of opinion remain between the new economists and proponents of traditional views. Tobin confronts two of the critics, Milton Friedman and William McChesney Martin, in his essays, "Barry's Economic Crusade" and "Lessons of Monetary History."

Whereas Heller would allocate a substantial or even predominant part of the recurrent fiscal dividend to expenditures on federal, state, and local levels, the Friedman-Goldwater program (taken from statements by then-Senator Barry Goldwater during the 1964 Presidential campaign) was to use all or part of it for tax reductions. Of course, it should be borne in mind that the use of the whole dividend or even an increase of taxes to provide for more expenditures is an alternative view not without its advocates. The broad agreement about the underlying economic mechanism and the effects of alternative fiscal policies as characterized by the New Economics is reassuring.

Another fundamental disagreement between Friedman-Goldwater and the new economists is about the use of discretionary fiscal policy. Both Heller and Tobin advocate additional flexibility through the enactment of stand-by authority for short-term manipulation of tax policy by the President. The Friedman-Goldwater alternative is an "automatic" policy geared to long-run growth trends in the economy and, presumably, to similar "automation" of other instruments of economic policy such as the supply of money. Another outstanding policy issue is the management of monetary policy by the Federal Reserve and, more generally, the design of policies for the achievement of balance-of-payments equilibrium and price stability along with full employment and rapid growth. Neither of these issues is close to settlement; the rapid evolution of views on the objectives of fiscal policy suggests that the ultimate consensus is unlikely to bear much resemblance to the positions advanced as alternatives at the current, essentially academic, phase of the debate.

The enhanced role of economists has raised the quality of public discussion of economic policy and expanded the range of government policies brought under professional scrutiny. Tobin's final essay, "Academic Economics in Washington," touches on the implications for university training and research in economics. Prior to 1961 the formulation of economic ideas and their ad-

vocacy as practical measures of policy were about the most one could expect of the most political of economists. The situation was eloquently summarized in another context by Samuelson: "The promise is always in the future; we are like highly trained athletes who never run a race, and in consequence grow stale."¹ In the Age of the Economist all the available athletes have a busy schedule of real races to run. The implications of this experience for university economics are summarized by Tobin as follows:

I think that any academician who has had this experience will come away from it with two feelings about his own profession: confidence and humility. He will have confidence that analytical economics can make a valuable and distinctive contribution to policy; it can raise significantly the level of the considerations of logic and of fact which go into policy discussions and decisions. He will have humility because he will have noticed many instances where decisions had to be based on incomplete information, inadequate research, and hasty analysis. He will return to his university, then, with a new sense of research priorities and an enriched agenda of problems for himself, his colleagues, and his students (p. 206).

It is unnecessary to recommend that these books be made required reading. They will be read avidly by economists and noneconomists alike.

Guidelines, Informal Controls, and the Market Place: Policy Choices in a Full Employment Economy. Edited by GEORGE P. SHULTZ AND ROBERT Z. ALIBER. Chicago: The University of Chicago Press, 1966. Pp. xi, 357. \$5.00; paper, \$1.95.

This conference volume reflects the rising tide of criticism of the President's wage and price guideposts in practice, if not in theory, as of April 1966. This tide led to the abandonment of the magic 3.2 per cent annual guidepost in the January 1967 *Economic Report of the President*. Yet the volume is still timely reading, since the principle behind the guideposts is far from dead. To quote from the 1967 *Annual Report of the Council of Economic Advisers* (p. 128): "The Council recognizes that the recent rise in living costs makes it unlikely that most collective bargaining settlements in 1967 will fully conform to the trend increase of productivity . . . (but) . . . The only valid and noninflationary standard for wage advances is the productivity principle. If price stability is eventually to be restored and maintained in a high-employment U.S. economy, wage settlements must once again conform to that standard."

The volume consists of eight papers presented at a conference held at the University of Chicago in late April, 1966, together with formal comments and summaries of four group discussions, on the subject of guidelines and informal controls. Although the bulk of the proceedings is devoted to wage-price guideposts, two papers, by Harry G. Johnson and Allan H. Meltzer, consider the guidelines for direct investment and bank credits abroad. There is a useful introduction and summary by George P. Schultz and Robert Z. Aliber.

In the initial essay, Milton Friedman argues that price inflation is always

and everywhere the result of increases in the supply of money relative to output. He notes that inflation can be suppressed to some extent, but this is harmful since suppression prevents the price system from working effectively. He views the wage-price guideposts as undesirable, since they divert attention from fundamental causes, and spotty compliance distorts relative prices of factors and products.

In the following passage (p. 21), Friedman conditionally admits the possibility of cost-push: "Unless the cost-push produces a monetary expansion that would otherwise not have occurred, its effects will be limited to at most a temporary general price rise, accompanied by unemployment, and followed by a tendency toward declining prices elsewhere." In his address to the conference, Gardner Ackley develops the rationale of the guideposts on the basis of "excessive income claims" (p. 68). That is, he observes the tendency of powerful unions to obtain wage increases in excess of productivity increases, and of oligopolistic firms to increase their markups as demand rises, beyond a point still short of full employment of resources. It is within this band of inflationary cost pressures, short of full employment, that guideposts are intended to be effective by appealing to the sense of social responsibility of business and union executives who have some discretion in price and wage determination. He rejects the notion that government should not validate excessive income claims by restraining aggregate money demand at the cost of at least temporary unemployment. While defending the guideposts and their application against some of the criticisms, Ackley admits "many undesirable aspects," and challenges his fellow economists to produce superior alternatives. At that time, he was not ready to relinquish guideposts until superior alternatives were found.

A defense of guideposts was also provided by Robert Solow, in a lower key as indicated by the title of his paper, "The Case Against the Case Against the Guideposts." Like Ackley, Solow rejects the anti-inflationary policies that produce unemployed resources as too costly. He sees the guideposts offering a little help at low cost in their influence on individuals and organizations with market power who, he believes, are sensitive to public opinion. In effect, the guideposts seek to educate such decision-makers to imitate the effects of competition. He adduces George Perry's relationship between wage changes and related variables for the period 1948-1960 to demonstrate that wages between late 1962 and 1965 rose significantly less than would be expected, presumably as a result of application of the guideposts. Yet Solow is disturbed by their unevenness in operation.

Much sharper criticism is expressed in the other papers. John Dunlop, while recognizing the concerns that gave rise to guidepost policies, scores them as not commanding wide assent in part because labor and management representatives had no real part in their drafting; for not being expressed in meaningful, operational terms from the viewpoint of private decision-makers and public mediators and arbitrators; and as having an inequitable impact, with no procedures for review "or provision for due process." He further raises a number of analytical questions, and maintains that the Council is ill-equipped

to serve as an administrative agency, even of an informal character.

Arthur Ross seems inclined to admit the validity of the cost-push factor in price inflation, and reviews the experience of several European countries as well as the United States in devising and administering wage-price, or "incomes," policies. He views the policies as still experimental, and unsatisfactory in many ways, as implied in a long list of questions he raises. His very general conclusion is (p. 130): "It may be that the problem is insoluble so long as wage and price policies are tied so closely to a single criterion, the trend productivity rate; and that the appropriate terms of wage and price restraint will have to be redefined from time to time on the basis of intensive study of the entire economic situation. Such an examination might provide a format for intimate consultation among leaders of government, industry, and labor."

This reviewer wonders what happens to the intended anti-inflationary impact of guideposts when criteria in addition to productivity are admitted into the formula. One also wonders what the other criteria should be, especially in view of Ross' statement (p. 130): "Attaching a cost-of-living escalator clause to the guideposts, under circumstances like those of the present, would not only contribute to a wage-price spiral but also yield a target figure beyond the reach of all but the most powerful unions."

Philip B. Kurland reviews relevant constitutional history, and concludes that "the present means of wage and price controls is constitutionally suspect" (p. 239), as well as ineffective. If effective controls are to be applied, he favors congressional legislation, but recognizes the political difficulties of this course. In his comments, another lawyer, Frederick R. Livingston agrees that the guideposts have not been effective at the collective bargaining table, and that if reformulated, they should be given a legislative base. He sets three standards (p. 260): "(1) There should be a procedure for public hearings to determine the appropriate guideline or the range of such guidelines; (2) there should be legal safeguards to assure equal standards for application and equal protection of the laws; and (3) there should be procedures for hearings with appropriate due process safeguards."

The conference was not notably strong in producing suggestions for practical, effective alternatives to the guideposts. Friedman's implied solution was to limit increases in money supply to probable increases in supply capacity, even if these should not validate possible excessive income claims resulting at least temporarily in reduced real demand, and increased unemployment. This does not seem politically feasible in the present environment, although it is clear that monetary and fiscal policy should be consistent with, and support, wage-price policy. Solow's plug for strengthening competitive forces was admittedly a long-range approach. Dunlop advocated a massive assault on bottleneck areas, in which prices are rising rapidly, in order to increase supply capabilities and possibly to restrict demand increases. While put forth as an alternative to guideposts, Dunlop's proposals also seem primarily long-range.

The type of wage-price policy which Kurland and others would legislate was not spelled out. The reviews of foreign approaches would suggest the pos-

sibility of creating a board which would receive advance notice of intended increases in wages and prices, with the power to investigate and possibly to disapprove those judged excessive. Ross raised the possibility of a potent consultative mechanism, involving major interest groups, to seek periodic agreement on basic wage-policy. Doubt was expressed that such agreements would necessarily be in the best public interest. Occasional temporary wage (or wage-price) "pauses" was another European device for slowing-down inflation, which has not been used here in peacetime.

The problems discussed at the Chicago conference remain a challenge to the creative thinking of economists. There must be a better means, or combination of means, of restraining inflationary tendencies in fully employed free economies than any suggested so far. The important thing is that any new method which is tried should preserve the great advantages inherent in market-direction of resource use.

Price and Allocation Theory; Income and Employment Theory; Related Empirical Studies; History of Economic Thought

Planning for Steady Growth. By GAUTAM MATHUR. New York: Augustus M. Kelly, 1965. Pp. xiv, 386. \$12.50.

The dust cover informs that this book presents "a fresh approach to development planning," laying down "the principles of constructing the framework of a long term plan of economic growth." This description can be misleading. There is hardly anything in the book in the way of practical aid to those concerned with framing development plans. It is, actually, an essay on a particular model of economic growth (the von Neumann model), written, unmistakably, in the spirit of the theoretical literature associated most often with the name of Joan Robinson. Indeed, to a large extent the book is an elaboration of various topics originating from previous works of Mrs. Robinson, in particular *The Accumulation of Capital* and *Essays in the Theory of Economic Growth*. Gautam Mathur provides in this book some careful thoughts and useful insights on a number of very complicated subjects, such as the choice of optimum techniques of production and the effects of technical progress thereupon.

The reader should be warned that working through this book is not easy. The discussion is usually too lengthy, quasi-formal, extremely abstract and intricate. It is doubtful, frankly, whether the numerical examples spread here and there are of much help. Mathur's proclivity to decorate his discussion with aphorisms such as "Bastard Golden Ages," "Forward Platinum Ages," "Reverse Wicksell-Effect Spectrum" and many other happy labels put afloat by Mrs. Robinson, makes it all the more difficult.

In spite of these faults, the book is a valuable contribution to capital and growth theory in that it focuses on and clarifies the kind of theory that has developed in Cambridge (England) in contrast to the so-called "neoclassical orthodoxy." Most rewarding, when you read the book carefully enough to penetrate the invective and terminology you realize that, despite differences of emphasis and description, there are many connecting links between these two schools. Obviously, in equilibrium long-run growth, the Robinson-Mathur, von Neumann or any of the various neoclassical models exhibit very similar characteristics. It is true that Mrs. Robinson and other neo-Keynesians have been mainly concerned with non-Golden Age situations, dominated by bottlenecks in production, unemployment, inflationary pressures and other disequilibrium indicators. But even here some convergence is in sight. For example, Mathur's discussion on the possibility of temporary labor unemployment if the capital stock lacks the capacity to employ the entire labor force is very similar to the results derived by Solow, Johansen, and others in the recent vintage models with *ex post* fixed proportions.

As stated at the outset, the book is devoted to the problem of the choice of the optimum path of accumulation which minimizes the time for achieving the full-employment Golden Age path of steady balanced growth (the von Neumann path). Since attainment of the von Neumann path usually takes time, the "*minimum time objective*" implies that society does not discriminate between various transitional consumption paths of equal duration. A social goal function of this kind is open to many objections, although various "Turnpike Theorems" suggest that even with more general criteria there is a long-run tendency for the efficient path of economic growth to approximate the von Neumann path. Thus, given certain institutional restrictions on consumption, the implied policy may well be appropriate, particularly for an underdeveloped country. It is regrettable, nevertheless, that there is no discussion in the book of the Ramsey and more general optimum accumulation under welfare criteria that attach values to transitional consumption. Economists are now busily concerned with the solution of this general problem which carries both theoretical interest and practical relevance.

In the first three parts of the book, Mathur outlines the various constraints imposed on a development plan, describes in detail the von Neumann type technology, and sets up the conditions for long-run Golden Age equilibrium. He then goes on either to relax various equilibrium conditions or to introduce rigidities (such as a floor wage rate which poses an "inflation barrier"), and analyzes the possible courses that the economy can pursue. The analysis of these situations follows pretty much that of Mrs. Robinson in her Model of Accumulation, and there is no need to review it here.

It is proposed to concentrate in what follows on the discussion of the choice of techniques of production contained in Parts IV and V of the book. The basic problem is as follows. Neoclassical aggregative models assume that there is a fundamental relation between the rate of profit and the capital-output (or capital-labor) ratio, such that when the rate of profit falls a more capital intensive method of production is chosen and vice versa. The assumption is, pre-

sumably, that a decrease in the rate of profit reflects the increased importance of a more capital intensive industry in its contribution to the aggregate output. The neoclassical one-sector model with a fixed saving ratio is therefore more or less self-contradictory (since the proportion of the consumption good to the investment good is constant by assumption). The problem of the choice of techniques can thus be appropriately analyzed only with a multisectoral model. It is the disaggregated aspects of growth equilibrium that now appear to cast doubt on the above neoclassical postulate.

Following Mathur, consider a closed von Neumann model, in which each sector has available a finite number of alternative processes. Thus, the economy can choose one technique (i.e., a set of processes adopted by the various sectors) among a whole feasible spectrum of techniques. Given a rate of profit, a vector of equilibrium prices (in terms of wage units) can be computed for each technique. The technique which gives the lowest prices for all goods (i.e., the highest real wage) is then termed optimal for the specified rate of profit. The dual to this problem states that, if the rate of growth is equal to the rate of profit (a Golden Rule condition), then the technique that minimizes prices also provides the highest consumption per capita. Having found the optimal technique corresponding to each rate of profit, one can then find the direction of the change in the capital-output ratio (in value terms) as the rate of profit varies. It turns out that no a priori hypothesis about the direction of change of this ratio can be justified: for some stretch of changes in rate of profit the ratio may fall, for some other stretch it may rise. The possibility of such non-monotonic behavior had been well known to Wicksell, and has since been proved by various writers such as Morishima (whose work, surprisingly, is not cited by Mathur). It got additional support in the recent discussion of the "reswitching problem" (*Quart. Jour. Econ.*, November 1966). The recurrence of optimal techniques at different rates of profit, if nothing else, is a definite indication that the assumption of opposite movement of the rate of profit and the capital-output ratio cannot, in general, be accepted.

Thus, for movements from one steady state to another, no pure technological ordering of techniques, as by the capital-output ratio, is possible. A much more interesting problem now comes up: starting at a nonsteady state situation, what is a typical optimum path for an economy in terms of the techniques chosen at each step in the growth process? For example, would it ever be optimal for an economy to readopt a technique which has once been used but has been discarded later in favor of a "more mechanized" (to use the term of Mrs. Robinson) technique? If some techniques are incapable, given the available resources, of employing all the labor force, is it optimal to adopt immediately a technique which provides employment to all, even if this occurs at the expense of a smaller output at the first stages of development? Or maybe the economy should adopt immediately the technique that will ultimately be optimal in Golden Age equilibrium and disregard any short-run considerations? These are very complicated problems and Mathur has made a brave effort to suggest possible solutions. This reviewer found his discussion of "strategy dams," "strategy corn" or "strategy tractors" very suggestive, but this method of analysis simply can not provide complete and rigorous answers.

A question such as under what conditions it is optimal to satisfy the terminal conditions with exact equalities rather than overfulfillment of the desired goals (whether capital can be costlessly discarded or not) can be solved only by dynamic programming methods of the kind used recently by T. N. Srinivasan, M. Kurz, D. Cass, and others.

Part VI of the book deals with the effects of neutral and biased technical progress on the choice of techniques. Economic obsolescence of capital equipment due to technical progress is introduced (The Upgrading Model) in a fashion reminiscent of the neoclassical vintage models. The book concludes with a disconnected mathematical appendix and some notes attacking neoclassicism "and all that."

I would like to comment finally that Mathur devotes little space to the price relations implicit in his model nor does he consider seriously the question of whether his planned economy could, partly at least, make use of a market system.

EYTAN SHESHINSKI

Harvard University

The Wage-Price-Productivity Nexus. By RONALD G. BODKIN. Philadelphia: University of Pennsylvania Press, 1966. Pp. 302. \$8.00.

In the midst of affluence we often find great poverty. The publication in book form of Ph.D. theses is a good case in point. Certainly the quality of dissertations has risen greatly in recent years. But the plethora of immature books spawned by the publishing revolution and the "publish or perish" syndrome can only be lamented by a profession already hard-pressed by an ever increasing avalanche of "scholarly" journals. Good theses, like Bodkin's, might make good articles, but they are not necessarily good books.

Typically, the slightly expanded and revised Ph.D. thesis book begins with a more or less extensive, but disorganized, and nonpenetrating review of the literature. The cacogenesis then moves on to a scanty theoretical model which is manipulated to produce a few interesting artifacts. If the study is an exercise in theory, subsequent chapters torture the model even further. If it is empirically oriented, the model is simplified and modified under the duress of a barrage of data and statistical findings. In either case, the final product bears little relationship to the earlier rationale. And to complete the anamorphosis, few individuals, in today's policy oriented climate, can resist the temptation to draw some unsupported conclusions for government action.

So much for the generalities. Now let us turn to the particulars. Bodkin's *Nexus* begins with a jumbled survey of post-1950-pre-1963 literature on the wage-price-productivity subject. Chapter 2 is a reprint of his *Metroeconomica* (Volume XV, No. 2) article with R. J. Ball. It describes a static income and price determination model with much emphasis (later ignored) on the role of the money supply, real balance effects, and the degree of monopoly power existing in the economy. Money wage rates here are a function of the levels of *employment* and consumer prices.

In Chapters 3 and 4, Bodkin develops and estimates a wage adjustment equation. Initially, the annual change in money wage rates (dollars per hour)

over the preceding year at time t are hypothesized to depend linearly on the number of *unemployed* (thousands of men) in year t and the absolute difference in the consumer price index between year t and $t - 1$. Absolute levels are used because preliminary runs (estimated for 1900-57) in percentage form had lower explained variances. Lags on the independent variables were determined by cross correlogram type analyses (sometimes from plots of the series). Even in the absolute form, the coefficient on unemployment only became significantly negative when a time trend variable was added. Bodkin justifies the latter's inclusion on two grounds: (1) either as a statistical consequence arising from stating the dependent variable in absolute rather than percentage terms; or (2) as a representation of wage push "as could occur from a growth in the membership and power of trade unions."

Some other ideas were tried. The first difference in unemployment, the ratio of corporate profits to net worth, a split of the consumer price index into positive and negative components (a weak test of irreversibility), and the change in output per manhour all were introduced, singly or in combination, as additional explanatory variables. None was successful; either they were not statistically significant themselves or they were collinear with other terms (especially unemployment).

Price equations were then estimated (on annual data, 1914-57) in similar fashion (in Chapter 4). The level of the wholesale price index for finished goods, after a series of bivariate tests, was made a linear function of manufacturing wage costs per constant dollar of output, the wholesale price index of crude materials for further processing, a time trend (which "may reflect savings in raw materials"), the percentage deviation of real output from its moving average (a proxy for "excess demand") and two dummies to correct for 1943-46 and 1951-53 wartime conditions—all variables were for the current year. An attempt was made to test irreversibility of price changes by splitting the demand term and including a previous peak unit labor cost or wage rate variable. Only the last was statistically significant after the equations were re-estimated using an Orcutt transformation (with assumed alternative values of ρ) to reduce serial correlation of residuals. Bodkin interprets his results as an affirmation of "the view that demand factors are of secondary importance in the determination of the level of final prices [which] has also been supported in studies by Dow, Yordon, Yance, Dicks-Mireaux, and Kuh."

Chapter 6 of the volume goes on to a shallow analysis of the average productivity of labor, (A), defined as the real gross output of the private domestic economy divided by total manhours of labor input. The annual rate of growth of this quantity (i.e., $\log A$) is related to time, the square of time (t^2) and the current rate of unemployment for 1900-57 data. The t^2 term is found not to be statistically significant after adjustment for autocorrelation of estimated residuals, thereby denying an acceleration of productivity growth. The unemployment variable is to represent cyclical productivity influences; several forms of an average weekly hours term were inserted as alternatives, but they gave inferior results. The chapter closes with a presentation of two-stage least squares estimates of the earlier equations, treating them as an endogenous system, with time and the war dummies as exogenous. The first

stage regressions use 10 additional exogenous variables. Not surprisingly, the standard errors of a number of the coefficients rise sufficiently to cast doubt on their statistical significance.

Some further reservations are given by Bodkin in the succeeding chapter where he draws heavily on the arguments of other writers who aver that inflation is an aggregation phenomenon. The principal strand is that of Charles Schultze's U.S. Joint Economic Committee study paper (1959), wherein inflation is caused primarily by price ratchets and demand asymmetries. Following Lipsey, a similar rationale is applied to labor markets. But this is immediately rejected by Bodkin on the grounds that his own wage-unemployment function is linear and Lipsey's nonlinear model is relatively untested. Bodkin goes on to hypothesize that the apparent nonlinearities are due to expectations of future tightness or looseness in labor market conditions. This and the sectoral phenomena then lead him to propose a "guideposts" policy very nearly identical to that expounded by the Council of Economic Advisers in its 1962 report (Bodkin says he first wrote this conclusion in 1961).

The final chapter contains a summary of earlier conclusions and a linear tradeoff relationship between the rate of change of prices and the level of unemployment. Bodkin finds, depending upon the wage function and method of estimation selected (single equation or two-stage least squares), that a 3 per cent "frictional" rate of unemployment in 1960 would lead to a predicted rate of increase of the price level of between 1 and 2 per cent. Alternatively, the rate of unemployment "required" for price level stability (i.e., $\Delta p = 0$) is 18.8 per cent.

In contrast, George L. Perry's recent study (*Unemployment, Money Wage Rates and Inflation*, Cambridge, 1966), with equations fitted to U.S. postwar quarterly data (1949: 1-1960:3), estimates that with 1960 $\Delta p = 0$ and a profit rate on stockholders' equity of 10 per cent, the rate of unemployment would be about 5 per cent. Perry's analysis is cast in percentage form, includes level and change in rate of profits variables, and has the *rate* of unemployment entering in nonlinear fashion.

Bodkin's study must be faulted on several grounds. First, it cannot be presumed that the structure of the economy remained unchanged from 1900 through 1957. While the included time trend variables also may capture the evolving structural change, they should not cavalierly be accepted and rationalized on other a priori grounds. At a minimum, an analysis of covariance (Chow test) splitting the period into subintervals would have been in order. Second, a sounder basis should have been given for the forms of the equations and the inclusion and exclusion of variables. What was done smacks too much of a "fishing" expedition to maximize explained variance. One would like an a priori profit and utility maximization model, constraints, and expected coefficient magnitudes more soundly grounded in fundamental theory. Third, since Bodkin himself raises the issue of disaggregation, at a minimum, wage and price behavior should have been analyzed for a number of industry divisions.

Bodkin's own modest view is that "The present author is satisfied if this work serves to advance, in some small degree, our understanding of wage and price

level relationships." It does that—but the contribution is small. Nevertheless, it should be surveyed by specialists working in the area and those with a general interest in the subject.

GARY FROMM

Brookings Institution

Theories of Economic Development and Growth. By Y. S. BRENNER. New York: Frederick A. Praeger, 1966. Pp. viii, 285. \$7.50.

In this volume the author purports to summarize all theories of development and growth at an elementary level of discussion, the topics ranging from the ancient Mercantilists and Physiocrats to modern growth theory. In addition he discusses some aspects of Soviet planning, as well as the "stage" theory of economic development. The volume is divided into broad, chronologically ordered sections dealing with the early and classical theories, the Marxian and neoclassical theories, modern and stage theories, Soviet planning, and development theories of underdeveloped economies.

In the first half of the volume, the author examines and summarizes the contributions of the following economists to the theory of growth: Adam Smith, Ricardo, Malthus, John Stuart Mill, Marx, Engels, Jevons, Menger, Edgeworth, Marshall, J. Clark, Walras, Pareto, Wicksteed, Irving Fisher, Wicksell and Pigou, in that order. The presentation of material is so organized that a good portion consists of direct quotations from the past economic classics. The reviewer feels that the volume is a brief summary of a course in the History of Economic Thought related to theories of development and growth, rather than *Theories of Economic Development and Growth*. This is particularly true in the discussion of neoclassical theories where a good portion of material is not "directly" related to the theory of development and growth. Nevertheless, these sections may prove to be useful to some economists whose primary interest is to acquaint themselves with the history of thought as related to economic growth.

The chapter devoted to contemporary theory is rather brief, considering the voluminous literature written in this field since the contributions of Harrod and Domar. The author discusses at great length the rudiments of the Harrod-Domar model. But the presentation is neither simpler nor clearer than the original articles of Harrod and Domar. The discussion of the neoclassical growth model is incredibly brief and ambiguous. For example, in discussing Solow's model, the author states, "Professor Solow developed a neoclassical system which may well be called an input adjustment model. To the familiar Keynesian accelerator he added two further assumptions which give the system a greater flexibility. First he assumed that at each point of time all labour and capital was [sic] readily available 'on the market' so to say, and secondly, that profits and wage rates are adjusting themselves automatically and without time interval. In other words he introduced a 'cost mechanism' which automatically adjusts labour and capital costs in a way which produced a capital output ratio to suit equilibrium growth requirement" (p. 190). The above quotation is the entire specification of Solow's model. Obviously, given a sufficiently fuzzy specification of the model any conclusions are possible. Aside

from its general ambiguity, another fault of the book is that nowhere can one find a reference to the problem of stability, nor is there any discussion of steady state and golden-rule paths.

Under the heading of "The Soviet Theories" the author gives a history of Soviet planning. Though interesting, no theoretical discussion of Soviet planning is made.

In the final section the book deals with growth problems of underdeveloped economies. The author points out numerous difficulties characterizing the growth problems of underdeveloped countries, and also suggests a few factors conducive to their development. But essentially no new idea is proposed.

In sum, the strength of the book lies in the first half of the volume, where the author presents a well-organized (though brief) summary of the history of economic thought related to economic growth.

Planning Without Facts. By WOLFGANG F. STOLPER. Cambridge: Harvard University Press, 1966. Pp. xx, 348. \$7.95.

Development Planning in East Africa. By PAUL G. CLARK. Nairobi: East African Publishing House, 1965. Pp. vi, 154. \$3.00; 16s. East Africa.

The keynote of both these studies is operational feasibility. Each author is a clear eyed economic theorist, applying modern tools of analysis to economic development problems. Each worked in a country going through the early stages of reorganizing its economic activity to produce higher incomes. Both studies show how rough estimates for aggregate economic variables can be used to improve the complex decisions involved in managing scarce resources wisely.

One basic issue in economic development is whether the scanty data available are meaningful, and, *a fortiori*, whether the data appearing in a development plan can be anything more than wild guesses. Skepticism here reflects deeper questions concerning the sources of development initiative, the factors that alter economic performance, and the most effective ways to promote development-inducing uses of scarce resources. As a skeptical realist, Stolper makes a major contribution to informed reflection on these matters. In more compact form, the statistics and discussion in Clark's monograph provide further practical evidence of what careful analysis can achieve. Both studies should be on every planner's bookshelf.

Stolper uses his experience during 1960-1962 in Nigeria, where he helped prepare the 1962-68 national plan, as a basis for wide-ranging reflections. The facts that are denied a planner, in countries like Nigeria, are technological and social, relating to the speed and extent of changes actually or potentially under way around him. Stolper argues, first of all, that the planner should study intensively his unique surroundings, being wary of applying foreign

analogies or empty universals. He argues, secondly, that development planning should be shaped from the present a short way into the future, with frequent revisions, rather than being shaped from a future vision backward to the current scene. He calls this approach "optimizing as one goes along" (p. 4). A third precept of "planning without facts" is that the very lack of adequate technological and social knowledge means that decision-making should be decentralized, since only those in close touch with fragmentary evidence can evaluate it accurately.

Another major theme in Stolper's analysis is the great importance of choosing profitable investments and avoiding unprofitable ones. Profitable investments made now will generate new output from which added investments can be made later. If aggregate current realizable "social profitability" falls far short of "economic profitability," there will be a large current drain on the recurring budget. Similarly, Stolper argues that market-clearing prices for the use of scarce resources should be charged now, in order to ration their use. "The application of shadow prices leads to the substitution of one problem, the budget, for another one, an imperfect market" (p. 195).

The eight chapters of Stolper's book are preceded by Chief S. O. Adebó's thoughtful foreword and a modest author's preface. Chapter 1 outlines a conceptual framework and Chapter 2 sets forth the Nigerian background. The "general view of planning" presented in Chapter 3 shows how the need for operational feasibility constrains a planner's efforts. In further detail, Chapters 4 through 7 discuss national accounting, investment criteria, monetary problems, and government-business relations "from a planning standpoint." The 13-page concluding chapter is an eloquent plea that the tensions of rapid change not be made worse by plans that misuse resources and coerce the people. A 15-page appendix sets forth an input-output table for Nigeria in 1959-60, together with a few derived structural tables, the work of Nicholas G. Carter.

Clark's monograph is directed to government officials, private leaders, and university students in East Africa, all of whom are affected by (and many of whom will help to guide) the economize development programs of their countries. Because his study summarizes valuable empirical evidence for three economies, organized within a quantitative model, it will also provide valuable comparative evidence for development planners and advanced students everywhere. Chapter 1 is a brief essay describing the elements of comprehensive planning. Chapters 2 and 3 describe economic trends in Uganda, Tanzania, and Kenya, and outline their earlier economic plans. In Chapter 4, Clark presents a macroeconomic model covering six producing sectors, seven kinds of imports, two classes of exports, four forms of capital formation, four kinds of government taxes, and certain other variables appropriate to these three economies. In its structural relationships, the model contains five autonomous variables: the quantity of agricultural exports, the prices of those exports, the value of manufactured exports, import substitution in manufactured products, and central government current expenditures. The parameters of the model have base-period values which are pragmatically reconsidered when projections to a future period are made. In Chapter 5, the author uses the model to

show the implications of two projections for Uganda in 1981, one "moderate" and the other "ambitious." The same quantitative framework, fitted with different values, is used to explore the implications of 1970 targets for Kenya and Tanzania. Clark's concluding chapter offers a number of suggestions on plan implementation and observations on economic coordination among the three East African economies.

Both studies deserve careful scrutiny, even by those who may not agree with the details of Clark's model or the judgments behind Stolper's reflections. Neither author is dogmatic; their professional craftsmanship deserves respect whether or not it compels assent. Stolper's study is especially valuable for its thoughtful reflections, Clark's monograph for its operational data.

Stolper is convinced that plans which impose a high degree of austerity will be self-defeating, since they will erode morale, undermine productivity gains, distort resource use, and create political instability. He agrees with W. Arthur Lewis (see his *Development Planning: The Essentials of Economic Policy*, New York, 1966), that the absolute level of living should not be depressed, even during a "big push." This is a humane, Western view, responding to the situation of countries in West Africa. It also stems from a belief that there are at any one moment of time only a limited number of sensible outlets for additional savings.

However, a reviewer familiar with the Soviet and Chinese approach to economic development, and aware of the grimmer dimensions of development problems in India, cannot help wondering whether this sensible advice will fit the desperate urgencies that loom over many countries today. We can all agree that belts should not be tightened unnecessarily, as a result of wasteful resource use, but strenuous efforts may still be required to fend off economic and political disaster. "Strenuous, but sensible"—perhaps that should be the development adviser's slogan.

Haverford College

The Economics of Underdeveloped Countries. By JAGDISH BHAGWATI. New York: McGraw-Hill, 1966. Pp. 254. \$4.95; paper, \$2.45.

This book by Jagdish Bhagwati is one of a specially commissioned, international series of books designed to present a broad contemporary treatment of particular topics which will serve as authoritative introductions for both student and general reader. With this goal Bhagwati has had outstanding success. Written simply and with astonishing clarity the book will furnish the new student an excellent foundation for further study in development and will give the general reader a sound understanding of this most pressing international issue.

Bhagwati uses a straightforward ordering of the book. Part I (The Incidence of Squalor) defines the problem of underdevelopment. Part II (The Economic and Social Structure) contains an incisive survey of both economic and noneconomic obstacles to development. In Part III (The Process of Transformation) Bhagwati outlines alternative development policies and pre-

sents an outstanding treatment of the planning framework. (If no other part of the book makes an assigned-reading list, this should.) Here the author treats planning from the inception of goals and targets through balancing and maintenance of consistency to plan completion. The final section, Part IV (The International Framework), incorporates the problem of development into a discussion of the international economy with its implications for aid, investment, and trade policies.

So much for the book as a general introduction to the field of economic development. There is another, more penetrating, and much more exciting side to this book which warrants the attention of everyone in the area of development. This is its searching appraisal of many ideas and theses which too often have tended to become part of the "conventional wisdom" of the developmental economist. If this is too extreme, then the economist bears responsibility for allowing these notions to become accepted as truths by the general public.

Here are some of the theses which are forced to run Bhagwati's gauntlet: (1) Wide differences in income inequality exist between countries. (2) The terms at which underdeveloped countries exchange their products for imports have been declining secularly. (3) Countries relying heavily on export earnings from a few primary commodities suffer consequently from sharp instability in their capacity to import their requirements. (4) The social institution of the joint-family is a significant barrier to economic development. (5) The caste system seriously impedes the growth of a modern industrial labor force.

Perhaps because Bhagwati represents a fortuitous blend of leading international economist and knowledgeable observer of Asian life, he has been able accurately to reappraise ideas too often taken for granted in the literature. Moreover, this rare blend also makes his analysis of such institutions as the joint-family, the caste system, and motivational aspects of eastern religions refreshingly original.

Another strong point of his work is its nondoctrinaire tone. Bhagwati attempts to draw from conflicting economic systems those aspects holding the most promise for the developing nations. Thus he sees an important role for public enterprise in a development program, yet urges strongly that detailed bureaucratic planning be minimized because of its tendency to lead to inefficiency and corruption.

In the final section of the book, "The International Framework," Bhagwati perceptively analyzes the standard questions on aid-giving: tied vs. un-tied aid, multilateral vs. bilateral aid (including an interesting account of consortia agreements) and the role of private foreign investment. With respect to the trade problems of the developing economies Bhagwati calls for a restructured GATT with major alterations in its policies toward: subsidization of exports, reciprocity, state trading, and preferential entry. Also included here are a discussion of the effective tariff-rate argument and a call to the industrial nations to remove nontariff barriers to the entry of the manufactured exports of the underdeveloped countries. An unfortunate omission in this section is failure to consider in any detail the vehicle of economic integration as an approach to development.

It is most fortunate that there seems to be a trend emerging in which economists working at the theoretical frontiers of their respective fields occasionally pause to condense, integrate, and simplify the body of contemporary literature. This is what Bhagwati has so effectively done. The same could be said about Harry Johnson's latest books. This keeps the lagging sector close enough to be still relevant and useful in policy formulation.

Boston College

Agricultural Production and the Economic Development of Japan 1873-1922.

By JAMES I. NAKAMURA. Princeton: Princeton University Press, 1966. Pp. xxiii, 257. \$7.50.

This is an imaginative and stimulating book. It says something radically new about the tired theme of Japan's rapid economic growth. The book argues that Japan's growth rate during the period under consideration was very much lower than what has been accepted. It also argues that Japan's standard of living at the beginning of industrialization was very much higher than conventionally supposed. Nakamura arrives at these conclusions by examining the flaws and biases in the official statistics on agricultural production in Meiji Japan. The agricultural output of early Meiji years is adjusted upward by 80 per cent above the widely accepted Ohkawa estimate. The subsequent rate of growth of the agricultural output comes down to about one per cent per annum in contrast to 2.4 per cent in the Ohkawa estimate. If Nakamura were right, all the merry variations on the theme of Japan's *wirtschaftswunder* would amount to a gigantic hoax. One would suddenly be precipitated into a gloomy task of explaining why Japanese development was so slow. This new task, giving relief to iconoclastic impulses, would not be without its *schadenfreude*, but before indulging let us examine Nakamura's case critically.

Nakamura regards agricultural output as consisting of two components: paddy rice and dryland crops. For either component, output is an arithmetic product of arable land area and yield per unit of area. The underestimate of output can be traced to the understatement of area or the underreporting of yield. The former arises from concealment, misclassification, or undermeasurement of arable land. Both the understatement of arable land area and the underreporting of yield derived from the landowners' desire to minimize the land tax burden and the public authorities' difficulty in obtaining full cooperation from the landowners.

On the whole, Nakamura does a convincing job in the adjustment of arable land area for concealment and misclassification (Ch. 2). This adjustment affects land statistics prior to 1890. His adjustment for undermeasurement is less convincing but its effect is not too serious (Ch. 3). He applies uniform undermeasurement indices to paddy and dryland areas for the entire period. His method of adjusting for underreporting of yield is least convincing and may even be regarded as a little too audacious (Ch. 4). This is all the more serious, because the adjustment for underreporting of yield accounts for a pre-

dominant part of the difference between the Nakamura and Ohkawa estimates of agricultural production.

Nakamura rejects the whole series of paddy rice yield obtained from the official statistics except for the average yield for 1918-22. He infers a range of yields from 1.5 to 1.7 *koku* per *tan* (1 *koku* = 4.96 bushels; 1 *tan* 0.245 acres) for the 1870s from historical findings on agricultural progress during the Tokugawa period and a common belief among the officials about the level of yield during early Meiji years. He then calculates a range of rates of increase in yield between the assumed range of yields for the 1870s and a range of yields from 1.9 to 2.0 *koku* per *tan* for 1918-22 obtained from averaging the official figures for these years.

Among the various considerations that have led Nakamura to adopt that particular range of yields for the 1870s, the following two seem to be most important: (1) the land survey of 1592-96 placed the average paddy rice yield at 1.18 *koku* per *tan* and (2) land productivity during the Tokugawa period must have increased slowly but steadily (pp. 75-77). At the annual rate of increase equal to one-tenth of one per cent during the Tokugawa period, paddy rice yield could easily have risen to 1.6 *koku* per *tan* by 1875 (Table 4-6, p. 103). The official statistics put the yield for 1878-82 at 1.166 *koku* per *tan* which was lower than the yield of 300 years before (pp. 79-80). Clearly there was something drastically wrong with the official figures, claims Nakamura.

He may well be right. But anyone who has used the Japanese official statistics in one way or another would find it extremely difficult to cast them aside as easily as Nakamura does. Nakamura pitches the full weight of Tokugawa history as it has recently emerged from the works of historians like E. S. Crawcour and T. C. Smith, against the canons of modern empirical research based on mass data applied to Japan by economists like B. Johnston, K. Ohkawa, and H. Rosovsky. Nakamura thus corners his readers into a *Shigemori*-dilemma of divided loyalties: e.g., to honor history is to challenge economics. It may perhaps be Tokugawa versus Meiji, for preferences for one would surely affect the evaluation of the other.

One way to resolve this dilemma is to hunt up masses of unofficial, but hopefully unbiased, data from a wide range of households, communities and prefectures, compare them with the official statistics having to do with these areas, and construct an "underreporting index" to be used for the adjustment of the official statistics. The task is no doubt arduous and costly. But its payoff may be worth the cost. In fact, Saburo Yamada, whose agricultural output estimates are called in for scrutiny by Nakamura, may well have adopted this kind of approach (pp. 119-21). It is a pity that Yamada has not published his method in sufficient detail. Interestingly enough, Yamada's results come up with an intermediate position between the Ohkawa and Nakamura estimates. Yamada's belief that the official-yield reports can be adjusted upward is sensible enough. Surprisingly, Nakamura takes a dim view of this kind of approach (p. 121), denying in effect the possibility of adjusting the official data. Could it be that Nakamura for once was carried away by his enthusiasm over Tokugawa history and his delight in the elusive ingenuity of Meiji farmers?

Given the uncertainties that shroud the yield estimates and the whole series of agricultural output built upon them, little need be said at the moment about Nakamura's re-interpretation of Japan's modern economic growth (Ch. 7), except for registering an admiration and amazement as to the variety of problems and promises that arise on the heels of so fundamental a revision of agricultural output, and the efficiency of skill and the elegance of exposition with which Nakamura has conquered problems and fulfilled promises. In conclusion, there is no gainsaying that Nakamura has written a very important book which raises studies on Japan to a new level of sophistication.

KOJI TAIRA

U.S. Aid to Taiwan: A Study of Foreign Aid, Self-Help, and Development.

By NEIL H. JACOBY. New York and London: Praeger, 1966. Pp. xviii, 364. \$8.50.

In the voluminous literature on economic development, systematic and rigorous study of the effects of U.S. economic assistance upon developing nations is only a recent phenomenon. Jacoby's book is certainly an urgently needed empirical study and is the most comprehensive yet published on this subject.

During the period 1951-65, Taiwan received a total of \$1,465 million in U.S. aid, amounting to about \$10 per capita per year and to 6.4 per cent of Taiwan's GNP over the entire aid period. Jacoby's major purpose is to examine the effects of such aid on the Taiwan economy. After presenting the scope and method of his study, he discusses the U.S. aid program in terms of its objectives, character, organization, and institutions; reviews Taiwan's economic, social, and political development and its military burden; and then devotes about one-third of the book to analyzing the relationships between aid and development. Appendices occupying about another third of the book provide abundant statistical data and three growth models of Taiwan's economy. It should be noted that Jacoby's study accepted, without evaluation, both the U.S. and the Republic of China's political and military policies and relied primarily upon their official statistics. Those "who must read as they run" are advised by Jacoby to turn immediately to the last chapter which summarizes the flaws and errors in the Taiwan aid program, reasons for success in Taiwan, and other lessons.

To evaluate the effects of aid on development, Jacoby developed seven criteria, e.g., target attainment criterion (actual growth versus Chinese government targets); and three simple models of the Harrod-Domar type, i.e., No-Aid, No-Military Burden, and Light-Aid Growth models. He admitted that each of his criteria and models has certain theoretical limitations and peculiar difficulties in application. Fortunately his seven criteria are more or less independent and all pointed toward the same conclusions.

It was found that "Aid more than doubled the annual rate of growth of Taiwan's GNP, quadrupled the annual growth of per capita GNP, and cut thirty years from the time needed to attain 1964 living standards" (p. 152). With aid, the Chinese government achieved economic independence in 1965,

three years ahead of the original goal set by the Agency for International Development (AID). Jacoby estimated that with aid but no-military burden, averaging 9 to 11 per cent of its GNP during 1951-65, "Taiwan's GNP might have expanded about 9.7 per cent a year—2.1 percentage points about the actual growth rate" (p. 124). The example of Taiwan shows, however, Jacoby believes, that a powerful military force and rapid economic growth in a semi-developed economy can be achieved simultaneously, provided that major military hardware is supplied by an external force.

One understanding achievement of Taiwan's development, Jacoby noted, is that the fruits of its progress were widely distributed among farmers, villagers, industrial workers, professional and civil service personnel, and business enterprisers. However, it is common knowledge that, despite some recent improvement, civil service salaries are still considered very low.

To Jacoby, it is a fallacious view that aid should have "no strings." He describes quite vividly how aid has been used to influence Chinese national policies (Ch. 10). The most important economic consequence was the creation of a booming private enterprise, which, by 1965, became the mainspring of Taiwan's economy.

U.S. aid also shaped political and social development in the areas of education, health, and public administration, admittedly with much less success. His discussion of policy influence in these areas, however, is disappointingly brief. More quantitative evidence is needed to substantiate some of his conclusions about aid allocation and selection of aid projects in Chapters 13-14. A typical conclusion reads, "Although the allocation of funds among sectors of the Republic of China's economy was close to optimal, choices of individual projects departed from the optimum by a material margin" (pp. 203-4). Neither "optimal" nor "material margin" is clearly defined. Such inadequacies are undoubtedly in part due to the lack of relevant data and to the difficulty of measuring the effects attributable to aid. But one's suspicion is also aroused that Jacoby is perhaps unaware of or reluctant to cite certain relevant literature. Several important studies, for example, A. F. Raper and E. S. Kirby's studies on Taiwan's social and rural development were not cited.

Throughout the book, he makes candid and penetrating observations on a number of controversial and vital issues. He gives more credit to the Japanese contributions to Taiwan's early development during her occupation from 1895-1945 than most Chinese are willing to admit (Ch. 6). He notes that political development has lagged behind the rapid economic and social development. "There was a measure of democracy—more than a facade, yet less than a genuine and full structure" (p. 113). He is much concerned about the problem of "brain drain"—an exodus of talented young people to foreign countries (Ch. 8 and p. 185).

In my judgment, Jacoby is quite successful in analyzing the effects of aid upon Taiwan's development. But the book is more than a case study. He is equally successful in drawing lessons of value for future aid programs. He also attempts to develop methods for aid evaluation, but with less success. His criteria and models are enlightening, but are built upon restrictive and static assumptions. These can be applied elsewhere only with great care and consider-

able modification. But his efforts are nevertheless an important step toward the development of a much needed proper theoretical framework for evaluating aid programs.

Considering the lack of such well-established theory and the many hazards in such pioneering analysis, Jacoby has, I believe, written an interesting book characterized by his skillful interpretations of factual materials.

CHARLES H. C. KAO

Wisconsin State University—River Falls

Ceylon: An Export Economy in Transition. By DONALD R. SNODGRASS. A publication of the Economic Growth Center, Yale University. Homewood, Ill.: Richard D. Irwin, 1966. Pp. xvii, 416. \$9.50.

In this volume, which is sponsored by the Country Analysis Program of the Yale Economic Growth Center, Dr. Snodgrass attempts to analyze the process of growth in Ceylon since her opening to the world trade system during the 1840s. His study is purported to show that economic changes of Ceylon are consistent with the "enclave" thesis *à la* Hans Singer, Raul Prebisch, and Jonathan Levin. "The growth of the estate sector and its continued prosperity, then, increased dividend levels for foreign shareholders and increased consumption levels within a growing enclave in Ceylon itself, but it did not materially raise levels of expenditure on Ceylon-produced goods and services, nor did it provide a surplus to be invested in other parts of Ceylon economy" (p. 70).

This pattern of growth (or non-growth) has prevailed, according to the author, during "period 1" (1840-1946), which is designated as the "classical or colonial period." Chapters 2, 3, and 4 are devoted to studying the growth pattern in this period. Here the author describes how British capital was introduced and Indian laborers were imported to combine with land in Ceylon. This resulted in the creation of a plantation type of "enclave system," growing coffee (now defunct), tea, rubber, and coconut to export. With qualified success, efforts are made to explain the reason for a weak intersectoral flow between the growing enclave sector and the nonexport sector (or the subsistence sector).

On the other hand, "period 2" (1946-1961) is characterized by the "revolt"—the independent government's effort to change the structure of the economy and thus to increase per capita income. Chapters 5, 6, 7, and 8 describe this period of "transitional, development-oriented or independent economy." The story is an unhappy one, however. The government effort has been frustrated because of "the high consumption and import propensities in the private sector, the sluggishness of public revenues, the shortcomings of public investment allocation, the failure to stimulate an adequate volume of private investment . . ." (p. 214). As a hindsight, the author diagnoses that "A higher growth rate could have been produced by converting more current expenditure to investment" (p. 214).

A few questions may be raised regarding the claim that Ceylon's experience is consistent with the enclave thesis. Other studies show the magnitude of the

export multiplier estimated at 2 to 2.5 for the period covering the 1920s to 1950s.¹ This is contrary to the implication of the enclave thesis wherein the marginal propensity to consume for domestically produced goods and services out of the export income is near zero. Further, Snodgrass' own words contradict the thesis: "Many of the services that were provided—electricity, roads, railways, and others—yielded substantial benefits to other parts of the economy and society as well as to the estates" (p. 63). To this list, education and health services must also be added. This evidence among others does not seem to support his claim.

According to the enclave thesis, imports consisted primarily of the "luxury imports." However, one finds that the "traditional goods" such as rice, fish, cotton goods, etc. composed as much as 51 per cent of total imports for 1929 (p. 61, Table 3-3). "Western style consumption goods" composed only 16.8 per cent. Thus, contrary to the enclave thesis, the size of the domestic market seems to have expanded rapidly. Obviously the domestic industries failed, in spite of the tariff protection, to increase their output to capture the rapidly increasing domestic market. The suggested explanation is: "the peasant economy created its own demand or, rather, its subsistence production was relatively unresponsive to market stimuli" (p. 67). But, Snodgrass himself found puzzling exceptions which indicate the farmers' "over-responsiveness."

In spite of the questions raised, this volume is a welcomed addition to the scanty stock of scholarly studies on the Ceylon economy. I concur with the author in hoping that this book will be interesting to "all three types of readers; those interested respectively in Ceylonese economic development, in the growth of export economies, and in the development process in general" (p. viii). The Appendix (160 pages) is impressive and useful. It contains a wealth of materials ranging from national income estimates of various types (1938-1960) to numbers of livestock (1871-1959). Reliability and the method of estimation are discussed in informative ways. The discussion of the development problems facing Ceylon today is illuminating.

Statistical Methods; Econometrics; Social Accounting

Input-Output Economics. By WASSILY LEONTIEF. New York: Oxford University Press, 1966. Pp. xii, 257. \$8.50.

At the beginning of his second essay in this volume, Professor Leontief claims that James Clerk Maxwell would have difficulty in keeping track of the discussion in modern meetings of physical societies, while John Stuart Mill would easily pick up the thread of argument at corresponding economics meetings. This is surely not so, largely because of the technical nature of economic

analysis stimulated by Leontief and others in modern quantitative economics. John Stuart Mill would have difficulty in following, without advance preparation, much of the material on input-output economics in the present volume. He would be completely at sea in modern discussions of more general econometric methods or applications and the advanced mathematical theories of programming, balanced growth, existence of equilibrium, stability of equilibrium, social accounting and other subjects with their own terminology, advanced equipment, and technical methodology.

Leontief has been a true leader in the transformation of economics into a quantitative science and gives good display of his accomplishments in the present volume of eleven previously published essays. Several come from *Scientific American*, others from *Harvard Business Review*, *Dun's Review*, *Proceedings of the American Philosophical Society*, and the *Review of Economics and Statistics*. The reader who expects to find new results in I-O analysis will be disappointed, but the now familiar material that is reprinted here is interesting and contains many surprises on a rereading.

The disadvantage of placing these collected essays together in a single volume is that much of the introductory material becomes repetitious. The reader must be taken, over and over again, through an elementary discussion of what constitutes I-O economics and the structure of a typical table.

Among the more well-known essays in this volume are the stimulating pieces on factor proportions in foreign trade and the economic effects of disarmament. On the re-reading as well as in the earlier reading, the famous paper on the American capital position has a sensational appearance. It is especially good to have this paper reprinted because it is not easily available in its original form. This is an important paper, but it distorts the picture by making calculations in U.S. technology alone. The succeeding chapter goes far towards giving some theoretical justification for the argument in terms of U.S. technology alone, but it is doubtful that Leontief has effectively dealt with the critique offered in 1954 by S. Valavanis and others.

The disarmament paper is also important, but the lack of a real and firm forecast about the possibility of absorbing slack demand generated in the armaments sector by a government-supported private sector gives the results an altogether too bold and optimistic tone. This points up the basic weakness of I-O methods of analysis; they are not adequate by themselves for making forecasts. I-O relationships deal with only part of the economy and do not give us a closed system of relationships. The title for Chapter 1, "Proposal for Better Economic Forecasting," seems in this respect to be misleading, for I-O methods by themselves are not suitable for use in forecasting. They are suitable for giving partial information on economic structure, especially technological structure, but they tell us little about final demand, price formation, monetary affairs or many other economic processes that would have to be considered in a more complete system that would be usable in forecasting. In the case of disarmament, the crucial question is the maintenance of overall demand. I-O methods throw hardly any light on this issue, and the secondary marginal effect of shifting people from military to civilian activities is of limited significance.

In the seventh essay, Leontief states that, "The Input-Output method is an adaptation of the neo-classical theory of general equilibrium to the empirical study of the quantitative interdependence between interrelated economic activities." This is a frequent overstatement found in the literature of I-O analysis. The I-O system and the Walrasian general equilibrium system simply are not the same. The I-O system could be used for a particular representation of the technology of a general equilibrium system, but so much of the functioning of the economy is left out of the I-O system that it is surely wrong to identify it with the general equilibrium system. It is just a partial system.

I-O methods of analysis are becoming important in development planning, both in centrally planned and market type economies. The chapter on the structure of development is especially useful as a way of making international comparisons among developing economies and in providing an expository aid to understanding the whole process of development.

The final chapter (written together with Alan Strout) makes a similar application at the regional level, for even in countries that are developed in an overall sense, there are important problems of regional development. This chapter shows how models of regional analysis might be constructed. It gives a clear indication of the immense data requirements that would be needed beyond the already large requirements of conventional I-O analysis.

For teaching purposes and for referring people with lay interests to an expository treatment of I-O methods, Leontief's new volume will be found to be extremely convenient. It is not a collection of new contributions to the subject, but, as ever, shows the inspirational abilities of the founder and leader in this area of research.

LAWRENCE R. KLEIN

University of Pennsylvania

A Statistical Model for the Greek Economy 1949-1959. By P. PAVLOPOULOS. Amsterdam: North Holland Publishing Co., 1966. Pp. xi, 333. \$12.50.

This book presents a macro model for the Greek economy based on data for the years 1949-1959. Four spheres of economic activity are described—those of private consumption, private fixed investment, imports, and changes in stocks of agricultural products—in terms of seventeen linear equations. Eight of the equations of the model are behavioral (consumption, investment in plant and equipment, investment in housing, imports, agricultural and nonagricultural income determination, and agricultural and consumer price formation); two are institutional (direct and indirect tax equations); and seven are definitional. The stated purposes of the model are to analyze the structure of the economy during the sample period, to forecast events, to prescribe economic policy—and, this reviewer would also add, to demonstrate in detail how one goes about constructing an econometric model (despite severe data availability and reliability constraints), and using it. The pedagogical goal is perfectly satisfied; the rest are satisfied to a degree that varies directly with their above stated rank.

Obvious data limitations account for most of the shortcomings of the model. There is lack of wage cost data, therefore a price-wage interaction relationship

is omitted. Employment data are not available and as a result the model incorporates neither production functions nor demand for labor equations. Only in the agricultural submodel appears a supply equation which involves agricultural capacity, prices (both proxied in a rough way), and the weather and which is formulated on the basis of a modification of Nerlove's model of adaptive expectations. Monetary policy, exchange rate policy and credit policy variables are omitted from the model, although in some instances only after experimentation with proxies for these variables gave poor results. Finally, the degree of aggregation of the model seriously circumscribes its usefulness as a tool for policymaking. Despite its impressive record of growth (5.5 per cent per year during the period of the model and higher thereafter) the Greek economy faces serious long-term structural problems, in contradistinction to short-term problems arising from fluctuations of economic activity due to pressures or inadequacies of effective demand. Yet, the supply side only indirectly enters the model. And detailed structural analysis at the sectoral level is not attempted. From this point of view, the Greek specialist might want to compare the Pavlopoulos model with the Suits model¹ and the Adelman-Chenery model²—both less sophisticated but more disaggregated models. (A highly sophisticated and disaggregated eight-sector model of the Greek economy has been constructed at the Center of Planning and Economic Research in Athens as a basis for the formulation of the *Draft for the Economic Development Plan, 1966-1970*.)

Pavlopoulos is keenly aware of the limitations of his data and of the resulting constraints to his model—and he is ingenious in trying to circumvent them. In Chapter 2, the specification of the model, he carefully discusses each equation presenting its theoretical underpinning and also the alternatives considered. One cannot help but be impressed (and also amused at times!) at the inventiveness that the author displays in his use of proxy variables in an attempt to make the most out of poor, incomplete, or dubious data! One may also suspect that an aftertaste of this use of proxy variables appears in the estimation of the model in terms of the covariance among the error terms of the structural equations. Chapter 3, which deals with estimation, is as methodical as Chapter 2. The author presents side-by-side the ordinary least squares and the two-stage least squares estimates; he presents the results for the alternative forms considered (he bases his choice of preferred forms on a priori notions about the derived estimates, on autocorrelation of residuals, on the significance of the regression coefficients and, lastly, on the power of otherwise similar equations to explain observations beyond the sample period); and he presents the time graphs for all the variables and the residuals. The results of the estimation of the structural equations are in general highly satisfactory.

In Chapter 4 the author presents the reduced form estimates and the impact multipliers. Although less satisfactory than the estimates of the structural parameters, these are generally acceptable—despite the absurdity of a negative

¹ D. B. Suits, *An Econometric Model of the Greek Economy*. Athens: Center of Economic Research, 1964.

impact multiplier of exports on income and the qualms one might have about accepting at face value a multiplier of autonomous government expenditures on gross national product of 1.50, especially in view of a lower multiplier that is usually estimated for the U.S. economy, e.g., by the Klein-Goldberger model. Still, the model survives the battery of tests it is submitted to, including a test for structural stability (Ch. 5 and 7).

Pavlopoulos' main contribution to econometric theory comes in Chapter 6, where very methodically he tries to detect the weak links of his model. The best known approach to the sources of distortion of an econometric model is due to Goldberger³ who analyzed the correlations between the reduced form residuals of GNP and the reduced form residuals of various endogenous variables. Pavlopoulos convincingly demonstrates that a better criterion of choosing among alternative forms consists of the combination of the quantitative measure of the error terms of the structural equations, of their variance, and of the covariance between the error terms of the different equations. Application of this criterion to the model leads to the result that all structural equations, with the exception of the one for indirect taxes and the one for agricultural price formation, share the guilt, although the main contributors to the model's distortions are the agricultural supply and demand equations and the equation for imports. Finally, Chapter 7 presents the truncated multipliers derived from the model, and Chapter 8, as an overview, discusses the use of econometric models in the policymaking process.

Pavlopoulos' work may not have provided the answers to the problems that smite Greek policymakers and planners. Yet, it provides a systematic, skillful, and comprehensive step-by-step account of how an econometric model is constructed, tested, and put to use. This didactic feature alone is sufficient to merit the attention of the practitioners of the art. The author's contribution on the methodology of locating the weak links of an econometric model remains as a consumer's surplus for the reader—and might even find a niche for Chapter 6 in the reading lists of courses in Econometrics.

Money, Credit, and Banking; Monetary Policy; Consumer Finance; Mortgage Credit

Banking in the Early Stages of Industrialization: A Study in Comparative Economic History. By RONDO CAMERON, with the collaboration of OLGA CRISP, HUGH T. PATRICK, AND RICHARD TILLY. New York: Oxford University Press, 1967. Pp. xv, 349. \$6.50.

Rondo Cameron, the impresario of this volume and the author of four of its seven country studies, concludes that private entrepreneurs have been (and still are) the driving force behind economic development, that instead of gran-

diose and monumental state-sponsored development projects "in general the state would do better to devote its own limited resources to creating the conditions in which private entrepreneurs flourish" (p. 320). And the same truth applies to the banking system: when freedom and competition are allowed, the banking system is quite likely to contribute greatly to economic development; when the state restricts banking, everyone usually suffers.

These conclusions come from Cameron's studies of banking and early industrialization in England (1750-1844), Scotland (1750-1845), France (1800-1870), and Belgium (1800-1875); and from similar studies by Richard Tilly for Germany (1815-1870), Olga Crisp for Russia (1860-1914), and Hugh T. Patrick for Japan (1868-1914). They are all interesting and competent studies, and apparently they were all done from a common outline, which compelled the authors to discuss similar topics and which now enables the reader to make some meaningful comparisons of the various countries' experiences. This outline contains a background discussion of the country's financial structure and evolution, a quantitative analysis of the role of banks in credit extension, especially in industrial finance, and in note issue and deposit creation. Each study concludes with an assessment of the impact made by the banking system on the country's economic development.

Banking seems to have played an important role in the early industrialization of Scotland, Belgium, and Japan; it played a modest role in England, perhaps even less in Germany and Russia; and it may have held back growth in France. According to Cameron, Scotland had a superior banking system because there was freedom of note issue, early development and widespread use of bank deposits, and the early establishment of branch banking, all within the context of intense banking competition and free enterprise. Cameron thinks that France had the worst banking system, brought on by too many artificial and unnecessary restrictions. "The root cause of these deficiencies lay in the monopolistic position of the Bank of France and in the restricted vision and inflexible attitudes of the men who controlled its destinies" (p. 127). Cameron's low opinion of officials is not confined to the French, for in the final chapter we find him saying: "The kinds of men to be found in the service of the state—and, more importantly, the kinds of incentives that impel them—are not necessarily those most conducive to innovation and economic growth" (p. 320). So, Scotland and her private entrepreneurs are at the top, France and her government officials are at the bottom. England lies somewhere in between. Her growth, as Cameron relates it, was held back at almost every point by wrong decisions of the authorities, but these very obstacles "stimulated the private sector to introduce the financial innovations necessary for realization of the full benefits of the technical innovations in industry" (p. 59). Hence, in this case, private entrepreneurs were clever enough to circumvent ill-considered and foolish government policies. However, Belgium seems to present a puzzle to Cameron, because her banking system, geared as it was to industrial banking, apparently contributed importantly to growth, despite strong government interference and a lack of banking competition. What's the answer? "The Belgian experience would seem to indicate that different institutional arrangements can produce equally favorable results. . ." (pp. 149-50).

In Germany, as Tilly shows, the banking system did not contribute much to growth before 1840. After that, bankers became more active in organizing new enterprises and in obtaining short- and long-term funds for them. They had to carry on this activity, however, in the face of heavy restrictions—imposed especially by the Prussian government on note issue, credit creation, etc. The Prussian Bank's monopoly of note issue and its other restrictive practices "did not meet the range of needs that a competitive, private controlled system of banks of issue might have" (p. 180). But, once again as in England, astute private entrepreneurs got around these barriers, this time by creating many types of money substitutes related to their promotional and investment banking activities. "One might therefore conclude that the Prussian government's policies contributed—albeit unwittingly—to an institutional development which was on other grounds congenial to German development needs" (p. 182).

Russian banking was under the strong influence of government—paternalistic supervision of joint-stock commercial banks, monopoly of note issue, direct participation in lending, etc. The poor performance of the economy up to 1890, according to Cameron, was owing partly to such official intervention, which in this case was not circumvented by the private businessmen because of their "backwardness and sluggishness . . . itself in part a product of a long tradition of paternalism . . ." (p. 294). The banking system assumed a more active role after 1890, as it increasingly provided long-term capital to industry and engaged in investment banking. Nevertheless, as Olga Crisp suggests, a great deal of the saving for industrial investment came from the state and from foreigners; the banking system apparently did not supply a major portion of the saving.

In Japanese banking development, the role of government was also important; according to Patrick: "it was vigorous in establishing a new and modern financial system" (p. 241). However, at the same time Patrick warns us that "The role of the government should not be overemphasized . . ." because private enterprise after all was mainly responsible for the development of banking and of the economy. He stresses that "an extremely important feature dominating governmental policy throughout this period was its explicit advocacy of a private, competitive, laissez-faire banking system" (p. 249). Cameron takes up this theme in his concluding chapter when he says that, while both the governments of Japan and Russia intervened strongly in the economy, the Japanese entrepreneurs "responded far more vigorously to their opportunities to establish privately owned banking companies" (p. 295). Whether the impetus came from the government or from profit-seeking individuals, there seems little question but that the Japanese banking system contributed a great deal to the industrialization of the country, for it seems to have attracted a large amount of individual saving and to have loaned these funds for industrial purposes. But, as Patrick makes clear, the banking system did not do everything; for at least part of the period, foreign investment was very important, and a great amount of the banking funds came from government deposits through taxes.

With the exception of Japan, the output growth rates of these countries

during their industrialization drives are not at all impressive; they range from $1\frac{1}{2}$ to 3 per cent per annum. And even Japan's average progress over this period of 4 per cent is nothing to write home about. The fact is that even these successful countries did not produce high levels of saving and investment, either through their banking systems as intermediaries or by any other means.

The underdeveloped countries in the present-day world that have moved ahead most rapidly have generated saving and investment levels (relative to national incomes) two to four times higher than those recorded by Cameron and his associates; and today's successful countries (e.g. Taiwan, Israel, Venezuela, and most of the Communist countries) have produced output growth rates many times higher than those established by their predecessors. By and large, they have not accomplished these records by heavy dependence on their banking systems as financial intermediaries between savers and investors, but rather by the utilization of other saving-investment techniques—taxation, foreign aid, self-finance by private business firms, and profits of state enterprises. Many socialist countries, for example, in recent decades have generated very high rates of saving and investment through taxation and state-enterprise profits, assigning only insignificant roles to their banking systems as intermediaries. Other underdeveloped countries have shot ahead, despite weak financial systems, through heavy doses of foreign aid.

Thus, recent experience strongly suggests that banking systems as intermediaries are not highly essential to the growth process. The evidence presented by Cameron and his associates suggests that banking, whether it developed competitively or monopolistically, did not generate high levels of saving and investment in "the old days" and in fact produced rather unimpressive results. While there is as yet no definite proof that banking systems as intermediaries could not perform well if properly utilized, the evidence against them is mounting up. The Japanese experience, both in the early and later periods, may offer counter evidence—but, then, it always does.

Public Finance

Federal Estate and Gift Taxes. By CARL S. SHOUP. Washington: The Brookings Institution, 1966. Pp. xvi, 253. \$6.75; paper, \$2.50.

Trusts and Estate Taxation. By GERALD R. JANTSCHER. Washington: The Brookings Institution, 1967. Pp. xv, 211. \$6.75; paper, \$2.50.

Economic Behavior of the Affluent. By ROBIN BARLOW, HARVEY E. BRAZER, AND JAMES N. MORGAN. Washington: The Brookings Institution, 1966. Pp. xiv, 285. \$6.75; paper, \$2.50.

These three monographs provide information about the behavior of wealthy people, how they respond to taxation, especially the federal estate tax, and about methods used to insulate property by the use of trusts and other legal devices, both from the tax collector and from its unrestricted enjoyment by living people. For public finance scholars, parts of each monograph are re-

quired reading; for other economists, the Barlow, *et al.* study, based on the Michigan Survey interview technique, is likely to be of greatest interest. The chapters in the Shoup and the Jantscher studies, based on a Treasury sample of decedents, provide a variety of illuminating information useful to anyone interested in the facts of life.

C. S. Shoup, a practiced hand at tax questions, analyzes the federal estate and gift taxes, giving much attention to gifts prior to death, so-called "generation-skipping devices," transfers between relatives, such as between spouses, parents to children, etc., and sketches a plan for revision of the federal estate tax. Appendices are contributed by Robert Anthoine, C. Lowell Harriss, Seymour Fiekowsky, and by Richard Bird, G. R. Jantscher, and Shoup himself.

The federal estate tax had a yield in 1964 of \$2.4 billion, an amount equal to about 2.3 per cent of federal tax receipts. As a revenue device, the estate tax is a failure. Why, then, continue federal death taxes? Shoup does not explore this question. The frame of reference of his study, and of the Brookings Conference on death taxation as reported by him, is the continuation of these taxes in substantially their present form with, hopefully, integration of the gift and estate taxes—the supposed great reform to be supported by all right-thinking people. This stance merely assures that a type of tax with no sensible rationale shall be continued.

Estate taxation generates a tax liability that depends on the size of the net estate and, apart from the marital deduction, the liability is independent of distribution of the estate. If wealthy decedents generally followed the religious doctrine that their estates were to be distributed to the poor, would tax experts advise governments to impose estate taxes? The simple, straightforward tax treatment of transfers at death or before death is inclusion of such gains in the income tax base of recipients, accompanied by effective averaging. If this were done, the tax revenue generated would become substantial. For example, if the total of such transfers amount to \$50 billion per year, and unfortunately Shoup does not provide an estimate of such transfers, the yield would be \$12.5 billion at the modest tax rate of 25 per cent. Shoup's own sketchy, proposed "reform" may be an improvement over the present law, but remains without clear justification in any known canons of taxation.

The Jantscher study is about half legal and half statistical and both parts are carried through with meticulous concern for accuracy. The social consequences of the use of trusts are found to be serious; the dead hand can and does place substantial amounts of property in legal arrangements that incidentally reduce tax liabilities and, what is more important, restrict the freedom of the living in the enjoyment of property.

Professor Jantscher combines a firm knowledge of the law, statistical sophistication, and clear mathematical and literary exposition to produce a first-rate work on a difficult subject. Thanks to a Treasury sample of the tax returns in 1957 and 1959, the actual practices of decedents can be studied in detail. Among the highlights is the perhaps comforting fact that more property is left outright than in trust; less comforting is the fact that trusts are used more frequently and for longer "life-expectancies" by very wealthy decedents than by others.

Jantscher explores various methods of treating transfers of interests in trusts, finding the British practice too easily evaded. His own proposal, described as a "backward-looking" approach, calls for computing the interest on a trust when it reaches its maximum present value. Assuming that the House Ways and Means Committee members could be instructed in the subtleties of the plan, and this one may doubt, its chief effect would be to discourage the formation of trusts.

If, as a matter of social policy, trusts and similar legal devices are to be discouraged, an alternative is a regulatory tax to be imposed on a trust device at a rate on the positive difference between the market value of the assets placed in trust and the present value of the interests of *living* beneficiaries in the trust. Where the trust devices "destroy" no present value to living beneficiaries, illustrated by a trust formed for legally incompetent persons, the tax base is zero. Where, however, the trust effectively limits the enjoyment of property by living beneficiaries, the dead hand taxes the beneficiaries. The government, in this event, could place a genuine tax on the dead-hand tax at a high rate, say 80 per cent, to discourage such antisocial practices. The gains of beneficiaries would be treated as income and taxed under the income tax. New trusts could be expected to dwindle fast if this plan were installed.

The Barlow-Brazer-Morgan monograph is based on data obtained in 1964 from interviewing a sample of 957 persons, whose incomes were \$10,000 or more in 1961. The sampling was roughly proportional to income and the questions asked were mainly designed to elicit information about asset management and work habits. Respondents give the impression of being hard-working, conservative people who let tax considerations influence their behavior slightly or not at all. Estate planners do not get much of their business; like other mortals, they vacillate—a fact that incidentally accounts for much of that \$2.4 billion yield of the federal estate taxes. On the work-leisure choice, they work on the average of 48 hours per week, 50 weeks per year. The interviewers did not ask about the three-martini lunch, and one wonders who are the customers of summer cruises and round-the-world golfing vacations. Rather mysteriously, those whose marginal tax bracket was in the neighborhood of 50-60 per cent, but not at higher percentages, reported that taxes reduced the hours they worked. Quantitatively, the "disincentive" effect of marginal income-tax rates appears to be trivial—the usual conclusion of empirical work in this area.

Subject to the inherent limitations of the interview method, this study adds substantially to our knowledge of the behavior of the affluent. It serves as a corrective to the idea that wealthy people spend much of their waking hours arranging their affairs to avoid taxation.

There is a lesson for economic theory in these studies. The time-preference doctrine continues to dominate what is called "capital theory" and theoretical pieces starting from the premise that people maximize consumption over their lifetimes or some successor's lifetime continue to use up much valuable journal space.

This view does not fit the behavior of wealthy Americans. As Seymour Fiekowsky in Appendix F of the Shoup minograph aptly states: ". . . these

wealth holders have a persistent affinity for assets. Their estates do not 'peak' at some age between 50 and 60 and then decline. Rather their estates continue to grow even beyond the age of 80!" (p. 229). The time-preference theory may be appropriate for aboriginals and even, perhaps, for British working classes of the 19th Century. Americans, however, like assets and this desire, unlike the desire for consumption, seems to be insatiable.

EARL R. ROLPH

University of California, Berkeley

Intergovernmental Fiscal Relations in the United States. By GEORGE F. BREAK. Washington: The Brookings Institution, 1967. Pp. xv, 273. \$6.75; paper \$2.50.

The fiscal crisis of state and local governments in the United States constitutes one of the major challenges to policy makers in this country. Rapid increases in the school-age population and growing congestion and pollution problems in urban areas have placed great pressures on state and local governments to expand both the range and levels of expenditures on public programs. To meet this challenge, the states and localities must have increased access to sources of funds. And this is the heart of the problem—state and local governments are subject to serious constraints in tax policy, constraints which suggest that it is unlikely that the necessary revenues will be forthcoming from state-local tax structures. The response of policy makers to this dilemma will in large part determine the future of federalism in this country.

Break's study of this problem begins with a survey of the projections of state-local spending and revenues for 1970. Projections of this kind are a tricky business; they are highly sensitive to the assumptions adopted in the study. Thus, Break settles for interval estimates of 1970 expenditures and tax receipts of \$100-120 billion and \$64-70 billion respectively. Much of this projected gap may be filled by a growth in receipts from user fees, increases in existing federal grant programs, and by a rise in state-local indebtedness. However, there is "... at least an equal possibility that the pressures will soon be too great to be met in conventional ways; it is this prospect that brought about this study."

In the next three chapters, Break treats the problems of tax coordination, functional grants-in-aid, and unconditional grants to states and localities. Following traditional theory, Break argues that the federal government should limit functional grants to those programs where substantial spillover benefits and costs exist. In principle, such grants should be open-end, matching grants, where the share of the federal government equals the ratio of spillover benefits to total benefits. Furthermore, as the grantor, the federal government should exercise some control over the character of the programs involving these funds. The federal government can then supplement these tied grants with unconditional grants. The latter would serve two basic purposes. First, they would provide added funds for all state and local governments. Because of the pressures resulting from the high intranational mobility of economic units, state and local governments are reluctant to increase tax rates or to adopt new taxes which might adversely affect new investment or migration into the state

or locality. Thus, the cost of a dollar of taxes to a state or municipality may be more than just the loss of a dollar of disposable income to its residents. As a consequence, states and localities may fail to provide important public services where the benefits exceed the real opportunity costs of resources. Unconditional grants could thus make available funds for genuinely desirable programs. Second, the federal government could employ unconditional grants for equalizing purposes by making relatively larger grants to the poorer states (and possibly localities). On this point, Break discusses a number of alternative grant formulas and presents calculations indicating the degree of equalization implied by each.

On the grant problem, I am a bit uneasy about Break's unqualified application of the Pigovian theory of functional grants to the question of intergovernmental fiscal problems. Economists have used the theory of optimizing grants to tackle the problem of spillover costs and benefits generated by individuals and firms. But it is somewhat tenuous, as Anthony Downs and others have argued, to assume that governments act to maximize net social benefits in the economic sense. A group of vote-maximizing politicians, as Downs shows, may behave in a way which diverges significantly from optimality in economic terms. Thus, we should, it seems to me, be developing a theory of intergovernmental grants which is more closely tied with what we know or can infer about social decision-making processes.

Break devotes his fifth chapter to metropolitan fiscal problems. It is here that the pressures of growing needs and limitations on revenues are most serious. Per capita expenditures in 1962 were \$234 within Standard Metropolitan Statistical Areas (SMSA's) as compared to \$180 outside the SMSA's. The gap would in all likelihood be even more pronounced if the urban areas could generate the funds they require to meet the bewildering array of problems which confront them. However, the mobility of resources at urban levels places even greater constraints on taxing powers than at the state level. In this chapter, Break presses for three types of reform: the reorganization of metropolitan governmental systems, the adoption of systems analysis for program evaluation, and the restructuring of metropolitan revenue systems. The organization of urban government is a problem of incredible complexity. Break's brief discussion is of some help, but the problem is clearly at least as much a political as an economic one. On the tax issue, Break's proposals for a rationalization of assessment procedures and a reduction in exempted property would definitely strengthen municipal tax systems. However, I cannot share his enthusiasm for "... the conversion of the property tax into a tax on all wealth holders levied annually on the market value of their equity interest in assets of all kinds" (p. 213). In spite of its desirable equity characteristics, a tax on mobile forms of wealth is precisely the kind of tax urban areas cannot adopt—it serves simply to chase much of the tax base away.

The great merit of this book is that it treats in a comprehensive and systematic way the whole area of federal-state-local fiscal relations in the United States. Break states the problems and examines the various proposals which have been advanced to deal with them. For this reason, it is undoubtedly the best available introduction to the subject. The theorist in public finance will,

however, find little new in this book. But it is nevertheless a useful contribution to the discussion of one of the major policy issues of the decade.

WALLACE E. OATES

Princeton University

International Economics

Discrimination in International Trade, The Policy Issues 1945-65. By GARDNER PATTERSON. Princeton: Princeton University Press, 1966. Pp. xiv, 414. \$10.00.

A coherent approach to the chronicling and analysis of the complex evolution of international trading relationships since World War II can be, and has been, attempted on the basis of a variety of organizing principles: dollar shortage, European integration, Britain's efforts to enter Europe, the new system of multilateral commercial diplomacy embodied in the General Agreement on Tariffs and Trade, the problem of promoting development through trade. In choosing the purposes and results of policies of trade discrimination among supplying nations as his point of reference for this study, Gardner Patterson has selected an organizing principle of surprising potency in rendering a mass of heterogeneous detail amenable to logical and comprehensible exposition. The detail itself comes largely from the invaluable records of GATT, supplemented by personal discussion with responsible officials of the various national and international organizations concerned. Patterson's skillful ordering and review of it provides a book that will be useful at more than one level: the reader may either skim it to obtain a perspective on contemporary trade policy issues, or consult it as a reference on the major policy issues raised in particular negotiating incidents, or mine it for comparative information on particular policy issues as they have arisen in various contexts (the book is carefully indexed).

The first chapter of the book defines the territory, and explains the reasons for the primacy of the principle of nondiscrimination in the planning of the postwar international trading system. Chapter 2 then examines immediate postwar experience with the main exception allowed by the planners, discrimination for balance of payments reasons. The central theme is that while such discrimination yielded immediate benefits, given national commitments to full employment and fixed exchange rates, the benefits eroded as the European economies recovered and dollar shortage disappeared, while the costs in terms of "incidental protection" and other effects mounted. The author gives considerable credit to the new international institutions for the rapid unravelling of this discrimination, once the desirability of ending it had become apparent. Chapter 3, on the temporary regional arrangements of the dollar shortage period—the European Payments Union and the OEEC Trade Liberalization Scheme—develops the same theme of mounting costs and falling benefits, and a swing of opinion and policy back towards the virtues of nondiscrimination.

The developments recounted in Chapters 2 and 3 could be regarded as a laggard return to the wisdom accumulated by interwar experience and em-

bodied in the planning of postwar economic reconstruction. Since the mid-1950s, however, the trend has been strongly the other way, with the exception of the Kennedy Round, itself an effort to stop the trend, or at least contain it. Chapters 4 and 5 deal with the establishment of and the trade policy issues raised by the European Coal and Steel Community, the European Economic Community, and the European Free Trade Association (and, briefly, the Latin American Free Trade Area). The author provides particularly valuable discussions of the unresolved issue of how balance of payments restrictions on imports should be applied when a member of such arrangements gets into difficulties, and of the serious problems raised by the association of overseas territories with the European Common Market, problems which excited little public attention at the time but planted the seeds of future difficulties in relations between developed and less developed countries. In evaluating the implications of these developments, Patterson makes the interesting point that since they evoked the Trade Expansion Act, their net effect may prove to have been favorable rather than unfavorable to nondiscriminatory liberalization of world trade if—as has actually happened—the Kennedy Round succeeds in achieving a substantial reduction of trade barriers on GATT principles.

Despite their discriminatory aspects, the EEC and EFTA can be argued to fall within the rules of nondiscrimination. More serious tendencies towards discrimination, in terms of positive espousal of discrimination as a principle, are evident in the use of discrimination as an overt tool of protection against low-wage competition, and in the demands of the less developed countries for preferential treatment of their exports of manufactures in the markets of the developed countries, which demands have been accepted as reasonable by a number of developed countries. The former trend is evident in the special treatment of Japan in GATT—"one of the more unsavory chapters in postwar international commercial policy" (p. 318)—and in the development of the "Long Term Arrangements Regarding International Trade in Cotton Textiles," discussed in Chapter 5. Patterson fears that this legitimation of the cheap foreign labor argument for protection could seriously hurt the less developed countries' export interests in the future. The latter trend is discussed in Chapter 6, which is particularly valuable for its marshalling of the precedents and policy discussions of the period before the World Trade Conference of 1964 publicized the proposal, and for its recognition of the subsequent weakening of the position on the issue the United States adopted at that Conference, by its support of the Ankara Agreement associating Turkey with the EEC, and the signing of the United States-Canada accord on trade in automotive products.

The concluding evaluation of the case for preferences substantially modifies the position Patterson adopted in his *Lloyds Bank Review* article of 1965, in the light of forth-coming work on the theory of preferences based on the concept of effective protection; while he continues to stress the political and administrative costs and difficulties of giving aid through preferences, he no longer denigrates their potential economic effects on a priori grounds, but instead argues the need for a major study of these effects to be undertaken.

There can be no doubt that the past ten years have witnessed a significant

reversal of the trend towards a return to the principle of nondiscrimination evident in the postwar decade. But it is questionable whether as yet this reversal can be called "a headlong flight toward a massive recrudescence of discrimination" (p. 395), threatening to undermine the whole process of negotiation of reciprocal tariff reductions. To take this view is to accept too readily recent words as evidence for imminent deeds; in particular, much depends on whether the 1968 meeting of United Nations Conference on Trade and Development proves a forum for world statesmanship or a wailing wall for stale complaints and recrimination. Nor does it seem very helpful to attempt to stem the tide by preaching the virtues of nondiscrimination, and warning of the costs of discrimination, the note on which the book concludes. One could instead argue that the frequent hypocrisy of the United States, in preaching nondiscrimination while practising massive continental protectionism, has induced first the Europeans and then the less developed countries to seek in their separate ways to obtain for themselves what they conceive to be the real source of U.S. economic power—a large protected market—and that what is needed to stem the tide of discrimination is not more sage preaching of nondiscrimination but more adventurous practising of free trade policies by the United States.

HARRY G. JOHNSON

*The London School of Economics
and The University of Chicago*

Economic Policies Toward Less Developed Countries. By HARRY G. JOHNSON. Washington: Brookings Institution, 1967. Pp. xvi, 279. \$6.75.

Despite the limited effect of the 1964 United Nations Conference on Trade and Development on the policies of advanced countries, it established a framework for continuing debate between the developed and underdeveloped countries that promises to endure. By juxtaposing the whole set of economic relations between the two worlds, UNCTAD called into question the fundamental principles which permitted a compartmentalization of trade, aid, and monetary policy in advanced countries. In each area, the claim was advanced that the existing international rules discriminate against the less developed countries and that taken together they seriously hamper the possibilities of development.

Harry Johnson's survey is one of the most stimulating and provocative contributions to the post-UNCTAD discussion. He brings out with great clarity and insight the essential features and interrelations among the leading proposals for improving international economic relations. Particular attention is given to three central questions: commodity agreements, trade preferences for manufactured goods, and the trade-aid option.

Johnson is at his best in exposing logical fallacies in arguments for various forms of interference with the free market. Protectionist approaches by both rich and poor countries are contrasted unfavorably with an optimal system which would combine free trade, realistic exchange rates, and the provision of aid on the basis of net resource requirements. Since unfortunately nothing approximating the optimal system appears politically feasible, the policy implications of the analysis hinge on comparisons among second-best, third-best, and *n*th best solutions.

One of Johnson's main contributions is to show the weakness of the U.S. argument against preferences for industrial goods, which is based on the fact that average nominal tariffs are already low. However, effective tariffs on value added are typically twice as high and those on products of interest to the less developed countries are higher still. Although preferences would create many administrative difficulties, these must be weighed against the drawbacks of other ways of stimulating manufactured exports.

My only serious criticism concerns Johnson's one-sided treatment of the trade-aid option. Here the choice of political assumptions is crucial to a realistic comparison of alternatives, and Johnson's assessments are more open to question. He implies that the administration of trade policy can be made enlightened and sophisticated, but that aid policy will inevitably be blundering and politically motivated. His implicit assumptions about the developing countries seem biased in the opposite direction: although they typically have inefficient trade policies and over-valued exchange rates, they are assumed to be better judges of resource allocation than the lending agencies of the advanced countries. While tariff negotiations are described with insight and realism, the process by which aid loans are negotiated and development policies influenced is ignored. A more balanced comparison would reveal some favorable aspects of aid as a means to better resource allocation, including pressure for better trade policies. Even Johnson is forced to conclude that "for the short run an increase in the supply of foreign aid would be more effective in supplying external resources for development than would the opening of trade opportunities" (p. 245).

The central facts which the United States refused to face at UNCTAD are (1) that most of the poorer countries must industrialize in order to transform their economies and raise their incomes, and (2) that the trade policies of the advanced countries have a dominant effect on the possibility of their carrying out this transformation. I would strongly support Johnson's advocacy of the free trade option over the protectionist approach favored by most of the underdeveloped countries if the aid part of the package could also be supplied. The problem is not disposed of if this effort fails, however, and the search for second-best solutions must be pursued. "What the United States cannot continue to do is to follow protectionist policies for itself, while using the language and concepts of the free-trade position to deny that these policies injure the less developed countries whose economic development it has pledged itself to help promote, and to reject their proposals for improvement of their trading opportunities" (p. 241).

Harvard University

Forward Exchange Speculation, and the International Flow of Capital. By HERBERT G. GRUBEL. Stanford: Stanford University Press, 1966. Pp. xiii, 192. \$6.50.

Forward exchange has been somewhat neglected in international economics because of the difficulty and narrow application of the concepts involved. Recently, however, it has acquired importance because of the possibility that it can be used to freeze the growing stock of short-term funds which can move

internationally in search of maximum interest yields and which thereby threaten the survival of independent national policies on interest rates.

Professor Grubel's book will serve the interest in forward exchange at three levels. It begins with a careful and thorough exposition of forward exchange that will be useful for those insufficiently familiar with international trade to absorb the subject from the concise expositions found in the journal literature. Just one slip was found in the development of the basic model, but it will cause confusion and should be eliminated: because the price of the forward exchange "insurance" demanded by those who place funds abroad for a higher short-term yield will be negative, the demand for it will *not* (contrary to pp. 42-44) become abnormally small and very insensitive to reductions in price when the value of the foreign currency held is close to its minimum value (the minimum set by the lower support point).

The author provides next some partial but worthwhile statistical tests of the validity of conventional forward exchange analysis. Some of the tests parallel those made prewar by Einzig and Bloomfield, but are of course more rigorous; they use weekly data from several countries and cover a variety of conditions which are of interest in forward exchange policy: the disturbed conditions of 1955-58 with partial inconvertibility of major European currencies, the stable, "normal" period of 1959-60, and periods of speculation against the dollar in 1960-61.

One of the tests confirmed the theory that in normal, nonspeculative periods the movement of short-term funds in search of higher interest rates would continue to the point where the net yield advantage (after payment of the cost of forward exchange cover) was very small, under one-half per cent. Unfortunately, the author did not have suitable data for testing whether it was only a small or a large movement of funds which caused the price of forward exchange "insurance" to move by enough to absorb most of the advantage from higher short-term interest rates abroad. If the price elasticity of supply of forward exchange actually was low—the prevalent view until the 1960s—then both the importance of the forward exchanges in international economics and the need for international harmonization of interest rates would be greatly reduced. (An approach to the necessary kind of information through the use of econometric models has been made by Jerome Stein, *Am. Econ. Rev.*, March 1965, and *Rev. Econ. Stud.*, April 1965.)

A test yielding indirect evidence that the elasticity of supply of forward exchange should—under certain conditions—be high enough to meet the demands arising even from very large transfers of short-term funds was made by determining that stabilizing speculators not having any advance information could have earned high rates of profit on funds invested in the forward sterling market during 1955-61. However, the demonstration is not convincing, even given continuation of the earlier conditions, not only because certain risks, costs, and enlargements of the necessary investment base were explicitly excluded from consideration, but also because income taxes on the resulting 16 per cent to 30 per cent annual rates of profit as well as the need for an additional amount of investment where the higher rates were claimed were neglected; and the fact that dealing at the "wholesale" exchange rates necessary for

earning the assumed profits required a capital stock of many millions per speculator was ignored.

A test which provided some ground for worry about the validity of the accepted analysis concerns equality in the costs of a foreign currency bought direct and bought by first acquiring a different currency. This test was successfully passed by spot exchange rates, but where Canadian dollars were concerned the nearly cost-free spatial arbitrage of the exchange dealers failed, for reasons unknown, to eliminate cost discrepancies of as much (according to a check of the author's basic data appended to the book) as one per cent in periods of exchange rate speculation.

The final part of Grubel's work provides an exhaustive and quite useful theoretical analysis of the possibilities for protecting a country's exchange reserves under a variety of conditions through official intervention in the forward exchange market. It should be noted, however, that the readers who benefited from the initial, elementary exposition may not survive these chapters. The inevitable unwieldiness of the multiple relationships which must be analyzed, complemented by a sprinkling of typographical errors and expository slips, will deter most nonspecialists from making the effort necessary for negotiating the terrain. (At the extreme, despite having presented similar conclusions through use of related concepts, this reviewer found the analysis of the infrequently examined triangular arbitrage problem practically impenetrable because it combined garbled text within mislabeled diagrams.)

Despite some concern about triangular problems, Grubel remains an advocate of official forward intervention. His own presentation of the case seems to provide somewhat weak support, however, for he states that official intervention can be undertaken only when the authorities are sure of success in defending the exchange rate (i.e., when the intervention is least needed); the capital losses in case of an ultimate forced devaluation are too great to risk. This policy would make forward intervention, when it was used, doubly successful, for bear speculators would know from the fact of official intervention that their case was hopeless. But the mirror-image consequence is that refraining from intervention because success is not a certainty would encourage the bears and convert a merely possible forced devaluation into a likely one. This implication of Grubel's analysis weighs against any use of official intervention. However, its importance is diminished when allowance is made for those possible enlargements of official exchange holdings (and hence reductions of the amount of net capital loss from devaluation) which official intervention can produce but which the author did not include: the diversion of traders and destabilizing speculators from buying spot exchange to buying the bargain-priced forward exchange being offered by the authorities.

WILLIAM H. WHITE

International Monetary Fund

Trade Policy and the Price System. By L. B. YEAGER AND D. G. TUERCK. Scranton, Penn.: International Textbook Co., 1966. Pp. vii, 294. \$3.95.

"The trouble with most economists," a colleague of mine recently remarked, "is their damn fair-mindedness. They see every side of a question." The first

virtue of this textbook is its refreshing, almost brazen, advocacy of unilateral free trade for the United States. The opening three chapters state the positive case for unfettered commerce, the next eleven catalogue and ably expose protectionist arguments, and the final two discuss strategy questions.

A second virtue of *Trade Policy* is its lively style. The title might suggest a geometrician's paradise of box diagrams, preference curves, and marginal cost schedules, but Yeager and Tuerck spend little time expounding these mysteries of the "Price System." Instead, relying on plain English, they give the student a readable, closely reasoned, analysis of policy arguments. One novel expository technique: the authors liberally quote protectionist testimony taken from Congressional annals. This testimony not only provides comic relief, it also illuminates "practical" thinking on trade matters.

A third virtue of *Trade Policy* is its use of fresh institutional material. The theory of free trade has changed little in the past half-century. But each generation of students deserves to see important policy issues framed in familiar surroundings. Yeager and Tuerck are better landscape architects than most textbook writers.

If the authors were to add another section, they might explain why, given its academic credentials, free trade enjoys so little political support. Certainly, the weakness of consumers, the strength of protectionists, the supposed sanctity of \$35 gold, and plain economic innocence all play a part. But it puzzles me why the 150 largest supercorporations care so little for free trade. These firms would surely benefit from complete elimination of trade restrictions, thanks both to their commanding grasp of technological and managerial skills, and to their present concentration in exportable goods. Do these powerful natural allies so poorly understand economic phenomena that they only see those tariffs which protect their *own* products? I hope that the explanation runs deeper than that.

The authors emphasize certain drawbacks in the free trade case. The static gains accruing to the United States from unilateral free trade would not be enormous, surely less than \$8 billion. This figure is exceeded by *quarterly* GNP increments during a good year. Moreover, devaluation of the dollar, either explicitly or through fluctuating rates, is recognized as a concomitant of unilateral free trade.

Unfortunately, Yeager and Tuerck are not altogether candid on certain other aspects of the free trade case. Labor must speedily relocate if gains are to be fully realized. The relocation burden would fall most heavily on labor-intensive, low-wage, "backward" industries. There are plenty of instances where the price system has accomplished such adjustment only slowly and painfully.¹ To be sure, many economic changes besides tariff reduction contribute to human distress in these least adaptive sectors. But Yeager and

¹ R. Vernon makes the point that free trade in advanced nations, like technological progress, would sacrifice weak industries for the immediate benefit of strong, better earning, activities. In view of this probable outcome, it would be interesting to estimate roughly the kind of welfare function and adjustment speeds required to *negate* the apparent money gains of free trade. Incidentally, free trade in developing nations would probably most penalize the newly ascendant and relatively prosperous manufacturing centers.

Tuerck see widespread misery as an argument *against*, not *for*, broad policies of adjustment assistance.

When the authors discuss infant industry and diversification tariffs, they neglect to emphasize the relevance of these arguments for emerging nations. Thus, while the thrust of *Trade Policy* is unfettered commerce for the United States, the student might finish this book believing that all nations should abolish trade restrictions.

I am sorry the authors throw cold water on those who advocate American tariff reduction and quota liberalization as a way of promoting economic growth among developing nations. But Yeager and Tuerck prefer to see free trade grounded entirely on self-interest. They fail to appreciate that "... self-interest . . . may serve as [a] powerful source of social energy, but not as [a] powerful avatar of the social imagination."² Gains of \$8 billion are marginal to the American economy. Gains of half that amount would have, for the poorer nations of Asia, Latin America, and Africa, very substantial consequences.

These omissions, policy non-recommendations, and nuances of emphasis, betoken more than simple neglect. Yeager and Tuerck are both associated with the economics department at the University of Virginia, which is ideologically close to the University of Chicago's department. As they state in the preface, "... we use [the free trade versus protection issue] for definiteness in comparing two broad lines of policy, one that welcomes and one that mistrusts the working of a free price system." Starting with this objective, *Trade Policy* belittles the need for *any* government interference in the marketplace.

The case for free trade is a strong case. It has survived since Hume despite concentrated and persistent opposition. Whether it can survive the company of Professor Friedman's policy nostrums remains to be seen.

² R. L. Heilbroner, *The Limits of American Capitalism*, New York 1965, p. 127.

The Future of the Dollar as an International Currency. By ROBERT Z. ALIBER. New York: Frederick A. Praeger, 1966. Pp. 169. \$6.00.

There is a continuing need for informative studies which deal with the complex issues of international currency. The topic is highly controversial, although not all can join in the controversy objectively because the issues are burdened with technicalities and prejudices. To the average reader, the topic of international money seems to have a decided mystique. For long periods of history, gold has served an important function as international currency. More recently, however, its function has declined relatively as the currency of the United States has assumed new and important international dimensions.

Professor Aliber's book deals with these new functions of the U.S. dollar in its expanding global activities. In brief, the most significant point which emerges from this study is that the international status of the dollar has been determined not by the U.S. authorities but by the preferences of other countries. Domestic as well as international economic objectives of the United

States therefore, have had to be modified in order to deal with international dimensions of the currency.

In order to deal with the future role of the dollar, Aliber has found it necessary to provide much interesting although not provocative background material. Included are discussions on international financial cooperation; the attempts to establish international financial policy; the special difficulties of reserve currencies and the conflicts which can arise between national interests and international financial arrangements. Only the final chapter deals directly with the topic suggested by the title of the book.

It is pointed out that the future of the dollar, as an international currency, will be conditioned largely by the institutions which emerge as payments mechanisms or as credit creating bodies. Adjustments by the United States to payments imbalances cannot be arrived at without affecting the volume of foreign reserves required by expanding world trade.

Aliber considers it extremely unlikely that institutional arrangements can be established that would obviate the need for reacting on an *ad hoc* basis to payments imbalances or that would dismiss the need for providing finance for payments deficits. This arises, he thinks, because countries cannot decide among themselves who should initiate adjustment. Aliber feels that priority should be given to the further negotiation of formal and informal multilateral arrangements so that adjustment mechanisms are more adequately provided for.

The author seems to weigh rather lightly the disadvantages of an increase in the world gold price, or resort to a system of flexible exchange. He finds, on balance, economic as well as political advantages accruing to the United States from either of these measures. Aliber sees some advantages in a system of flexible exchange rates in which the U.S. authorities cease to buy and sell gold at a fixed price. He claims that in a world of flexible exchanges the dollar would possibly be the best store of value given the long term record of price stability in the United States. None of the devices widely broached as solutions to contemporary difficulties would seriously demote the dollar as a prime international currency. At present, it is the dollar which gives gold its value and not the other way around.

Aliber attempts to show the value of having options for policy making. However, the chapter that deals with the decision making process is rather disappointing. Instead of being taken behind the formal conference tables of the international bodies, we are presented with a quick tabulation of formal authority for several of the international financial institutions with a hasty analysis of power in the executive branch of the U.S. government. The policy options are not precisely outlined by the author. Many sections of the book are repetitive and the use of quantitative material is neither original nor deft.

There is an attempt in this book to produce a balanced view of the alternatives open to the United States and other countries in dealing with serious problems of payments deficits and reserve currencies. This book does not argue one consistent point of view. Rather it is for all those desiring to know the outstanding issues in a multicurrency world.

KENNETH J. ROTHWELL

University of New Hampshire

American Investment in Australian Industry. By DONALD T. BRASH. Cambridge: Harvard University Press, 1966. Pp. xv, 366. \$7.50.

Dr. Brash's book not only is about American investment in Australia, it is itself a part of it: the name of Harvard University Press turns out to cover a book which was "printed and manufactured in Australia." The study represents the author's doctoral thesis instigated and written under the auspices of Professor Sir John Crawford at the Australian National University. The subject matter is essentially a report on the results of a survey of 208 manufacturing companies operating in Australia in 1962 that were at least partially American-owned. The criterion for inclusion was a minimum of 25 per cent American ownership, "American" being defined to include United States and Canada. The purpose of the book is "to add to the meagre stock of information currently available on the subject of foreign investment and to attempt answers to at least some of the questions being asked in the field" (p. 7).

The author starts with a discussion on Australian attitudes toward foreign investment—an issue of some concern especially since the spectacular success of General Motors-Holden in the 1950s. As would be expected, there is a considerable degree of ambivalence about this matter, perhaps best illustrated by the contrast between the negative attitude of the Federal Labor Party and the encouraging actions of the party's State and local dignitaries. Following this introduction, the author proceeds to examine the importance of foreign capital to see whether it justifies the public concern which it provokes. The evidence presented by the author indicates that American-affiliated companies in Australian manufacturing industry made up a little less than 7 per cent of total employment, with British and other foreign affiliated companies raising the foreign share to no more than 20 per cent. If value of production rather than employment is used as a yardstick, the respective percentages are somewhat higher. Thus the magnitude of the foreign share is far from negligible and may justify interest if not concern.

Most of the remaining chapters deal with the results of the survey conducted in 1962. These results are grouped into topics such as reasons for investment, ownership patterns, management characteristics, transfer of technology, and so on. With minor exceptions the method is always the same: the author introduces the topic, presents answers in tabular form, gives a verbal description of the main features of each table, quotes some respondents who gave interesting or illuminating answers, and adds his own comments and observations. No formal hypotheses are set up and no statistical tests are attempted. Only two chapters depart substantially from this pattern, Chapter 8 which contains a discussion on "some effects on Australians" and Chapter 11 called "Conclusions." Both chapters deal with foreign investment from a theoretical standpoint.

In general, the approach of the author is purely empirical. This is rarely rewarding, but in the case under review the approach leads to particularly serious drawbacks. The first of these is the obvious lack of guidance by economic theory in the choice of questions asked in the survey. This neglect of economic theory is noticeable throughout, but it is most striking in the chapter on reasons for investing in Australia. The respondents were given a choice of twelve reasons none of which included profitability; it took one of the responding ex-

ecutives to spell out that "the big reason a company decides to invest abroad is because it believes it can get a better return on its investment abroad than at home" (p. 40). The second drawback arises when we come to assessing the answers: while we are told here and there that such and such result is "significant," we are never told for what it is significant. Another difficulty of neglecting theory is that it leads the author to an implied surprise (if not moral condemnation) when he finds evidence of profit-maximizing behavior. Thus, for example, in the chapter on management the author takes a long journey to come to the conclusion that "there is little doubt that most American subsidiaries, like most Australian companies, pay wages which are no higher than necessary" (p. 135). Finally, there are answers which have little or no informational content—for example, statements about demand without mentioning price, or comparisons of salaries without mentioning productivity differentials. The frustrations of the reader on this account are not alleviated when reaching the final chapter where the conclusions presented are not related to the results of the survey but are based on an almost independent theoretical discussion. In any case, at least one conclusion, viz. "as long as private direct investment benefits Australia, it should be encouraged" (p. 286), is not very profound.

But it would be uncharitable and unfair to Brash to finish this review on an entirely negative note. The author has done a great amount of work in collecting the survey results and in gathering other statistical information from a variety of sources. All this material is well organized and interestingly presented. The style of writing is lively and well balanced: the one joke in the book is offset by one equation. But the most important part is that the author's vision is in the right place. He sees quite clearly that any criticism of the behavior of American-affiliated companies should be directed at the Australian institutions which permit restrictive trade practices and give generous tariff protection to local manufacturers.

Business Finance; Investment and Security Markets; Insurance

Corporate Dividend Policy. By JOHN A. BRITTAİN. Washington: Brookings Institution, 1966. Pp. xvii, 254. Paper, \$2.50.

The purpose of this book is to estimate the determinants of corporate dividends and to isolate the influence of tax laws on dividend payments. Starting with the standard Lintner hypothesis, Brittain tests the importance of various alternative measures of profits and cash flow in the dividend function. He then examines the effect of various other variables on the explanation of dividends. Next several alternative regression equations found to be successful are estimated at the industry and firm level. He then attempts to pool time series and cross section data as a further method of testing the results. Finally the findings are summarized and the implications of the results for policy purposes are analyzed.

The early chapters of this book are well done and present little cause for disagreement, following as they do the familiar work of Darling, Kuh, and others. It is shown that cash flow—profits after taxes plus depreciation—explains dividend behavior much better than balance-sheet profits after taxes or other series of profits adjusted by more realistic depreciation allowances. For the aggregate function, the fit (adjusted for degrees of freedom) is better when cash flow is used alone than when profits and depreciation are both included explicitly in the equation.

Brittain tests the two halves of the sample period (1920-41 and 1942-60) separately and finds that the corresponding coefficients of the two subperiods are significantly different. This suggests that increases in income tax rates result in lower dividend payout ratios. Several "tax shelter" variables are proposed to test this hypothesis. The one chosen is the marginal tax rate for that income level which cuts off recipients of 25 per cent of all dividends at the top of the income scale. This rate of course varies from year to year but has averaged about 20 per cent for the interwar period and 60 per cent for the postwar period. Such a variable is highly significant and improves the fit of the equation substantially. However, with the inclusion of this tax shelter variable Brittain finds that the fit of the equation is better if profits and depreciation are treated separately instead of being combined in a single cash flow term. Further experimentation leads to the choice of the ratio of balance sheet depreciation to "realistic" depreciation (figures of the Machine and Allied Products Institute are used) for use in additional regression analysis.

In his chapter on other factors influencing corporate dividend policy, the author tests the effect of the interest rate, growth rates (measured by the change in sales), corporate tax rates, investment demand, corporate liquidity, inflation, and changes in stock prices in the dividend function. None of these variables is successful except the interest rate. These results may partially be due to the way in which the dividend function is estimated. Brittain uses the form

$$(1) \quad \Delta D = a_0 + a_1 r P - a_2 D_{-1}$$

where D = dividends, P = profits, and the short-run payout ratio $r = \Sigma d_i X_i$ (X_i are all the other variables being tested in the equation). Thus in actual estimation all of the X_i are multiplied by profits, which leads to serious problems of multicollinearity. Brittain comments on this at one point and calculates the matrix of simple correlation coefficients, most of which are well above 0.9. This problem could have been mitigated by dividing the equation by profits and estimating the dividend yield as the dependent variable, i.e.

$$(2) \quad \frac{\Delta D}{P} = b_0 + b_1 \Sigma d_i X_i - b_2 \frac{D_{-1}}{P}.$$

Writing the equation in this way would also have made it easier to see that the significantly negative interest rate coefficient measures the general inverse cyclical relationship between dividend yields and interest rates. It is not clear

whether this relationship can correctly be transformed into the causal relation that high interest rates "may discourage dividends by making internal finance relatively more attractive" (p. 104). If such a direction of causality does exist, it would then seem that other sources and uses of corporate funds would also be important determinants of dividends; yet this is found not to be the case.

The results obtained from the industry and firm time series regressions are broadly consistent with the aggregative results. Of the 17 industries subjected to examination, depreciation or cash flow is significant in 12, the tax-shelter variable in 13, and the interest rate in 7. For 40 individual firms the findings, as might be expected, are not so good. Depreciation or cash flow is significant in 12 regressions, the tax-shelter variable in 16 and the interest rate in 11. It is not clear whether Brittain considers these latter conclusions satisfactory. At first he writes "... the frequent significance of these variables is impressive in light of the relative stability of the aggregate payment ratios for this group of firms" (p. 159) but later decides that "the earlier findings of this study concerning the influence of depreciation, tax rates and interest rates were only partially supported by time series analysis of individual firms, and were given no support by the firm sample total" (pp. 187-88).

In his last chapter of empirical results "Pooling of Time Series and Cross-Section Data," Brittain considers cross-section analysis for the first time. This could have been the most interesting chapter, but in this reviewer's opinion his method contains some defects. The cross-section regressions consist of estimating the simple function $D = b_0 + b_1P$ for all 40 firms and obtaining a given value of b_1 for each year. After spending a good part of the book showing that dividends depend more on cash flow rather than net profits, it is a little surprising that Brittain reverts to the latter measure at this point in the analysis. Furthermore, no adjustment is made for heteroscedasticity so that the estimates are dominated by the larger firms. While this may not be inappropriate, which is the position taken by Brittain (p. 174), the resulting parameters are not cross-section estimates in the usually accepted sense of the word. More serious, this lack of adjustment virtually forces the equation through the origin, so that the estimate of b_1 is simply the average dividend/profit ratio. The time series of b_1 obtained in this manner is then regressed on the depreciation ratio A/A_2 , the tax shelter variable t_{25} , and the interest rate, or

$$(3) \quad \frac{D}{P} = c_0 + c_1 \frac{A}{A_2} - c_2 t_{25} - c_3 i.$$

This equation is identical to equation (2) above, with the important exception that lagged dividends are now excluded. Not surprisingly, the fit is much lower and significant positive autocorrelation of the residuals appears for almost the first time in this study. This suggests the inclusion of additional variables in the equation, and investment and corporate liquidity (both relative to sales) are again tried. This time both are significant. If these results are to be

taken at face value, investment affects dividend policy in the long run but not the short run. Brittain states, "the investment coefficients have the expected negative sign, supporting for the first time in this study the proposition that a high investment demand will tend to restrain dividend policy *in the long run*" (p. 183, italics added). Since investment is measured relative to sales, this implies that more capital-intensive firms have lower long-run dividend payout ratios. Since highly capital-intensive firms such as public utilities have relatively high payout ratios, this view does not seem to agree with the facts.

In Brittain's concluding chapter, he summarizes the results of tax rates on dividend policy and finds that "... federal fiscal policy exercises substantial influence over corporate dividend-saving policies, even without resort to special devices such as an undistributed profits tax" (p. 207). This comes about through the importance of depreciation allowance and individual income tax rate variables in the dividend function as well as the obvious relationship that a change in corporate income tax rates will modify the percentage of profits available for dividend payments. He also discusses the pros and cons of corporate income retention, but does not take sides on the issue. The analysis in this section is a bit sketchy; probably the claim that high corporate saving promotes the concentration of economic power deserves more than one sentence.

In summary, the effects of depreciation allowances and tax rates on corporate dividend policy have been shown by Brittain to be quite substantial at the aggregate and industry level. While this section is thoroughly and competently done, it does not offer a great deal of new information. Since dividends are merely one use of corporate funds and as such must compete with alternative uses, particularly investment, it is somewhat disappointing that this important relationship was not studied in greater detail.

MICHAEL K. EVANS

University of Pennsylvania

Insider Trading and the Stock Market. By HENRY G. MANNE. New York: The Free Press, 1966. Pp. xiii, 274. \$6.95.

Professor-lawyer Manne suggests that we take another look at the assumption that insider trading is harmful to the welfare of stockholders and the workings of our economic system. His book contains no empirical evidence on that point, but rather a lawyer's defense, well documented with legal, economic and financial references.

The argument goes something like this: (a) no one has established proof that insider trading is harmful, barring fraud and manipulation which are illegal regardless of insider rules; (b) existing laws prohibiting insider trading are difficult to administer and there are many ways to avoid detection; (c) insiders can provide an important economic service, that of innovation in the firm, which is not adequately compensated by present methods of salaries, bonuses, and options for management; (d) there is a market for valuable information where an innovator could take inside information and receive compensation for innovative changes in a company; (e) most long-term investors are not harmed by insider trading; therefore (f) insiders should be allowed free

trading in their company's stock as a means of encouraging and compensating innovation.

To complete his brief, Manne concludes with a discussion of the exceptions, indicating that: (g) most objections against corporate insider trading are not persuasive and (h) government employees should not be allowed to trade on inside information, as they have no innovative contributions to make toward corporate activity (administration of rules is again difficult, but necessary in this case, according to Manne).

Manne has prepared his brief well, although it is not without logical flaws. As he notes after one argument, "Some of the evidence to establish this point is a bit dated to be sure, but recent studies indicate no fundamental changes. And, if empirical evidence is lacking, we can fall back on logical inference" (p. 75). The book is offered as a "theoretical treatment" of the subject; and Manne hopes that it will be convincing without the much-needed empirical research which he calls for from time to time. Perhaps the greatest value of the book, however, is that it does emphasize the need for research to establish some background for what is otherwise only a debate in logic.

Let us concede that it has not been proven that insider trading is always harmful, that detection and administration under present rules are difficult, and that innovation is important but difficult to compensate. We might even concede that stock market trading is one method of compensating inside innovators, although it is difficult to imagine a private information distribution system within a corporation where only the innovator—or those he wishes to favor—would be compensated. Still, we cannot agree that Manne's conclusion (point f) follows.

The insider will have limited financial means with which to take advantage of his inside information, will have to act fast, and may, himself, affect the price of the stock so that he receives only a small profit compared to the actual value of the news. He can nonetheless make up this loss by the barter of stock information, according to Manne.

To establish the presence of a market for such information, Manne names four essentials for an information clearinghouse: (1) it is a repository of valuable information, (2) it can distribute valuable information to those who make deposits of information, (3) it can maintain a priority or preferred list indicating those entitled to information, and (4) it has some method (such as discretionary accounts in brokerage firms) to assure that individuals do not withdraw more information value than they are entitled to. Manne then shows that investment banking houses, including large brokerage houses, could perform each of these functions separately. Therefore, they must be available to provide the entire package, orderly trading of valuable inside information. The conclusion: "Until convincing evidence to the contrary is available, we should assume that this market exists and is efficiently maintained by important functionaries in the financial community" (p. 75).

Although informal bartering of information is undoubtedly present in investment banking and elsewhere among those of sophistication and position, this does not imply that these channels are open for the random innovator pictured by Manne. This innovator, or entrepreneur, is not top management but,

rather, anyone with an idea up or down the line. Is there, indeed, an organized market for such innovators to trade information? They may have a bit of information to trade but once in a lifetime and may not be privy to these high-class bartering techniques. Certainly there is no evidence of investment banking firms including the casual stranger in their trading circles. Will the non-management innovator be able to convince anyone of the worth of his information? Will he have the funds to take advantage of the information by independent trading?

But insider rules are directed primarily at those in control—officers, directors, or 10 per cent shareholders of a corporation. The officer-innovator among the insider group, in fact, can be compensated by salaries, bonuses, and options. “But what incentive does he have to perform the unusual or to revolutionize a company or an industry?” (p. 133). Surely our present corporate system, although not perfect, has found some method of evaluating the services of officers and rewarding those of greatest value. Furthermore, from what we know of entrepreneurs, it must be assumed that they are motivated by more than monetary gains.

A fundamental point of the book is that no significant injury to corporate investors can result from insider trading; and here we must take issue. Manne’s point is simple: the effect of insider trading is to raise the price of a stock to where it represents the new value after the inside information is made public. Instead of random short-term traders or speculators benefiting, the insider benefits. The long-term investor merely realizes an increase in stock value and is otherwise unconcerned. (Although Manne contends that the effects of good news are more important than the effects of bad news, it is difficult to agree with him on that point. The long-term investor argument is simply not appropriate when bad news is concerned.)

Even long-term investors sell at some time; and many of them may be caught in the change between one value and a higher one, while insiders profit. Furthermore, the long-term investor may be influenced specifically by a rapid increase in a stock price, without apparent reason, and may sell before the stock reaches its “new true” value.

We cannot be as unconcerned about short-term traders, speculators, and specialists as Manne is. Manne is aware of the need for a continuous market in the shares of a corporation, but he would substitute trading by discouraged speculators with trading by the deserving insider. Presumably the marketability of a stock would be maintained. However, it is difficult to see how occasional insider trading in large volume can replace the daily activity of short-term traders and speculators in creating a continuous market.

But the most important omission in the book is the institutional investor. These long-term investors enter the market at frequent intervals because of the size of funds they have to invest. They sell frequently also, although we would hesitate to consider them short-term traders or speculators. Is this large share of the market also to watch out for itself? Or shall we put institutions in the market for insider information? What effect would such power have on the stock market?

Obviously we need much more empirical research before we can argue that

few worthwhile investors are hurt by insider trading. Even if Manne is right about entrepreneurship and compensation, we would like to see some evidence regarding the many different types of investors and investment decisions likely to be affected by free trading by insiders.

Business Organization; Managerial Economics; Marketing; Accounting

Accounting: A Programmed Text. By JAMES DON EDWARDS, ROGER H. HERMANSON, AND R. F. SALMONSON. Homewood, Ill.: Richard D. Irwin, Inc., 1967. Pp. xxi, 1613, Two Vols., \$8.95 each.

The techniques of programmed instruction have gained increasing attention in recent years, and a programmed instruction format has been utilized in business and economics texts, including accounting principles. However, this new two-volume text is the first *comprehensive* treatment of basic accounting employing programmed instruction methods.

As the authors concisely point out in their preface, "the primary objectives, indeed, the advantages, of a programmed text are three-fold: (1) to permit a more active participation by the student in the learning process; (2) to permit immediate reinforcement of correct understanding and immediate correction of misinterpretations; and (3) to permit a possible reduction in the contact time between each student and instructor with no loss of comprehension or coverage of the materials studied." The advantages of programmed instruction are well established and the utility of the method is unquestioned. Nevertheless, possibly because the technique is relatively new, it has not been applied extensively in business and economics texts.

The scope of materials covered in this new accounting principles text resembles that of others, although the arrangement of subjects is significantly different. Topics included are: financial accounting, financial management, and managerial accounting. Managerial accounting has been given more emphasis here than in some books. This may enhance the value of the text for nonaccounting majors interested in developing an understanding of the application of accounting data to decision-making. Nevertheless, the nuts and bolts techniques of data recording, classifying, and summarizing have not been ignored.

The text is divided into two volumes, each suitable for a one-quarter or one-semester course. Volume I is devoted to consideration of accounting functions, data accumulation, the concept of the accounting cycle, and recording procedures. The arrangement of materials represents a significant departure from traditional texts; i.e., certain subjects often deferred to the end of a one-year program are presented early in the first volume, while other principles usually stressed relatively early in most texts have been relegated to the latter part of the second volume.

The revised organization should be very useful in the early development of

students' awareness of the accountant's role in a modern business enterprise. Further, economics students may find the arrangement of topics valuable because the utility of accounting data can be appreciated without becoming deeply involved in recording and data accumulation techniques.

Volume II is divided into three sections: earnings determination and asset and liability valuation; internal accounting; and special topics, which include discussion of subsidiary ledgers and journals, the voucher system, and single proprietorships and partnerships. The development of special topics at the end of Volume II represents an important departure from the customary presentation. No major weakness appears to have resulted from the new arrangement. A basic understanding of some of the problems of record-keeping may be adequate for students, many of whom will not become professional accountants. Placement of detailed recording procedures in the latter part of Volume II enables an instructor to omit more than an introduction of the subject early in the course, but include the material for comprehensive coverage if desired. The authors' decision to de-emphasize recording procedures and partnership accounting is a logical departure from traditional approaches, and one which more adequately fulfills the requirements of contemporary students.

Each chapter in the text includes a summary of important concepts, a glossary of terms, and a review of principles through questions, exercises and problems. Further, supplementary review questions, exercises and problems form an appendix at the end of each volume.

A note about certain structural techniques in the text is necessary. This programmed text employs the scrambled method of materials presentation, and does not follow the page-by-page progression found in standard texts. A concise explanation of the programmed method is included in the preface to each volume; and a few moments spent in understanding the scheme of presentation is vital to effective utilization of the text.

In summary, this two-volume text is well written, concisely organized, and it represents a substantial departure from the format of traditional accounting texts. Educators faced with constantly increasing enrollments and rising costs have been offered an alternative to present methods of accounting principles instruction. With publication of this text, the programmed instruction approach finally has moved toward maturity in the presentation of business subjects. Its success may presage application of the technique to other business disciplines and to economics subjects as well.

Industrial Organization; Government and Business; Industry Studies

Competition and Oligopsony in the Douglas Fir Lumber Industry. By WALTER J. MEAD. Berkeley and Los Angeles: University of California Press, 1966. Pp. x, 276. \$6.00.

While the title of this book refers to the Douglas Fir lumber industry, shown to be a subset of the national market for softwood lumber, the most

original and useful analysis deals with the local oligopsonies in the purchase of timber from federal lands. Little timber is sold by other owners. Within the two-state region of Oregon and Washington the author identifies 43 "working circles," or local timber markets, each delimited by the cost of hauling logs to established sawmills. The intensive study of these local markets is delayed by an overly meticulous development for the national lumber market of the familiar structure-practices-performance procedural steps from timber ownership through sawmill operations to selling and distribution of lumber. Not surprisingly, this national market is found to be competitive. With the expected prices for lumber in that vast market as data, the few mills located so that they can economically cut and saw particular stands of timber are cast in the oligopsonists' role. Added features influencing timber buyers' behavior are the government's practices in selling timber and the fact that some mills have the alternative of cutting timber they own.

Because this local market oligopsony must reflect the efficient size of sawmills, the survivor test is applied to changes over a decade in shares of regional output by mills of different sizes. While the author notes some of the difficulties in applying this test he does not recognize that location affects costs and feasible mill size. The only available measure of mill size is board feet of output. This groups together the quite unlike "dimension" mills turning out only lumber of two inches or more in thickness and "grade recovery" mills producing a wide variety of thicknesses and widths. Fortunately what these faulty data show—a marked increase in the share of regional volume obtained by the middle-size mills—is reinforced by the engineers' estimates of minimum optimal size of sawmills built *de novo*.

While that scale is not so large absolutely as to pose a serious capital supply problem for a new mill, the volume of an optimal plant would add such a large percentage to the local demand for timber that Bain's "percentage effect" barrier to entry is high. A potential entrant could anticipate that the price of timber would be increased substantially by his addition to the demand. The likelihood of this outcome would be enhanced by the fact that the amount of timber offered by the government is unaffected by the price of timber.

Buying behavior by existing mills is conditioned by several unique factors. A floor is placed on bid prices by the government's appraisal price. Local mills face the possibility, however, that a mill outside the working circle may bid, but only over the hurdle of substantially higher costs for hauling the logs. The government's policy is to sell timber stands when they are deemed to be mature regardless of whether it expects a high or low price. Consequently, the amount of timber put up for sale in a particular call for bids is perfectly inelastic, and the same condition holds for a succession of timber sales. (The supply curve in the chart on page 166 is confusing.) However, mills that own timber may elect to cut more of these trees when lumber prices (and presumably the competitive bid prices for government timber) are high. This alternative tends to put a ceiling on what is bid for timber. Furthermore, various mills' demand for timber from a particular government offer must reflect their differing backlogs of purchased but uncut timber. If this timber is not cut on schedule it goes up for bid again. A lucid summary of these facts and of their

significance would have helped the reader to follow through the detailed study of bidding behavior.

Against this factual background and by use of bargaining and duopoly theory, the author makes an illuminating and skillful exposition of the bidding process which can be only highlighted here. There is more than a suggestion of collusion on occasion, with evidence also of frequent breakdown of tacit and what may be formal agreements. There is much attention to behavior of individual bidders whose situation is well known by rivals. At least some outcomes are predictable in light of the number and characteristics and the current operating situation of various mills. Sometimes longer-run considerations enter, both in the actions of a particular buyer and in a united front against bidders from outside the working circle.

There emerges a fascinating and instructive moving picture of an oligopsonistic market in operation, the results of which are tested by regression analysis. A statistically significant negative relationship is found between the *ratio* of the sale price to the government's appraisal price and each of the following independent variables: the absolute size of bidders, the number of bidders, and the size of the block of timber up for sale. The latter is positively correlated with the sum required to build the access roads. These findings mean that smaller buyers are generally at a disadvantage in bidding.

Questions follow about the government's practices in timber resource management and in setting the conditions for bidding for timber. Some of these handicap bidding by small firms. Particularly where bidders are numerous enough and independent in their interests for the price to be competitive, the large margin by which the government's appraisal price is set below what proves to be the sales price suggests deficient analysis by those setting the appraisal price. Consequently, this study not merely tests theories of behavior of a few-buyer market but also points out defects in public policy and in the decisions made in its application.

Labor Economics

Married Women in the Labor Force: An Economic Analysis. By GLEN G. CAIN. Chicago and London: University of Chicago Press, 1966. Pp. xiii, 159. \$6.50.

To the growing stock of empirical studies on labor force participation, this compact monograph is a welcomed and highly important addition. The immediate focus of Professor Cain's study is on the determinants of participation decisions by married women in the United States at a point in time—a subject of great interest in its own right. But his main objective is a better understanding of why Negro married women have higher participation rates than their white counterparts, and why the participation of both groups has increased over time.

The book consists of four chapters and nine appendices. Following a short introduction that sets forth the plan of the book, Chapter 2 develops a the-

oretical model of participation decisions, including its application to aggregated and disaggregated cross-sectional data, and reviews previous studies of participation. The third chapter contains Cain's very extensive findings, and the fourth summarizes his main conclusions.

While the book is clearly written, the sheer volume of regressions summarized in Chapter 3 makes that chapter rather hard to navigate, and so does the fine print in some of the tables. (Table 20, for example, manages to compress all of the coefficients from eight multiple regressions into 3.4 square inches of space—a typographical tour de force that may deserve a prize, but not from the reader.)

Cain's model, constructed on theoretical foundations developed by Jacob Mincer and Marvin Kosters, relates the wife's participation decision to her market and nonmarket earnings opportunities, family income (minus her earnings), and tastes. The problems of finding satisfactory empirical measures of these variables and estimating their effects on participation by means of single-equation, least-squares, multiple regression techniques are carefully explained.

The author's review of the literature does not give the reader much overall perspective on what previous studies have unearthed, but it does provide an excellent critical assessment of their individual achievements and shortcomings. Empirical research in this area—particularly the selection of explanatory variables—is beset with many pitfalls, and Cain points out a number of instructive examples.

Cain's main contribution, of course, lies in his own research findings, and it is a large contribution indeed. On the basis of his analysis of data for metropolitan areas (from the last three censuses of population) and for individual wives (from the Scripps Population Foundation's Growth of American Families Survey and from the One-in-a-Thousand Sample of the 1960 Census), a number of interesting conclusions emerge, only a few of which can be mentioned here.

First, in each of the last three census weeks (1940, 1950, and 1960), the net effect of higher unemployment in a metropolitan area has been to reduce the overall participation rate of married women, even though the disaggregated data show that wives with unemployed husbands are considerably more likely to be in the labor force than are wives whose husbands are employed. There is, of course, no contradiction in these results: the discouragement effect of higher unemployment (operating on all wives) simply overpowers the additional-worker effect (which influences only those wives with jobless husbands).

Second, Cain constructs a large number of estimates of the elasticity of wives' participation rates with respect to wives' earnings and family income minus wives' earnings. Both sets of estimates span a rather wide range (0.4 to 1.0 for the former, -0.3 to -0.7 for the latter), so that Mincer's earlier finding that the wage elasticity substantially exceeds the income elasticity is, in Cain's judgment, "weakened . . . but not overturned" (p. 117). The size of these elasticities has special relevance to the secular uptrend in the participation rate of married women: since both male and female earnings have been

rising at about the same percentage rate, a (positive) wage elasticity that is larger than the (negative) income elasticity would help to explain this trend. Cain concludes, however, that less of this trend can be accounted for by these variables than had previously been believed. Undoubtedly, many other forces have been at work, and Cain emphasizes the need for additional research to find out what they are.

In this connection, it is interesting that Cain finds larger income-elasticity estimates (relative to wage-elasticity estimates) for nonwhite wives than for white wives, a result which is consistent with the slower growth of Negro wives' participation in recent decades. Cain attributes part of this differential rate of growth to the concentration of nonwhite wives in domestic service—a declining trade. But he has no explanation for the white-Negro income-elasticity differential itself.

Cain's work also sheds considerable light on why Negro wives have higher participation rates than white wives—even after adjustments for differences in earnings, family income, husband's employment status, the presence of small children, and the wife's schooling have all been taken into account. He finds evidence that this persistent differential is largely attributable to (1) the greater prevalence of part-time work by Negro wives; (2) the greater incidence of "poorer housing conditions, smaller dwelling units, and more doubling up" among nonwhite families (p. 119)—all leading nonwhite wives to seek more work in the labor market since there is less for them to do at home; and (3) the greater chance that a Negro wife has of losing her husband—and having to support her family on her own wages—before she grows old.

One conclusion that appears to be in error concerns the deterring effect of small children in the home on the participation of white and Negro wives. On the basis of his regressions using data from the 1/1000 Sample, Cain concludes that "only when children aged 7 to 11 were present did Negro wives work more readily than white wives" (p. 120), a conclusion that seems to have stemmed from an unfortunate choice of dummy variables and a misreading of their coefficients. The results of independent research by William G. Bowen and myself lead to the opposite inference—that the tendency for Negro married women to have a higher participation rate than their white counterparts is more pronounced in the case of women with children *under six* years of age than for women with older children only or with no children in the home at all. (On the basis of correspondence with Cain, it should be added that he has now reached the same conclusion after ingeniously reworking his data. He will be happy to send a revised section of Table 34 to any interested reader.)

To sum up: the quality of Cain's work is first rate, and he has made a major contribution by his painstaking and incisive analysis of the labor force behavior of married women. More generally, this piece of research displays the praiseworthy qualities of ingenuity, scholarly objectivity, and a willingness to present all of the relevant evidence.

T. ALDRICH FINEGAN

Vanderbilt University

The Technical Elite. By JAY M. GOULD. New York: Augustus M. Kelley, 1966. Pp. 178. \$5.00.

Thorstein B. Veblen anticipated a continuing and irreconcilable conflict between entrepreneurs and technicians. In Veblen's scheme of things, technicians were engaged in rationalizing production, optimizing use of resources, and maximizing output while entrepreneurs were working to curb production and stifle innovation. The motives of the technicians were attributed to a scientific spirit of inquiry while the motives of the entrepreneurs were attributed to self-interest, i.e. protection of markets by preventing oversupply and distress selling, and protection of invested capital by preventing new ideas from being used to undermine the value of such invested capital. Among the conclusions that Veblen drew from observing this conflict was that production and profits would be maximized if entrepreneurs relinquished their leadership role to technicians, as the technicians were better equipped to manage business enterprises.

In a compact book that was originally planned as an introduction to a new edition of Veblen's "The Engineers and the Price System," Gould reviews the chain of reasoning that led Veblen to his conclusions. Veblen argued that the demands of the marketplace required a continuing "withdrawal" of efficiency by entrepreneurs to offset the productivity advances introduced by technicians. At the same time, Veblen recognized that entrepreneurs were becoming increasingly dependent upon technicians to advance production. What Veblen apparently did not realize, and what Gould demonstrates, is that the technicians are increasingly becoming the entrepreneurs and captains of industry, and in this way, the Veblenian conflict is being reconciled.

In his study of the penetration of business ranks by technicians (persons with a college degree or higher in natural sciences or engineering, or those without such formal education discharging technical functions), Gould shows that technicians dominate the ranks of middle management today, and thus will be the major manpower source for the ranks of top management in the future. Original research on the education and social background of top managers and technicians was drawn upon to demonstrate that the need for technically educated people in business was overcoming barriers to their entrance into the ranks of top management, even when drawn from social classes that traditionally were barred from top management positions. This research was particularly enlightening because it exposed the educational and technical weaknesses of top management as well as their strengths.

A section on productivity gains has a breakdown on employment of technicians in specific industries. The data show a high correlation between rates of gain in value added per employee and employment of technical and scientific personnel. As part of the study of productivity trends, Gould demonstrates that an exponential growth curve for the technical labor force had brought about a steady increase in numbers of technicians for two centuries. Commencing when Benjamin Franklin was apparently the only scientist in the labor force to the present day when there are 1.5 million technical members, the ratio of growth of the technical labor force has been very stable. But contrary to the expectations of many that the technical labor force will grow at

an accelerating pace in the future, Gould assumes that the rate of growth of the technical labor force will taper off in the next few decades because of limitations on the supply of persons capable of absorbing a technical education.

Veblen's antagonism towards the entrepreneurs did not carry so far as to attack the profit mechanism which he saw as a reward for efficiency. In a chapter on the controversies in the U.S.S.R. about the use of the profit mechanism as a measure of economic efficiency, Gould notes ". . . that Russian economists are only beginning to grapple with the true nature of the paradoxical tie that binds the truly efficient management of enterprise . . . to the unmanageable and disruptive forces of scientific creativity, which cannot be planned." Pointing out that "Veblen too saw in the profit margin a device to harness the energies of both to the task of advancing economic development," the author then speculates that ". . . the Russians too will come to accept the use of profit for this purpose, perhaps within some more or less flexible framework provided by a central plan."

In sum, Gould contends that Veblen has won a "quiet victory" because the demands of a highly technical economy have changed the role of technicians from servants to partners of the captains of industry, and that in the future, the technicians will actually be the captains of industry.

NOTES

EIGHTIETH ANNUAL MEETING OF THE AMERICAN ECONOMIC ASSOCIATION

Sheraton Park Hotel, Washington, D.C.—December 27-30, 1967

Preliminary Announcement of the Program

Wednesday, December 27, 1967

12:30 P.M. EXECUTIVE COMMITTEE, American Economic Association

9:00 P.M. A HAPPENING, ECONOMICS AND THE ARTS

Thursday, December 28, 1967

8:30 A.M. TRANSPORT FOR ECONOMIC AND SOCIAL DEVELOPMENT (Sponsored jointly with the Transportation and Utilities Group)

(Arranged by WILFRED OWEN, The Brookings Institution)

Chairman: GEORGE W. WILSON, Indiana University

Papers: Simulation of Transport Policy Alternatives for Colombia

PAUL O. ROBERTS, Harvard University

DAVID KRESGE, Council of Economic Advisers

A Transport Financing Model for Development

ALAN A. WALTERS, Massachusetts Institute of Technology and
the University of Birmingham, England

Transport Policies for European Economic Integration

JAMES R. NELSON, Amherst College

Discussants: GUSTAV RANIS, Agency for International Development

BENJAMIN CHINITZ, Brown University

ERIC SCHENKER, University of Wisconsin

GRADUATE STUDENT SESSION (Sponsored jointly by *The American Economist*,
Journal of the Honor Society in Economics and Omicron Delta Epsilon)
(Arranged by DANIEL E. DIAMOND, New York University)

Chairman: EGON NEUBERGER, State University of New York at Stony
Brook

Papers: Increasing Returns to Scale and Market Mechanism

MASAHIKO AOKI, University of Minnesota

An Aircraft Routing Model for the Airline Firm

JAMES C. MILLER III, University of Virginia

A Theory of Economic Growth and Inflation

RICHARD W. MONTGOMERY, Oklahoma State University

Discussants: To be announced

THE EFFECTS OF SHIFTS IN AGGREGATE DEMAND UPON LABOR MIGRATION
AND INCOME DISTRIBUTION (Sponsored jointly with the American Farm
Economic Association)

Chairman: C. E. BISHOP, University of North Carolina

Papers: Farm-Nonfarm Labor Mobility

DALE E. HATHAWAY, Michigan State University

BRIAN B. PERKINS, University of Guelph

Effects of Shifts in Aggregate Demand Upon Income Distribution

HYMAN P. MINSKY, Washington University

Discussant: LOWELL E. GALLAWAY, Ohio University

10:30 A.M. ROUND TABLE ON THE ECONOMICS OF HIGHER EDUCATION

Moderator: CHARLES C. KILLINGSWORTH, Michigan State University

Panel: CLARK KERR, University of California, Berkeley

WILBUR J. COHEN, U.S. Department of Health, Education and Welfare

ALLAN M. CARTTER, New York University

GERARD BRANNON, U.S. Treasury

ROUND TABLE ON THE ECONOMICS OF ENVIRONMENTAL MANAGEMENT

Moderator: JOSEPH L. FISHER, Resources for the Future, Inc.

Panel: JACK W. CARLSON, Council of Economic Advisers

M. MASON GAFFNEY, University of Wisconsin (Milwaukee)

MORRIS E. GARNSEY, University of Colorado

LESTER B. LAVE, Carnegie-Mellon University

INTERNAL AND EXTERNAL LABOR MARKETS (Sponsored jointly with the Industrial Relations Research Association)

Chairman: ARNOLD R. WEBER, University of Chicago

Papers: Voluntary Labor Mobility in the U.S. Manufacturing Sector

JOHN F. BURTON, JR., University of Chicago

JOHN E. PARKER, University of Michigan

A Computerized Labor Market Information System

FRAZIER KELLOGG, Massachusetts Institute of Technology

Negro Employment Practices in the Internal Labor Market

HERBERT R. NORTHRUP, University of Pennsylvania

Discussants: To be arranged

2:30 P.M. INTERNATIONAL LIQUIDITY

Chairman: JOHN M. LETICHE, University of California, Berkeley

Papers: The Present State of International Liquidity Theory

RICHARD G. LIPSEY, Essex University, England

The Current Relevance of International Liquidity to Developed Countries

RICHARD N. COOPER, Yale University

The Current Relevance of International Liquidity to Developing Countries

ALEXANDRE KAFKA, University of Virginia

Discussion: The Case of the United Kingdom

ALEXANDER CAIRNCROSS, Adviser United Kingdom Treasury (Invited)

The Case of the Common Market

EMIL VAN LENNEP, Chairman of the Monetary Committee, EEC (Invited)

The Case of the United States

FRANCIS M. BATOR, Harvard University

Synthesis and Appraisal

JOHN M. LETICHE, University of California, Berkeley

2:30 P.M. BEHAVIORAL AND ECOLOGICAL ECONOMICS

Chairman: KERMIT GORDON, The Brookings Institution

Papers: Consumer Behavior: Theory and Findings on Expectations and Aspirations

GEORGE KATONA, University of Michigan

The Supply of Effort and the Interpretation of Inequality

JAMES N. MORGAN, University of Michigan

Ecological Processes in Economic Change: Models, Measurement and Meaning

RUTH P. MACK, Institute of Public Administration

THE AMERICAN ECONOMIC REVIEW

Discussants: PETER E. DE JANOSI, Ford Foundation

HAROLD W. WATTS, University of Wisconsin

ECONOMICS OF ARMS CONTROL AND DISARMAMENT

Chairman: ARCHIBALD S. ALEXANDER, U.S. Arms Control and Disarmament Agency

Papers: The Monetary and Real Costs of National Defense

EMILE BENOIT, Columbia University

Economic Sanctions and Rewards in Support of Disarmament Treaties

MORRIS BORNSTEIN, University of Michigan

Arms and the American Economy: A Domestic Convergence Hypothesis

MURRAY WEIDENBAUM, Washington University

Discussants: WILLIAM CAPRON, The Brookings Institution

HOLLAND HUNTER, Haverford College

8:00 P.M. RICHARD T. ELY LECTURE

Chairman: KENNETH E. BOULDING, University of Michigan and University of Colorado

The Economics of Inquiring, Communicating and Deciding

JACOB MARSCHAK, University of California, Los Angeles

Friday, December 29, 1967

8:30 A.M. MEASUREMENT FOR PUBLIC POLICY (Sponsored jointly with American Statistical Association)

Chairman: WILLIAM CAPRON, The Brookings Institution

Papers: Analysis for Health Planning

ROBERT N. GROSSE, U. S. Department of Health, Education and Welfare

Supply and Demand Analysis of Public Timber

HOWARD W. HJORT, U.S. Department of Agriculture.

Policy Objectives and Aggregative Measurements

NESTOR E. TERLECKYJ, U.S. Bureau of the Budget

Discussants: OTTO ECKSTEIN, Harvard University

EDWARD FOSTER, University of Minnesota

8:30 A.M. EXPERIMENTS IN TEACHING ECONOMICS (Arranged by the American Economic Association Committee on Education, G. L. BACH, Stanford University, Chairman)

Chairman: MARSHALL R. COLBERG, Florida State University

Papers: An Experiment with TIPS, a Computer-Aided Instructional System for Undergraduate Education

ALLEN C. KELLEY, University of Wisconsin

A Simulation Policy Game for Teaching Macroeconomics

RICHARD ATTIEYEH, University of California, San Diego

WILLIAM C. BRAINARD, Yale University

F. T. DOLBEAR, The Brookings Institution

An Experiment with Television in the Elementary Course

CAMPBELL R. MCCONNELL, University of Nebraska

Discussants: MYRON L. JOSEPH, Carnegie-Mellon University

RICHARD S. BOWER, Amos Tuck School, Dartmouth College

HENRY H. VILLARD, City College of New York

THE ENTREPRENEUR

Chairman: ARTHUR H. COLE, Harvard University

Papers: The Entrepreneur in Economic Theory

WILLIAM J. BAUMOL, Princeton University

The Entrepreneur in Economic Development

HARVEY LEIBENSTEIN, Harvard University

The Entrepreneur in Economic History

JAMES H. SOLTOW, Michigan State University

Discussants: EVSEY D. DOMAR, Massachusetts Institute of Technology

EVERETT E. HAGEN, Massachusetts Institute of Technology

ALEXANDER GERSCHENKRON, Harvard University

10:30 A.M. ROUND TABLE ON THE GRANTS ECONOMY

Chairman: MARSHALL A. ROBINSON, The Ford Foundation*Panel:* JOSEPH A. PECHMAN, The Brookings Institution

JAMES M. BUCHANAN, University of Virginia

KENNETH E. BOULDING, University of Michigan and University of Colorado

ROUND TABLE ON THE SCIENTIFIC-MILITARY-INDUSTRIAL COMPLEX AND THE NEW INDUSTRIAL STATE

Chairman: EDWARD S. MASON, Harvard University*Panel:* WALTER ADAMS, Michigan State University

GEORGE J. STIGLER, University of Chicago

H. L. NIEBURG, University of Wisconsin, Milwaukee

SEYMOUR MELMAN, Columbia University

12:30 P.M. JOINT AMERICAN ECONOMIC ASSOCIATION—AMERICAN FINANCE ASSOCIATION LUNCHEON

The Economic Outlook: An International View

MILTON GILBERT, Bank for International Settlements

2:30 P.M. THE ECONOMIC IMPLICATIONS OF 3 PERCENT GROWTH (Sponsored jointly with the Society for the History of Technology)

Chairman: ROBERT L. HEILBRONER, New School for Social Research*Paper:* Technological Possibilities for 3 Percent Growth

MICHAEL MICHAELIS, Arthur D. Little Inc.

Discussant: JOSEPH L. FISHER, Resources for the Future, Inc.*Paper:* Economic Implications for Consumption of 3 Percent Growth

HENRY H. VILLARD, City College of New York

Discussants: VICTOR FUCHS, National Bureau of Economic Research

BEN G. SELIGMAN, University of Massachusetts

ECONOMETRIC MODELS, THEIR PROBLEMS AND USEFULNESS (Sponsored jointly with the Econometric Society)

Session in honor of the 100th Anniversary of the Birth of Irving Fisher

(Arranged by ALBERT ANDO, Massachusetts Institute of Technology)

Chairman: JACOB MARSCHAK, University of California, Los Angeles*Papers:* Pitfalls in Financial Model Building

JAMES TOBIN, Yale University

WILLIAM C. BRAINARD, Yale University

FRB-MIT Econometric Model: Its Special Features and Implications for Stabilization Policies

HAROLD SHAPIRO, University of Michigan

Discussant: JOHN LINTNER, Harvard University

8:00 P.M. PRESIDENTIAL ADDRESS

Chairman: ARTHUR F. BURNS, Columbia University

Can Full Employment Be a Criterion of Monetary Policy?

MILTON FRIEDMAN, University of Chicago

Saturday, December 30, 1967

8:30 A.M. REGIONAL ECONOMIC MODELS

Chairman: RICHARD RUGGLES, Yale University*Papers:* An Open Growth Model for a Regional Economy

GEORGE H. BORTS, Brown University

Regional Impact Models

WERNER Z. HIRSCH, University of California, Los Angeles

An Intra-Regional Simulation Model

JOHN MEYER, Harvard University

JOHN KAIN, Harvard University

Discussants: to be arranged

ECONOMICS AND NON-ECONOMICS OF POVERTY

Chairman: MARTIN COHNSTAEDT, University of Saskatchewan, Regina*Papers:* A Clinical Economist in Rural Poverty

WILLIAM H. COOPER, Bucknell University

Casualty Rates and the War on Poverty

ROBBIN R. HOUGH, Oakland University

The Natural Law of Human Reproduction

RICHARD A. LABARGE, Louisiana State University, New Orleans

Discussants: JAMES D. SMITH, Office of Economic Opportunity

WILLIAM B. NEENAN, University of Michigan

HERMAN G. BERKMAN, New York University

INVITED STUDENT DISSERTATIONS

Chairman: FRITZ MACHLUP, Princeton University*Papers:* Terms of Trade and Economic Development: A Case Study of IndiaDENNIS R. APPELYARD (Ph.D., University of Michigan, 1966),

by the American Economic Association, the Association for Comparative
Economics and the Association for the Study of Soviet-type Economies)*Chairman:* E. E. HAGEN, Massachusetts Institute of Technology*Papers:* The U.S.S.R.ROBERT W. CAMPBELL, Indiana University
Czechoslovakia

GEORGE J. STALLER, Cornell University

Yugoslavia

BENJAMIN WARD, University of California, Berkeley

Discussants: ABRAM BERGSON, Harvard University

JOHN M. MONTIAS, Yale University

ROUND TABLE ON THE SELECTION AND TRAINING OF FOREIGN GRADUATE
STUDENTS IN ECONOMICS*Chairman:* HAROLD F. WILLIAMSON, Northwestern University*Panel:* RALPH K. DAVIDSON, The Rockefeller Foundation

WYN F. OWEN, University of Colorado

ALBERT G. SIMS, National Association for Foreign Student
Affairs

JAMES S. WORLEY, Vanderbilt University

ROUND TABLE ON PRODUCT QUALITY IN THE AMERICAN ECONOMY (Sponsored
jointly by the American Economic Association and the Commission for
Product Quality, American Society for Quality Control)

Panel to be arranged

12:30 P.M. LUNCHEON JOINTLY SPONSORED WITH THE U.S. NATIONAL COMMISSION FOR UNESCO

Chairman: WILLIAM H. NICHOLLS, Vanderbilt University

Speaker: CHARLES FRANKEL, Assistant Secretary of State for Education and Cultural Affairs

2:30 P.M. PROBLEMS IN PRICING AND GROWTH

Chairman: ROBERT SOLO, Michigan State University

Papers: Relative Prices in Macroeconomic Models

L. R. WEBB, University of Melbourne

Demand and Supply for Securities and Economic Growth

PAUL DAVIDSON, Rutgers—The State University

Pricing and Optimum Size in a Non-Profit Institution: The University

HANS H. JENNY, The College of Wooster

Discussants: to be arranged

2:30 P.M. NON-MARKET DECISION-MAKING

Chairman: GORDON TULLOCK, Rice University

Papers: The Peculiar Economics of Bureaucracy

WILLIAM A. NISKANEN, Institute for Defense Analyses

Some Organizational Influences on Urban Renewal Expenditures

CHARLES PLOTT, Purdue University

Democracy and Duopoly: A Comparison of Models

JAMES M. BUCHANAN, University of Virginia

Discussants: STEPHEN ENKE, General Electric-TEMPO, Santa Barbara

OTTO A. DAVIS, Carnegie-Mellon University

EARL THOMPSON, University of California, Los Angeles

ARTISTS ARISE!

Once more the oeconomical artists assemble at the Christmas Meetings, Sheraton Park Hotel, Washington, D.C., December 28-30, 1967. Members of the Association who have art work to exhibit at the next AEA annual meetings should write at once to William J. Baumol, Department of Economics, Green Annex, Princeton University, Princeton, N.J. Please indicate whether you propose to submit painting, sculpture, or other, the number of pieces, and the approximate size of each.

INTERNATIONAL ECONOMIC ASSOCIATION WORLD CONGRESS

The Third Congress of the International Economic Association will be held in Montreal, Canada, at the Queen Elizabeth Hotel, from September 2 to 7, 1968.

The program will be under the general heading of "The Future of International Economic Relations." Morning sessions will be devoted to the discussion of the main papers, each of which will be introduced by two to three speakers. In the afternoons less formal round table discussions will be under the direction of five chairmen who will be responsible for organizing a number of smaller meetings on various aspects of the topics. A preliminary program follows.

Monday, September 2, 1968

H. MYINT (London School of Economics): International Trade and the Developing Countries

Organization session for afternoon round tables

Presidential Address by PAUL A. SAMUELSON (Massachusetts Institute of Technology)

Tuesday, September 3, 1968

HARRY JOHNSON (London School of Economics and University of Chicago): The Theory of International Trade

Round table discussions on International Trade and the Developing Countries, and on the Theory of International Trade

Wednesday, September 4, 1968

A. NOVE (Glasgow) and I. VAYDA (Budapest): The Problems of East-West Trade
Afternoon free—no round table discussions

Thursday, September 5, 1968

G. ÖHLIN (Stockholm): International Trade in a Non-Laissez-Faire World
Round table discussions on the Problems of East-West Trade, and on International Trade in a Non-Laissez-Faire World

Friday, September 6, 1968

TIBOR SCITOVSKY (University of California, Berkeley): International Liquidity and Basic-Mechanism Reform
Round table discussions on International Liquidity and Basic-Mechanism Reform

Saturday, September 7, 1968

Summary Reports by five chairmen of afternoon round tables and close of Congress at noon.
Participation in the program is now planned to include, among others, Fritz Machlup, Charles P. Kindleberger, Jacques Rueff, Evsey Domar, Robert Triffin, Milton Friedman, Kenneth Boulding, Murray Kemp, J. Bérard, J. M. Montias.

All members of the associations that are affiliated to the International Economic Association are invited to take part in the Congress. On behalf of the IEA, the Montreal Convention and Visitors' Bureau will be responsible for the registration of participants, for the collection of the Congress fee, and for hotel reservations. Those wishing to participate should write as soon as possible to the Montreal Convention and Visitors' Bureau, 1400 Metcalfe, Montreal 2, Quebec, Canada, or to the International Economic Association, 92 rue d'Assas, Paris 6^o, France. It is advisable to register as soon as possible.

FOURTH CONGRESS OF THE INTERNATIONAL ECONOMIC HISTORY ASSOCIATION

The Fourth International Congress of the International Economic History Association will be held on the invitation of the University of Indiana at Bloomington, Indiana, September 9-13, 1968, inclusive.

The following main themes, each encompassing a number of sessions, have been established. The subject of the main theme is followed by the name and address of the organizer of the theme. Those who wish to participate in the work of preparation or in the discussion of a particular theme may contact the appropriate organizer:

Formation and Development of Capitalism: F. RUIZ MARTÍN, University of Bilbao, Spain
Twentieth Century Changes in Economic Structure: P. MATHIAS, Queen's College, Cambridge, England

Technology and Economic Growth: A KLIMA, University of Prague, Czechoslovakia
Consumption and Distribution of Production: W. KULA, University of Warsaw, Poland
Demography: D. EVERSLEY, University of Birmingham, England

Ancient History: I. DIAKONOFF, University of Leningrad, USSR

Relations Between Developed and Underdeveloped Regions: O. KUMAR, 9 Ashoka Road, New Delhi, India

Agrarian Organization and Land Policies on the Frontiers: A. JARA, Universidad de Chile, Santiago, Chile

A detailed circular with a registration blank will be sent out in January 1968 to all the participants of previous Congresses and to anyone else who requests one. Requests should be sent to the Secretary General of the Association, Professor Jean-François Bergier, Université de Genève, rue de Candolle, 1205, Genève, Switzerland.

VISITING SCIENTIST PROGRAM IN ECONOMICS

The American Economic Association has received a grant of \$6,540 from the National Science Foundation to continue its "Visiting Scientist Program in Economics" during the 1967-68 academic year. The purpose of this program is to stimulate improved teaching and interest in modern economics at colleges and universities whose major focus is at the undergraduate level. Visits to about 20 campuses have been provided by the program in 1966-67.

The NSF grant provides financing for visits to such campuses by distinguished economists, who normally will spend a day or a day and a half on such a visit. The program for each visit is planned jointly between the visitor and the host institution; customarily it includes a talk to undergraduate major students, perhaps an informal seminar with faculty and students, discussion of current course and research interests of the host faculty, and other activities as may be desirable. While the ultimate concern is to encourage greater interest in, and better teaching of, economics at the undergraduate level, visitors' talks may be on research, current developments in economics, policy issues, or other topics that may seem appropriate to the needs of the particular institution.

This program is under the general direction of the Association's Committee on Economic Education. Professor Phillip Saunders, Department of Economics, Carnegie Institute of Technology, administers the program, under the policies established by the Committee. Professor Saunders works with an informal roster of economists around the country who may be available for such visits, depending on their own schedules and the degree of common interest between them and the inviting institutions. Institutions are free to suggest visitors they would especially like to have, so long as these are within a radius of 100-200 miles of the campus, in order to minimize traveling costs. The host institution is expected to provide lodging and meals for the visitor when he is on the campus; other costs will be covered by the NSF grant.

Any institution that wants further information on this program, or wishes to submit a request for a "visiting scientist" during 1967-68, is invited to write directly to Professor Saunders at Carnegie Institute of Technology, Pittsburgh, Pennsylvania 15213.

FACILITIES IN HONG KONG FOR ECONOMISTS

The American Economic Association is attempting to bring about closer cooperation between Asian and U.S. economists. AEA members who are planning to visit, teach, or do research in Hong Kong are welcome to call on the following Hong Kong individuals and organizations for assistance: Professors R. Hsia and S. Klein, Economics Dept., Hong Kong University; Director of Studies, Economic Research Center, Chinese University of Hong Kong, Kowloon; Chief Economic Section, U.S. Consulate General, 26 Garden Road; Universities Service Center, 155 Argyle St., Kowloon; Union Research Institute, 9 College Rd., Kowloon; and The Asia Foundation, No. 2 Old Peak Road. Mainland China and Hong Kong economy specialists should note that the Universities Service Center has an excellent research library, facilities for the duplication of research material, and some office and desk space. Similar facilities exist at the Institute of Modern Asian Studies, Hong Kong University, and the Union Research Institute. The U.S. Consulate General sometimes is able to arrange briefings for visiting economists. The Hong Kong Economic Association welcomes academic, government, and business economists to its meetings. Requests for information or the use of facilities should be made as far in advance as possible.

FELLOWSHIPS AND GRANTS

The Social Science Research Council's annual announcement describing fellowships and grants to be awarded in 1967-68 is now ready for distribution. It lists research training fellowships, foreign area fellowships, faculty research grants and grants for research on foreign areas. Inquiries about research training fellowships, offered to postdoctoral and advanced predoctoral candidates, and faculty research grants should be addressed to Social Science Research Council Fellowships and Grants, 230 Park Ave., New York 10017. Inquiries about co-sponsored programs should be addressed to the other offices

indicated below. To avoid missing deadline, correspondence should be initiated no later than early October.

Foreign area fellowships for multidisciplinary predoctoral or postdoctoral training relating to Asia and the Near East, the Soviet Union and Eastern Europe, Africa, Latin America, or Western Europe are under the joint auspices of SSRC and the American Council of Learned Societies. Address inquiries to the Foreign Area Fellowship Program at 444 Madison Ave., New York, N.Y. 10022.

Grants for research on foreign areas will be offered by joint committees of SSRC and ACLS to social scientists holding the Ph.D. degree or its equivalent. Grants for research on Africa, Contemporary China, Latin America, and the Near and Middle East are administered by the SSRC. Grants for Asian and for Slavic and East European Studies are administered by the American Council of Learned Societies, 345 East 46th St., New York, N.Y. 10017.

Announcements

The Johns Hopkins University announces that the Second Conference on the Economics of Health has been scheduled for three days during the late fall of 1968. About fifteen papers will be delivered and discussed, and a volume based upon them will be prepared. The following subject headings, among others, will be covered: (1) Productivity, including cost functions for delivering various forms of health services; (2) Demand for health services, including demographic changes and price and income elasticities; (3) Organizational arrangements, including the structural characteristics of the health services industry from the standpoint of both buyers and sellers; (4) Cost-benefit and cost-effectiveness analyses for health services in this country or abroad; and (5) Prices and financing of health services, including methods of payment, the use of incentives, and the flow of intergovernmental grants-in-aid.

Prospectuses from persons who presently may be working in one of these areas and who may wish to present papers at the Conference are invited for the consideration of the Planning Committee. They may be sent to Mrs. Helen Jaszi, Executive Secretary, Second Conference on the Economics of Health, 4910 Cumberland Ave., Chevy Chase, Maryland 20015.

During November 19-22, 1967, in Washington, D.C., the National Center for Education Statistics, U.S. Office of Education, will sponsor a symposium on "Operations Analysis of Education." Further information may be obtained by writing Dr. Stephen C. Clark, Program Chairman, Division of Operations Analysis, NCES, U.S. Office of Education, Washington, D.C. 20202.

The Committee on Shipping of the United Nations Conference on Trade and Development is making a series of studies in shipping economics. Research is being undertaken on the determination and impact of freight rates, port economics, the economic problems and consequences of developing national merchant marines, and consultation machinery between shipowners and shippers. Parallel studies in the fields of shipping statistics and the economic implications of technological changes are also in progress. It is intended to arrange international seminars at which work in all these fields may be discussed.

To enhance the value of this research and to contribute to similar work elsewhere, organizations and persons engaged in research on any aspect of shipping economics are invited to communicate with the Secretary-General of UNCTAD, Palais des Nations, Geneva. He hopes that such contacts and the discussions and exchanges to which they may give rise will be to the benefit of all concerned with research in this field.

Deaths

Henry F. Andersson, associate professor of business administration, Long Beach State College, February 9, 1967.

Ralph E. Freeman, professor emeritus, Massachusetts Institute of Technology, May 12, 1967.

Martin G. Glaeser, emeritus professor of economics, University of Wisconsin, March 19, 1967.

Naum Jasny, Washington, D.C., April 22, 1967.

Ellis Newsome, associate professor of marketing and advertising, University of Iowa, March 12, 1967.

Albert B. Wolfe, professor emeritus, Ohio State University, June 3, 1967.

Retirements

Thomas J. Anderson, Jr., professor of economics, School of Commerce, New York University.

John C. Blommestein, assistant professor of economics, University of Notre Dame, June 1967.

Frank E. Dykema, professor of economics, University of Alabama.

John S. Gambs, professor of economics, Hamilton College, June 1967.

Simon Naidel, professor of economics, American University.

W. A. Neiswanger, professor of economics, University of Illinois, Urbana.

Paul W. Paustian, professor of economics, University of Alabama.

Paul N. Rosenstein-Rodan, professor of economics, Massachusetts Institute of Technology, June 1967.

Reginald H. Scott, assistant professor of economics, University of Pittsburgh, April 15, 1967.

Nelson L. Smith, professor of business, Graduate School of Business, Columbia University, June 30, 1967.

Ruth J. Woodruff, professor of economics, Whittemore School of Business and Economics, University of New Hampshire, June 30, 1967.

Visiting Foreign Scholars

Noel G. Butlin, Australian National University: Irving Fisher research professor, department of economics, and research associate, Economic Growth Center, Yale University.

Lauchlin Currie, National University, Colombia: visiting professor of economics, Simon Fraser University, 1967-68.

Malcolm Fisher, Cambridge University: visiting professor of economics, University of Chicago, winter 1968.

Flemming Hansen, Copenhagen School of Business Administration: visiting associate professor of business administration, Whittemore School of Business and Economics, University of New Hampshire.

Philip Hansen, University of Exeter: visiting lecturer in economics, University of Michigan, 1967-68.

Werner Hildenbrand, University of Heidelberg at the Technische Hochschule at Karlsruhe: visiting associate professor, department of economics, University of California, Berkeley, fall-winter 1967-68.

Jack Johnston, University of Manchester: distinguished visiting professor of econometrics, Bernard M. Baruch School of Business and Public Administration, and Graduate Center, City University of New York, 1967-68.

Toshinoske Kashiwazaki, Waseda University, Tokyo: visiting professor of economics, Lafayette College, fall 1967.

Erich Klinkmuller: visiting professor of economics, University of Arizona, 1967-68.

Heinz Lampert, Technical University of Berlin: visiting professor of economics, Massachusetts Institute of Technology, fall 1967.

Maurice Levy-Leboyer, Université de Caen: visiting professor of economic history, Massachusetts Institute of Technology, spring 1968.

E. Victor Morgan, University of Manchester: visiting professor, department of economics and commerce, Simon Fraser University, fall 1967.

Gunnar Myrdal, Stockholm University: visiting professor, Ohio State University, fall 1967.

John O'Shaughnessy, Sr., College of Aeronautics, Cranfield, England: visiting associate professor, Graduate School of Business, Columbia University.

Marshall Sarnat, Hebrew University: visiting associate professor of finance, Graduate School of Business Administration, New York University.

David Smyth, University of Birmingham: visiting professor of economics, State University of New York at Buffalo, 1967-68.

T. N. Srinivasan, Indian Statistical Institute: visiting professor of economics, Stanford University.

Bernard H. Slicher van Bath: visiting professor of economics, University of Chicago, 1967-68.

Carl Christian von Weitzsaker, University of Heidelberg: visiting professor of economics, Massachusetts Institute of Technology, spring 1968.

Promotions

Robert F. Adams: associate professor of economics, University of Maryland.

Peter S. Albin: associate professor of economics, Washington Square College, New York University.

Ralph Andreano: professor of economics, University of Wisconsin.

Wallace Barr: professor, department of agricultural economics and rural sociology, Ohio State University.

W. Bruce Bassett: assistant professor, Graduate School of Business, Columbia University.

William F. Beazer: associate professor of economics, University of Virginia.

Laurie D. Belzung: associate professor of economics, University of Houston.

R. Albert Berry: associate professor of economics, Yale University.

Robert C. Bingham: professor of economics, College of Business Administration, Kent State University.

Gordon C. Bjork: associate professor, Graduate School of Business, Columbia University.

Alan A. Brown: associate professor of economics, University of Southern California.

Andrzej Brzeski: associate professor of economics, University of California, Davis.

Omer L. Carey: associate professor of business administration, Washington State University.

Kang Chao: associate professor of economics, University of Wisconsin.

Glen G. Cain: associate professor of economics, University of Wisconsin.

David Cass: associate professor of economics, Yale University.

Janet G. Chapman: professor of economics, University of Pittsburgh.

Charles R. Chittle: assistant professor of economics, Bowling Green University.

George Dalton: professor of economics, Northwestern University, Evanston.

Martin David: professor of economics, University of Wisconsin.

John Deiter: associate professor of economics, University of South Florida.

George Delehanty: associate professor of economics, Northwestern University, Evanston.

John Doll: professor of economics, University of Missouri.

Magdi M. El-Kamash: associate professor of economics, North Carolina State University.

Edgar Feige: associate professor of economics, University of Wisconsin.

Charles Floyd: associate professor, department of banking and finance, College of Business Administration, University of Georgia.

Helmut J. Frank: professor of economics, University of Arizona.

Frank W. Gery: professor of economics, St. Olaf College.

Fred H. Goldner: associate professor, Graduate School of Business, Columbia University.

Jean S. Goodman: associate professor of accounting, University of Maine.

Henry G. Grabowski: assistant professor of economics, Yale University.

Alan G. Green: associate professor of economics, Queen's University, Kingston, Ontario.

Marshall Hall: associate professor of economics, Washington University.

Reed R. Hansen: professor of economics, Washington State University.

Einar Hardin: professor of labor and industrial relations, Michigan State University.

John Henning: associate professor of economics, Syracuse University.

Bernard P. Herber: professor of economics, University of Arizona.

Dale Hiestand: associate professor, Graduate School of Business, Columbia University.

Glenn C. Himes: associate professor, department of agricultural economics and rural sociology, Ohio State University.

William T. Hogan: professor of economics, Fordham University.

David B. Houston: professor of economics, University of Pittsburgh.

John D. Huffnagle: associate professor of economics, College of Business Administration, Kent State University.

Saul Hymans: associate professor of economics, University of Michigan.

Charles H. Ingraham: associate professor, department of agricultural economics and rural sociology, Ohio State University.

Paul E. Junk: professor of economics, University of Missouri.

Ralph S. Kaczor: professor of economics, College of Business Administration, Kent State University.

Allen C. Kelley: associate professor of economics, University of Wisconsin.

Wade R. Kilbride: associate professor of economics, U.S. Air Force Academy.

David Klahr: assistant professor, Graduate School of Business, University of Chicago.

Philip Kotler: professor of marketing, Graduate School of Business Administration, Northwestern University.

E. John Kottman: associate professor of marketing and advertising, University of Iowa.

V. N. Krishnan: professor of economics, Bowling Green University.

Robert A. Lynn: professor of business administration, University of Missouri.

Allan B. Mandelstamm: professor of economics, Michigan State University.

Bruce W. Marion: associate professor, department of agricultural economics and rural sociology, Ohio State University.

Joseph Mason: assistant professor of economics, Boston University.

Jon P. McConnell: associate professor of business administration, Washington State University.

R. Marvin McInnis: associate professor of economics, Queen's University, Kingston, Ontario.

Robert W. McKenzie: associate professor of finance, Graduate School of Business Administration, New York University.

Peter M. Mieszkowski: associate professor of economics, Yale University.

Deborah D. Milenkovich: assistant professor of economics, Barnard College.

David W. Miller: professor, Graduate School of Business, Columbia University.

Richard A. Miller: associate professor of economics, Wesleyan University.

Roger F. Miller: professor of economics, University of Wisconsin.

- Jerry Miner: professor of economics, Syracuse University.
- Herbert Mohring: professor of economics, University of Minnesota.
- Bernard Munk: assistant professor of economics, University of Michigan.
- Robert Murphy: associate professor of economics, University of South Florida.
- William B. Neenan: assistant professor of economics, University of Michigan.
- Joseph Newhouse: associate professor, College of Commerce, West Virginia University.
- Fred Nordhauser: assistant professor of economics, U.S. Air Force Academy.
- G. Warren Nutter: Paul Goodloe McIntire professor of economics, University of Virginia.
- Martin P. Oettinger: associate professor of economics, University of California, Davis.
- Ernest C. Pasour, Jr.: associate professor of economics, North Carolina State University.
- Ralph J. Peeler, Jr.: associate professor of economics, North Carolina State University.
- Martin M. Perlman: associate professor of economics, Wichita State University.
- Donald R. Plane: associate professor of economics, U.S. Air Force Academy.
- John Quigley: assistant professor of accounting, School of Business Administration, American University.
- Kenneth J. Rothwell: professor of economics, Whittemore School of Business and Economics, University of New Hampshire.
- Peter P. Schoderbek: associate professor of production management, University of Iowa.
- Harold T. Shapiro: associate professor of economics, University of Michigan.
- Karl Shell: associate professor of economics, Massachusetts Institute of Technology.
- Kenneth L. Shellhammer: assistant professor, College of Commerce, Regional Research Institute, West Virginia University.
- Hirofumi Shibata: associate professor of economics, Queen's University, Kingston, Ontario.
- Irwin Silberman: associate professor of banking, School of Commerce, New York University.
- Hugo Sonnenschein: associate professor of economics, University of Minnesota.
- Clarence A. Spencer, Jr.: assistant professor of finance, School of Commerce and Business Administration, University of Alabama.
- Charles F. Stewart: professor, Graduate School of Business, Columbia University.
- Bernt P. Stigum: associate professor of economics, Cornell University.
- Peter Temin: associate professor of economic history, Massachusetts Institute of Technology.
- Paul R. Thomas: assistant professor, department of agricultural economics and rural sociology, Ohio State University.
- Richard Thorn: professor of economics, University of Pittsburgh.
- Arthur B. Treadway: assistant professor of economics, Northwestern University, Evanston.
- Elias H. Tuma: associate professor of economics, University of California, Davis.
- Carl B. Turner: associate professor of economics, North Carolina State University.
- Arlon R. Tussing: associate professor of economics, University of Alaska.
- Kenneth P. Uhl: professor of marketing and consumer behavior, University of Iowa.
- J. F. Vallery, Jr.: assistant professor of economics, University of Alabama.
- Richard Wallace: associate professor of economics and community health and medical practice, University of Missouri.
- Leon L. Wegge: associate professor of economics, University of California, Davis.
- Finis R. Welch: associate professor of economics, Southern Methodist University.
- Charles K. Wilber: associate professor of economics, American University.

Paul Wonnacott: professor of economics, University of Maryland.

Patrick Yeung: assistant professor of economics, University of Illinois, Urbana.

Edward Zabel: professor of economics, University of Rochester.

Jack Zwick: associate professor, Graduate School of Business, Columbia University.

Administrative Appointments

Khamis Abdul-Magid: chairman and professor, department of economics, Guilford College.

Hugh G. J. Aitken: chairman, department of economics, Amherst College.

Merrill D. Bartlett: associate professor and assistant dean, College of Business Administration, University of Maine.

Louis F. Biagioni: associate professor and chairman, department of accounting, University of Iowa.

Charles E. Bishop, former head of department of economics, North Carolina State University: vice president of public service programs, Consolidated University of North Carolina, Chapel Hill.

Harvey E. Brazer: chairman and professor, department of economics, University of Michigan, 1967-70.

Frank P. R. Brechling: chairman, department of economics, Northwestern University.

Robert D. Calkins, retiring president of Brookings Institution: vice chancellor, social sciences, and professor of economics, University of California, Santa Cruz.

Edwin G. Caudill: assistant professor of business administration and assistant director of doctoral program, American University.

Jan E. Clee: dean, Whittemore School of Business and Economics, University of New Hampshire.

Tom E. Davis: professor and chairman, department of economics, Cornell University.

Hugh N. Emerson, Albright College: professor of economics and dean, business administration, New Haven College.

James S. Earley, University of Wisconsin: chairman, department of economics, University of California, Riverside.

Frederic H. Glade, Jr.: assistant dean, School of Business Administration, American University.

Kermit Gordon: president, Brookings Institution.

Daniel Hamberg: chairman, department of economics, State University of New York, Buffalo.

Niles M. Hansen, University of Texas: associate professor of economics and associate director, Center for Development Change, University of Kentucky.

William T. Hicks, University of Mississippi: chief, Economics Branch, Mississippi River Commission and U.S. Army Corps of Engineers, Vicksburg.

Richard H. Holton: dean, School of Business Administration, University of California, Berkeley.

John W. Hooper: chairman, department of economics, University of California, San Diego.

Edward Samuel Howle: assistant professor of economics and assistant dean of the Graduate School, University of North Carolina.

Max B. Jones: acting chairman, department of business management, Old Dominion College.

James R. Longstreet, University of Pennsylvania: professor and chairman, department of finance, College of Business Administration, University of South Florida.

John E. MacNab: associate professor of economics and chairman, division of social science, Algoma College, Sault Ste. Marie.

Ray Marshall, University of Texas: Alumni professor and chairman, department of economics, University of Kentucky.

Robert H. Marshall: head of department and professor of economics, University of Arizona.

Robert A. Minick: associate professor and chairman, department of economics, Fresno State College.

Gail E. Mullin: associate professor of economics and associate dean and director of graduate programs, College of Business Administration, Kent State University.

Wladimir Naleszkiewicz: acting manager, Economic Analysis and Forecasting Department, Financial Planning Division, Communications Satellite Corporation, Washington, D. C.

Dick Netzer: head, department of economics, Graduate School of Arts and Science, New York University.

Merton J. Peck: chairman, department of economics, Yale University.

Svetozar Pejovich: coordinator of graduate programs, department of economics, Texas A&M University.

Gustav Ranis: director, Economic Growth Center, Yale University.

Laurence C. Rosenberg: director, Office of Planning and Research, Treasury Department, Bureau of Customs, Washington, D. C.

Milton R. Russell: associate professor and chairman, department of economics, Southern Illinois University.

Herbert E. Scarf: director, Cowles Foundation for Research in Economics, Yale University.

John C. Shearer: professor of economics and director, Manpower Training and Research Center, Oklahoma State University.

William D. Shipman: chairman, department of economics, Bowdoin College.

Norman Simler: chairman, department of economics, University of Minnesota.

Irvin Sobel, Washington University: chairman and professor, department of economics, Florida State University.

Harold M. Somers: dean, division of social sciences, University of California, Los Angeles.

Leo T. Surla, Jr.: head, Economic Development Program, Regional Service Institute, Southern Colorado State College, Pueblo.

William D. Toussaint: head, department of economics, North Carolina State University.

Louis D. Volpp, University of Illinois: professor and chairman, department of business administration, Duke University.

Marshall D. Wattles: associate dean of faculties, University of Oregon.

James H. Weaver: chairman, department of economics, American University.

Sidney Wertimer, Jr.: Leavenworth professor and head, department of economics, Hamilton College.

Stephen T. Worland: acting chairman, department of economics, University of Notre Dame.

James E. Young, University of Arizona: professor of economics and director, Bureau of Economic and Business Research, College of Business Administration, Kent State University.

Appointments

Brian H. Aby: economist, Economic Development Administration, U.S. Department of Commerce.

Hamdy H. Afifi: lecturer in economics, University of Illinois.

Dennis J. Aigner, University of Illinois: associate professor of economics, University of Wisconsin.

- Robert J. Allison: assistant professor of economics, Fresno State College.
- Guvenc Alpander, University of Maine: assistant professor, department of economics and commerce, Simon Fraser University.
- Jay K. Alperin: instructor in business administration, University of Maine.
- Edward Altman: assistant professor of finance, Graduate School of Business Administration, New York University.
- John A. Anderson: instructor in economics, University of South Florida.
- Henry G. Aubrey, Sarah Lawrence College: senior fellow, European Institute, Columbia University, 1967-69.
- Harvey Babiak: lecturer in accounting, Graduate School of Business, University of Chicago.
- Trevor Bain, University of Arizona: visiting associate professor of economics, University of Michigan.
- Helmy H. Baligh, University of Illinois: associate professor of economics and business administration, Duke University.
- Solomon Barkin, OECD, Paris: professor of economics and associate of the Labor Center, University of Massachusetts.
- Martha V. Barnett, Washington College: lecturer in economics, Vassar College.
- Steven L. Barsby: assistant professor of economics, University of Arizona.
- Peter S. Barth: visiting assistant professor of industrial relations, Graduate School of Business, University of Chicago, winter quarter 1968.
- Allen M. Beals, Jr.: instructor in economics, North Carolina State University.
- William J. Beeman: assistant professor of economics, University of Maine.
- Carl R. Beidleman: instructor in finance, Lehigh University.
- Robert D. Beland: instructor in economics, U.S. Air Force Academy.
- Frederick W. Bell: associate professor of economics, Clark University.
- Arthur Benavie: associate professor of economics, University of North Carolina.
- Lee Benham: instructor in business economics, Graduate School of Business, University of Chicago.
- Sylvester E. Berki, Cornell University: Michigan State University.
- Irwin Bernhardt, Carnegie Institute of Technology: assistant professor of economics, Pennsylvania State University.
- Richard Bilas, University of Southern California: associate professor, Georgia State College.
- Charles W. Bischoff: research staff economist and lecturer in economics, Yale University.
- Claude A. Bitner: associate professor of economics, University of Houston.
- W. E. Black, Air Staff College: assistant professor of finance, College of Business Administration, University of Georgia.
- Bernard H. Booms: assistant professor of economics, Pennsylvania State University.
- Elbert V. Boden: associate professor of economics, Texas A&M University.
- David F. Bramhall, Johns Hopkins University: professor of economics, University of Pittsburgh.
- John Brandl, St. John's University: assistant professor of economics, University of Wisconsin.
- Phillip D. Brooks: assistant professor of economics, University of Kentucky.
- Byron B. Brown, Jr., Wisconsin State University: associate professor of economics, East Carolina College.
- Murray Brown, George Washington University: professor of economics, State University of New York at Buffalo.
- Herrington J. Bryce: assistant professor of economics, Clark University.

Phillip J. Bryson: assistant professor of economics, University of Arizona.

Robert C. Bushnell, Oberlin University: assistant professor of economics, Ohio State University.

Stewart E. Butler, University of Rhode Island: assistant professor of economics, Hamilton College.

Ralph N. Calkins: associate professor of economics, University of Alaska.

Joseph Caltigirone: assistant professor of finance, Graduate School of Business Administration, New York University.

J. Martin Carovano: assistant professor of economics, Hamilton College.

Robert C. Cauthorn: associate professor of economics, University of Arizona.

Neil Chamberlain, Yale University: professor of business, Graduate School of Business, Columbia University.

Winston Chang, University of Rochester: assistant professor of economics, State University of New York at Buffalo.

John H. Chapman, Jr., West Virginia University: associate professor of economics, Coe College.

Samuel B. Chase: professor of economics, University of Montana.

Walter A. Chudson, United Nations Industrial Development Organization: professor of business, Graduate School of Business, Columbia University.

W. Douglas Cooper: instructor in economics, North Carolina State University.

Dennis R. Cox: assistant professor of economics, University of Arizona.

Helen Crafton: lecturer in economics, University of Michigan.

Robert Crawford: management specialist, College of Commerce, West Virginia University.

William J. E. Crissy, Michigan State University: visiting professor, department of economics and commerce, Simon Fraser University, spring 1968.

William M. Crosswhite: associate professor of economics, North Carolina State University.

Larry L. Cummings, Indiana University: visiting associate professor, Graduate School of Business, Columbia University.

William W. Curtis: assistant professor of economics, University of Montana.

James M. Cypher: lecturer in economics, Fresno State College.

Norman E. Daniel, University of Alabama: associate professor of transportation, University of Houston.

James R. Davis: assistant professor of economics, Iowa State University.

Robert K. Davis, Resources for the Future, Incorporated: economic adviser to Kenya's Ministry of Tourism and Wildlife.

J. D. DeForest: consulting economist, staff of Deputy Assistant Secretary for Policy Coordination, Economic Development Administration, U.S. Department of Commerce.

Thomas R. De Gregori: assistant professor of economics, University of Houston.

Jacob De Rooy: instructor in economics, Lehigh University.

Floyd R. Dill: assistant professor of economics, Washington State University.

Robert R. Dince: regional economist, Sixth National Bank Region: resigning professorship but remaining head, department of banking and finance, University of Georgia.

Alberto DiPierro: assistant professor of economics, University of Virginia.

William P. Dommermuth: associate professor of marketing, University of Iowa.

Louis A. Dow: professor of economics, University of Houston.

Thomas D. Duchesneau: assistant professor of economics, University of Maine.

Dennis C. Duell: assistant professor of economics, Wichita State University.

Dean Dutton: assistant professor of economics, University of Iowa.

William Dwyer: instructor in economics, Lafayette College.

Peter C. Eckstein: assistant professor of economics and research associate, Center for Research on Economic Development, University of Michigan.

Mathew D. Edel, Yale University: assistant professor of economics, Massachusetts Institute of Technology.

Francis J. Egan, College of New Rochelle: instructor in economics, Trinity College.

Kenneth Elzinger: assistant professor of economics, University of Virginia.

John Fair, University of Illinois at Chicago: assistant professor of finance, College of Business Administration, University of Georgia.

Bernhard Felderer: lecturer in economics, University of North Carolina.

Max E. Fieser: senior associate, Robert R. Nathan Associates, Washington, D. C.

H. Gordon Fitch: assistant professor of business administration, School of Business, University of Kansas.

Max E. Fletcher: visiting professor of economics, University of Texas.

Ivan Flores: visiting professor of computer methodology and statistics, Bernard M. Baruch School of Business and Public Administration, City University of New York.

Peter A. Formuzis, Jr.: assistant professor of economics, University of Montana.

Charles R. Frank, Jr., Yale University: associate professor of economics and international affairs, Princeton University.

Richard B. Freeman: lecturer in economics, Yale University.

Peter Frevert: associate professor of economics, University of Kansas.

Klaus K. J. Friedrich: assistant professor of economics, Pennsylvania State University.

A. Blake Friscia: associate economist, Chase Manhattan Bank, N. A.

Rolf Funck: visiting associate professor of economics, University of North Carolina.

David Funk: lecturer in economics, Boston University.

James Funna: instructor in economics, Boston University.

Eirik G. Furubotn: professor of economics, Texas A&M University.

Bradley Gale: assistant professor of economics, University of Massachusetts.

Gerald Garb: professor of economics, Lehigh University.

Paul D. Gayer: lecturer in economics, Yale University.

George R. Gebhart: assistant professor of economics, University of Texas.

Hourmouzis Georgiadis: associate professor of economics, New York University.

Shaikh Ghazanfar: instructor in economics, Washington State University.

Roland Gibson, retiring chairman, department of economics, Washington College: New Hampshire College of Accounting and Commerce.

Herman L. Gilster: instructor in economics, U.S. Air Force Academy.

Victor P. Goldberg: assistant professor of economics, University of California, Davis.

Kenneth D. Goldin: assistant professor of economics, University of California, Davis.

Henry N. Goldstein: associate professor of economics, University of Oregon.

Dale I. Gramley: instructor in economics, North Carolina State University.

William P. Gramm: assistant professor of economics, Texas A&M University.

Harry Grubert, University of Rochester: Bureau of the Budget, Washington, D. C.

Gerald A. Gunderson: assistant professor of economics, University of Massachusetts.

K. L. Gupta: assistant professor of economics, University of Saskatchewan.

Paul F. Hass, U.S. Army: assistant professor of economics, Bowling Green University.

Robert E. Hall: acting assistant professor of economics, University of California, Berkeley.

Gerald D. Hansen: instructor, department of economics and commerce, Simon Fraser University.

John L. Harpell: assistant professor, College of Commerce, West Virginia University.

William Hamberger, University of North Carolina: associate professor of economics, graduate faculty, New School for Social Research.

K. Peter Harder: assistant professor of economics, Wichita State University.

Leonard J. Hausman: assistant professor of economics, North Carolina State University.

George A. Hay: lecturer in economics, Yale University.

Donald G. Heckerman: instructor in business economics, Graduate School of Business, University of Chicago.

Lloyd A. Helms, retiring dean of the Graduate School, Bowling Green University: professor of economics, Bowling Green University.

Robert Hessen: associate in business, Graduate School of Business, Columbia University.

Gerald F. Higgins: assistant professor of economics, University of Texas.

Reginald V. Hobbah: research scientist, staff of State of Connecticut Research Commission.

James Holmes, Purdue University: assistant professor of economics, State University of New York at Buffalo.

Donald C. Horton, Bowling Green University: Northern Illinois University.

William R. Hosek: assistant professor of economics, Whittemore School of Business and Economics, University of New Hampshire.

H. Keith Hunt: assistant professor of marketing and advertising, University of Iowa.

Zia Husain: lecturer in finance, Graduate School of Business Administration, New York University.

Raymond Jackson: assistant professor of economics, Boston University.

Rosella James, Temple University: assistant professor of economics, University of South Florida.

Jerry J. Jasinowski: instructor in economics, U.S. Air Force Academy.

R. Steven Jenks: assistant professor of business administration, Whittemore School of Business and Economics, University of New Hampshire.

Ivan Johnson: visiting assistant professor of economics, University of Virginia.

Norris O. Johnson: Maine Bankers Association professor of economics, University of Maine.

Shirley Johnson, Washington Square College, New York University: associate professor of economics, Vassar College.

Jon M. Joyce: lecturer in economics, Wesleyan University.

Arnold Katz, Columbia University: associate professor of economics, University of Pittsburgh.

Bernard Katz: instructor in economics, Lafayette College.

Woo Sik Kee: associate professor of economics, College of Commerce, West Virginia University.

Warren J. Keegan: associate in business, Graduate School of Business, Columbia University.

Michael Keenan: assistant professor of finance, Graduate School of Business Administration, New York University.

Jerry S. Kelly, Harvard University: assistant professor of economics, Syracuse University.

Jay B. Kennedy, Arabian American Oil Company: associate professor of economics, University of South Florida.

Kwan S. Kim: assistant professor of economics, University of Notre Dame.

Bruce W. Kimzey: instructor in economics, Washington State University.

Walter J. Klages: assistant professor of economics, University of Alabama.

- Charles Klasson: professor of management, University of Iowa.
- Alvin K. Klevorick: research staff economist and lecturer in economics, Yale University.
- Benjamin E. Laden, Johns Hopkins University: assistant professor of economics, Ohio State University.
- Arthur B. Laffer: instructor in business economics, Graduate School of Business, University of Chicago.
- Jose D. Langier, Michigan State University: visiting assistant professor of economics, Washington University.
- Jerome La Pittus, Cornell University: First National City Bank, New York.
- J. William Leasure, University of North Carolina: associate professor of economics, San Diego State College.
- Francis A. Lees: associate professor of economics, Brooklyn College.
- Nathaniel H. Leff, Harvard University: assistant professor, Graduate School of Business, Columbia University.
- Jane Leuthold: instructor in economics, University of Illinois.
- Irving Leveson: research economist, New York City Health Services Administration.
- David H. Levey: lecturer in economics, Yale University.
- Frank S. Levy: acting assistant professor of economics, University of California, Berkeley.
- Ben W. Lewis: program advisor, International Division, Ford Foundation.
- Raymond Lewis: instructor in accounting and business administration, School of Business Administration, American University.
- William Long, University of California, Berkeley: assistant professor of economics, Cornell University.
- Thomas C. Lowinger: assistant professor of economics, Washington State University.
- Taylor D. MacLafferty: associate professor of business administration, Emory University.
- G. S. Maddala, Stanford University: associate professor, University of Rochester.
- John L. Madden: assistant professor of economics, University of Kentucky.
- John E. Maher, Joint Council on Economic Education: lecturer in economics, Harper College, State University of New York at Binghamton.
- Dennis R. Maki: instructor, department of economics and commerce, Simon Fraser University.
- Fred A. Mangum, Jr.: assistant professor of economics, North Carolina State University.
- Huntley G. Manhertz, National Planning Association: assistant professor of economics, University of Pittsburgh.
- Patrick Mann: assistant professor of economics, College of Commerce, West Virginia University.
- Richard G. Marcis: assistant professor of economics, Bowling Green University.
- Bernard J. Marks, Southern Illinois University: visiting research professor of economics, University of Arizona.
- Jacob Marschak, professor emeritus, University of California at Los Angeles: visiting professor, department of economics and Center for Research in Management Sciences, University of California, Berkeley.
- Joseph B. Mason: lecturer in marketing, School of Commerce and Business Administration, University of Alabama.
- John Masten, University of Kentucky: Georgia Bankers Association professor of banking, College of Business Administration, University of Georgia.
- Charles Maurice: assistant professor of economics, Texas A&M University.

Alex Maurizi: assistant professor of economics, University of Iowa.

Bennett McCallum: assistant professor of economics, University of Virginia.

F. William McElroy, Georgetown University: assistant professor of economics, State University of New York at Buffalo.

William McFarland: assistant professor of economics, University of Michigan.

Martin C. McGuire, Office of the Assistant Secretary of Commerce: associate professor of economics, University of Maryland.

David L. McKee: assistant professor of economics, Kent State University.

William H. McWhinney: visiting associate professor of industrial administration, Graduate School of Business, University of Chicago.

Frederic Meyers, University of California, Los Angeles: visiting professor of industrial relations, Massachusetts Institute of Technology.

Constantine Michalopoulos, Trinity College: assistant professor of economics, Clark University.

Norman C. Miller, Bowling Green University: Carnegie Institute of Technology.

Reuben G. Miller, University of Massachusetts: assistant professor of economics, Smith College.

Richard L. Mills: assistant professor of economics, Whittemore School of Business and Economics, University of New Hampshire.

Albert Mitchell: associate professor of accounting, University of Iowa.

Paul M. Montrone, Office of the Assistant Secretary of Defense (Systems Analysis): assistant professor of business, Graduate School of Business, Columbia University, January 1968.

John Morris: assistant professor of economics, University of Iowa.

Kent D. Nash: instructor in economics, North Carolina State University.

Leo J. Navin: assistant professor of economics, Bowling Green University.

Wallace L. Nelson, Jr.: assistant professor of economics, Wichita State University.

Howard W. Nicholson: professor of economics, Clark University, returning from leave.

John H. Niedercorn: assistant professor of economics and urban and regional planning, University of Southern California.

William D. Nordhaus: research staff economist and lecturer in economics, Yale University.

Gur Ofer, Harvard University: lecturer, Massachusetts Institute of Technology.

Frank Otterstrom: instructor in economics, U.S. Air Force Academy.

George G. C. Parker, Stanford University: associate in business, Graduate School of Business, Columbia University.

Malvika S. Patel, University of Southern California: assistant professor of economics, San Diego State College.

A. Paus-Jenssen: assistant professor of economics, University of Saskatchewan.

Walter H. Pearce, University of Kentucky: visiting lecturer in economics, University of Arizona, spring 1968.

Arnold Pearlman: assistant professor of economics, Hampden-Sydney College.

Carlos Palaez: visiting assistant professor of economics, University of Pittsburgh.

Joseph D. Peno, Michigan State University: instructor in economics, Hamilton College.

Boris P. Pesek, Michigan State University: University of Wisconsin at Milwaukee.

Louis F. Pisciotoli: lecturer in economics, Fresno State College.

Hugh M. Pitcher: assistant professor of economics, University of Kentucky.

James L. Plummer: instructor in economics, U.S. Air Force Academy.

Donald E. Pursell: assistant professor of economics, College of Commerce, West Virginia University.

Robert C. Puth: assistant professor of economics, Whittemore School of Business and Economics, University of New Hampshire.

H. Raymond Radosevich: assistant professor of business administration, School of Business, University of Kansas.

James J. Rakowski: assistant professor of economics, University of Notre Dame.

Roger Ransom, University of Virginia: visiting lecturer in economics, University of California, Berkeley.

T. V. S. Rama Mahan Rao: visiting lecturer in economics, University of Southern California.

L. T. Reeves, Samford University: professor of finance, School of Commerce and Business Administration, University of Alabama.

Ricardo C. Reinoso: instructor in economics, North Carolina State University.

Nagesh S. Revankar, University of Wisconsin: assistant professor of economics, State University of New York at Buffalo.

Michael Rieber: associate professor of economics, University of Missouri.

Blaine Ritts: assistant professor of accounting, University of Iowa.

Stefan H. Robock, Indiana University: professor of business, Graduate School of Business, Columbia University.

Robert J. Rohr, Purdue University: assistant professor of economics, Brown University.

Alfredo Roldan: associate professor of economics, University of Nebraska.

M. Richard Roseman: assistant professor of economics, University of Iowa.

David F. Ross: associate professor of economics, University of Kentucky.

Gilbert L. Rutman, University of Arizona: assistant professor of economics, College of Commerce, West Virginia University.

Krishan G. Saini: assistant professor of economics, University of Texas.

Ryuzo Sato, University of Hawaii: professor of economics, Brown University.

Sidney Schoeffler, University of Massachusetts: General Electric Company, New York.

Myron S. Scholes: instructor in finance, Graduate School of Business, University of Chicago.

Linus E. Schrage: assistant professor of applied mathematics and production management, Graduate School of Business, University of Chicago.

Marc C. Scriven: assistant professor of economics, Washington State University.

Lawrence H. Seltzer, Wayne State University: visiting professor of economics, University of Pennsylvania.

Nathaniel E. Shechter: associate professor of economics, Old Dominion College.

James J. Sherman, University of Buffalo: assistant professor of economics, University of South Florida.

James S. Shulman: visiting professor of management, Massachusetts Institute of Technology.

David L. Siders: instructor in economics, College of William and Mary.

Horst Siebert: visiting lecturer in economics, Texas A&M University.

Bertram Silverman, Cooper Union: assistant professor of economics, Hofstra University.

Barbara Simpson, University of Maryland, Munich: assistant professor of economics, College of William and Mary.

Rafael A. Sison: senior economist, Asian Development Bank, Philippines.

Richard E. Slitor, Office of Tax Analysis, U.S. Treasury: professor of economics, University of Massachusetts.

Wilbur J. Smith: assistant professor of economics, College of Commerce, West Virginia University.

Philip Sorensen, University of California, Santa Barbara: visiting assistant professor of economics, University of California, Berkeley.

Mrs. Graham Spry: visiting associate professor of economics, University of Saskatchewan.

Dennis Stene: instructor in economics, St. Olaf College.

Edmund B. Stewart: instructor in economics, U.S. Air Force Academy.

Clark W. Strausser, University of Minnesota: assistant professor of economics, State University of New York at Buffalo.

Lanny Streeter, Hunter College: assistant professor of economics, University of Miami.

Robert R. Sterling: associate professor of business administration, School of Business, University of Kansas.

Donald L. Sternitzke, University of Arizona: associate professor of economics, Bowling Green University.

Richard A. Stevenson: assistant professor of finance, University of Iowa.

Joseph E. Stiglitz: assistant professor of economics, Yale University.

M. Richard Sussman, Emory University: professor of finance, College of Business Administration, University of Georgia.

Richard C. Sutch: acting assistant professor of economics, University of California, Berkeley.

Leopold Sveikauskas: assistant professor of economics, Brooklyn College.

P. A. V. B. Swamy, University of Wisconsin: assistant professor of economics, State University of New York at Buffalo.

Donald G. Tailby: department of economics, University of New Mexico.

Vito S. Tanzi: associate professor of economics, American University.

Ben B. Tarwater: assistant professor of economics, Bowling Green University.

Rasesh Thakkar, University of Rochester: assistant professor of economics, State University of New York at Buffalo.

Arthur A. Thompson: associate of economics, University of Alabama.

Russell G. Thompson, University of Missouri: associate professor of economics, Texas A&M University.

James Thornblade, Massachusetts Institute of Technology: assistant professor of economics, Syracuse University.

Victor Tidwell: associate professor of accounting, University of Iowa.

Douglas J. Tigert: assistant professor of marketing, Graduate School of Business, University of Chicago.

Ralph D. Tomkin: research associate, department of economics, Iowa State University.

John J. Treacy, Texas A&M University: associate professor of economics, Wright State University, Dayton.

Jack E. Triplett, University of Oregon: assistant professor of economics, Washington University.

Edwin M. Truman: lecturer in economics, Yale University.

Allen T. Unsworth: instructor in economics, Pennsylvania State University.

Myron Uretsky, University of Illinois: visiting associate professor of business, Graduate School of Business, Columbia University.

Dan Usher, Graduate School of Business, Columbia University: associate professor of economics, Queens University, Kingston, Ontario.

Richard G. J. Vangermeersch: assistant professor of accounting, University of Maine.

C. Daniel Vencill: lecturer in economics, University of California, Davis.

Frenck Waage, University of California: associate in business, Graduate School of Business, Columbia University.

- William P. Wadbrook, Ithaca College: assistant professor of economics, Trinity College.
- John E. Walker: associate professor of economics, Lehigh University.
- John C. Wardlaw, Jr.: assistant professor of economics, Old Dominion College.
- Darwin Wassink: assistant professor of economics, University of Iowa.
- Douglas W. Webbink: lecturer in economics, University of North Carolina.
- John C. Weicher, University of California at Irvine: assistant professor of economics, Ohio State University.
- Robert M. Weidenhammer, University of Pittsburgh: professor of finance, School of Business Administration, American University.
- Steven J. Weiss: visiting lecturer, University of Colorado.
- Thomas Weiss: assistant professor of economics, University of Kansas.
- Martin L. Weitzman: research staff economist and lecturer in economics, Yale University.
- John Whitaker: visiting professor of economics, University of Virginia.
- Gary A. Wicklund: assistant professor of quantitative methods, University of Iowa.
- B. J. Widick, University of Michigan—Wayne State University, Labor and Industrial Relations Institute: visiting associate professor, Graduate School of Business, Columbia University.
- Sam Williamson: assistant professor of economics, University of Iowa.
- James E. Willis: assistant professor of economics, University of Houston.
- John O. Wilson: assistant professor of economics, Yale University.
- Lloyd Woodman, Jr.: instructor in economics, U.S. Air Force Academy.
- Robert G. Wyckham: instructor, department of economics and commerce, Simon Fraser University.
- Richard Y. C. Yin, University of Southern California: associate professor of economics, George Washington University.
- Paul Zarembka: acting assistant professor of economics, University of California, Berkeley.
- James A. Zwerneman: Operations Research and Economics Division of the Research Triangle Institute, North Carolina.

Leaves for Special Appointments

- Edmund L. Auchter, Fresno State College: Office of Planning, Bureau of Viet Namease Affairs, Agency for International Development, 1967-68.
- Vernon M. Briggs, Jr., University of Texas: U.S. Department of Health, Education and Welfare, June 1967-January 1968.
- Sherrill Cleland, Kalamazoo College: visiting professor of economics, University of Beirut, 1967-1969.
- Robert Eisner, Northwestern University: fellow at Center for Advanced Study in the Behavioral Sciences, Palo Alto, January-June, 1968.
- David Felix, Washington University: Center for International Affairs, Harvard University, 1967-68.
- Helmut J. Frank, University of Arizona: University of Denver, Research Institute, 1967-68.
- Izzat I. Ghurani, University of Texas at Arlington: Fulbright lecturer in economics, University of Liberia, Monrovia.
- Bruce Herrick, University of California, Los Angeles: Instituto de Economía and ESCOLATINA, Santiago, Chile.
- Benjamin H. Higgins, University of Texas: professor of economics, University of Montreal, 1967-68.

Gary C. Hufbauer, University of New Mexico: Harvard University Center for International Affairs, Development Advisory Service in Lahore, Pakistan, 1967-1969.

Saul Hymans, University of Michigan: staff member, Council of Economic Advisors, 1967-68.

Paul R. Johnson, North Carolina State University: Economics Department, RAND Corporation, Santa Monica, 1967-68.

C. P. Kindleberger, Massachusetts Institute of Technology: Clark College, Atlanta University Center, 1967-68.

Lawrence R. Klein, University of Pennsylvania: Ford rotating research professor of economics, University of California, Berkeley, January-June 1968.

Sidney Klein, Rutgers University: visiting professor of economics, University of Hong Kong, 1967-68.

Fred D. Levy, Jr., Syracuse University: Agency for International Development, Rio de Janeiro, Brazil.

Bevars D. Mabry, Bowling Green University: visiting professor, Thammasat University, Bangkok, Thailand, 1967-68.

Erwin E. Nemmers, Northwestern University: professorial research fellow in industrial economics, Case Institute of Technology, 1967-68.

Roger G. Noll, California Institute of Technology: professional staff, Council of Economic Advisers.

Bernard Okunsi, Brooklyn College: Makerere University College, Kampala, Uganda. 1967-68.

R. G. Penner, University of Rochester: consultant, government of Tanzania, first semester 1967-68.

Richard C. Porter, University of Michigan: mission to Colombia, Development Advisory Service, Harvard University, 1967-68.

Richard H. Puckett, American University: Federal Reserve Board, 1967-68.

Sherwin Rosen, University of Rochester: National Bureau of Economic Research, 1967-68.

Peter P. Schoderbek, University of Iowa: visiting professor, Michigan State University, 1967-68.

William G. Shepherd, University of Michigan: economic advisor, Antitrust Division, U.S. Department of Justice, 1967-68.

Shih C. Yu, University of Maine: visiting professor of accounting, University of Florida, 1967-68.

Resignations

Herbert A. Adamson, U.S. Air Force Academy, June 1967.

William W. Alberts, Graduate School of Business, University of Chicago, September 30, 1967.

Merrill J. Bateman, U.S. Air Force Academy, June 1967.

Robert E. Coleberd, Jr., Western Maryland College, June 1967.

S. Dasgupta, University of Saskatchewan.

Charles Goetz, University of Illinois.

Robert S. Johnson, University of Virginia.

J. Daniel Khazzoom, New York University.

Robert W. Knapp, Graduate School of Business Administration, University of California, Los Angeles, June 30, 1967.

Leonard J. Konopa: University of Iowa.

Ichirou Inukai: University of Alaska.

Harvey Leibenstein: University of California, Berkeley, June 30, 1967.

Marvin J. Levine, Ohio State University, September 1967.
Paul A. Montavon, University of Notre Dame, June 1967.
Bruce W. Morgan, University of Illinois, Urbana.
Clarence C. Morrison, University of Virginia.
John Peterman, University of Virginia.
Ronald G. Ridker, Syracuse University.
James Robinson, University of Missouri.
Wilson E. Schmidt, George Washington University, June 30, 1967.
James D. Smith, American University.
Gordon L. Tullock, University of Virginia.
Clinton L. Warne, Ohio State University.

SIXTY-FOURTH LIST OF DOCTORAL DISSERTATIONS IN POLITICAL ECONOMY IN AMERICAN UNIVERSITIES AND COLLEGES

EDITOR'S NOTE

The present list specifies doctoral degrees conferred during the academic year terminating June 1967. The list excludes theses undertaken in the same period. Last year the Editorial Board decided to terminate its long-standing practice of publishing titles of "Theses in Preparation," and to begin the publication of brief abstracts of completed doctoral dissertations. These decisions were carried out in the September 1966 issue and are continued in this one. We invite comments on and criticism of these decisions.

General Economics; Methodology

MARTIN R. BLYN, Ph.D. New York 1966. Essays in innovation among academic economists.

ROBERT G. FABIAN, Ph.D. Florida 1966. The structure of economic theory and the goals of scientific analysis.

JERRAL C. RAYMOND, Ph.D. Virginia 1967. Factors affecting the production of economic knowledge by American economists.

This study has attempted to investigate the relationship between the production of economic knowledge and five biographical characteristics in the life histories of the individual producers. First a conceptual framework was created by adapting the tools of conventional price theory. Then the framework was applied to actual data, with statistical tests evaluating the results. It was found that four of the five biographical characteristics were associated with higher levels of knowledge production.

Price and Allocation Theory; Related Empirical Studies

GEORGE A. AKERLOF, Ph.D. Mass. Inst. Technology 1967. Wages and capital.

CHARLES BLACKORBY, Ph.D. Johns Hopkins 1967. Rational rules for intertemporal decision making.

The purpose of this thesis is to examine concepts of rationality in intertemporal allocation problems. Using discrete time a consistent path is found, but myopia prevents a consumer from following it. A definition of intertemporal rationality is offered which requires consistency. This definition allows the consumer to avoid his myopia and justifies the consistent path found earlier.

KENNETH M. BROWN, Ph.D. Johns Hopkins 1967. Efficiency, profits, and the regional growth of manufacturing in the United States.

This study attempts to explain interstate differences in growth rates of SIC two-digit industries in the United States during the 1954-62 period. In a simultaneous equation model of the firm, it is shown how a variety of regional differences may affect growth. Of greatest empirical significance is the "efficiency parameter," a broad term which measures differences in output resulting from causes other than differences in quantities of capital and labor inputs.

FREDERICK CLEVELAND, Ph.D. Columbia 1967. Resource allocation in the firm.

MARK DANIELS, Ph.D. Johns Hopkins 1967. International differences in productive efficiency.

The primary objective of the study is to provide some evidence on the nature of efficiency in production among manufacturing industries in developing countries. The gen-

eral method employed is to analyze efficiency estimates obtained by utilizing a CES production function for two-digit manufacturing industries. Results indicate that no country studied clearly has a majority of relatively efficient or inefficient industries, rather industrial efficiency appears to vary systematically across the countries for which data were available.

HAMID HABIBAGAHI, Ph.D. Purdue 1966. Qualitative analysis of dynamic stability in general equilibrium theory.

FRED H. LEONARD, Ph.D. Michigan 1966. An analysis of short-run changes in functional income distribution.

WILLIAM F. E. LONG, Ph.D. George Washington 1967. Price and nonprice practices under the uncertain conditions of rapidly improving technologies—a case study.

The dissertation is a case study of cost-plus pricing to reduce the uncertainty as to which of the several techniques of producing the types of transistors that are used in computers will be the lowest-cost technique. Price is set as a constant function of average variable cost. The trends in price are valid indicators of the relative rates at which technologies are being improved and they therefore identify the surviving technology at an early date.

C. A. KNOX LOVELL, Ph.D. Duke 1966. A comparison of statistical properties of aggregate production functions.

WILLIAM D. NORDHAUS, Ph.D. Mass. Inst. Technology 1967. Theory of endogenous technological change.

NANDIRAJU K. RAO, Ph.D. Stanford 1967. Returns to scale and the production function with an application to the steam power generating plants in the U.S., for the period 1937-1961.

A constant elasticity of substitution production function of two variable inputs which under conditions of cost minimization by the firm implies first increasing and then decreasing returns to scale is derived and applied to the steam electric power generating plants newly built in the U.S., during the period 1937-61. *Ex ante* substitution possibilities, returns-to-scale changes due to technological change and differences in size of plant are studied. Also, the concept of returns-to-scale-envelope curve is introduced.

GEORGE N. REYNOLDS, Ph.D. Tulane 1967. User cost and intertemporal allocation in a holding firm.

A firm summarizes its future profit anticipation from the use of capital in its marginal efficiency of capital. But market prices which the firm faces as the future becomes the present may diverge from expected prices. The marginal efficiency of capital must therefore diverge from initially expected values. Keynes' definition of user costs takes into account this type of risk in planning the use of capital and the dissertation develops the definition in a mathematical model of a firm.

JOHN W. ROWE, JR., Ph.D. Illinois (Urbana) 1966. The production function: its history, properties and importance of the firm.

WILLIAM A. SCHEFFER, Ph.D. Duke 1966. Structural changes and plant-employment proportions, 1954-57.

CHANDLER H. STEVENS, Ph.D. Mass. Inst. Technology 1967. Information and the division of labor.

ARTHUR B. TREADWAY, Ph.D. Chicago 1967. Rational entrepreneurial behavior and the dynamics of investment.

A theoretical study of maximizing entrepreneurial behavior under adjustment costs, including (a) a model of rational excess capacity, (b) analysis of the determinants of the firm's (flow) demand for investment and (c) a derivation of the "flexible accelerator" equation as a linear approximation to an optimal adjustment path with a resulting model of the adjustment coefficient and an evaluation of the hypothesis of its constancy.

JAMES P. WALLACE, III, Ph.D. Brown 1967. Market stability under simultaneous price and quantity adjustment.

A simultaneous price and quantity adjustment model, having the Walrasian and Mar-

shallian processes as degenerate cases, is presented and its stability investigated. The problem of the diametrically opposite stability conditions of Walras and Marshall, when supply is downward sloping, is resolved. Market models are then formulated as Volterra integral equation systems to exhibit mathematically the feedback nature of market adjustment and to increase the adjustment process generality. Stability analysis is performed using theorems of Laplace Transformation.

Income Theory; Related Empirical Studies

THEODORE C. BERGSTROM, Ph.D. Stanford 1967. Human capital in an economic growth model.

A growth model is constructed in which human capital is a factor of production. Human capital need not be a perfect substitute for either raw labor or physical capital. The supply of human capital depends on income with an income elasticity which may exceed unity. The interaction between income and the stock of human capital is explored, stability conditions are derived, and the parameters relevant for stability are estimated.

JAMES R. DAVIS, Ph.D. Virginia 1967. Pre-Keynesian economic policy proposals in the United States during the Great Depression.

Despite modern descriptions to the contrary, leading economists in the United States during the Great Depression were not recommending wage reductions as the solution to unemployment and depression. Instead, most of them prescribed deficit budgets and other expansionary policies. By 1936, the notions of compensatory public spending and counter-cyclical balancing of the budget were commonplace, but Washington was not to be dissuaded from contractionary policies. Accordingly, myths regarding "classical" economists and economic policy during the Depression should be dispelled.

PATRICK B. DEFONTENAY, Ph.D. Yale 1967. Inflation growth and cost structure: an international comparison.

FREDERICK O. GODDARD, Ph.D. Duke 1966. A two-sector model of economic growth with technological progress.

ROBERT E. HALL, Ph.D. Mass. Inst. Technology 1967. Essays on the theory of wealth.

DONALD J. HARRIS, Ph.D. California (Berkeley) 1966. Inflation, capital accumulation, and economic growth: a theoretical and numerical analysis.

HENRY F. LEE, Ph.D. Pennsylvania 1966. Relative prices and cereal consumption functions—Korea, 1952 to 1962.

F. JOHN MATHIS, Ph.D. Iowa (Ames) 1966. The concept of underemployment theory and policy.

EUGENE MELANDER, Ph.D. Minnesota 1966. Longer-term household saving: some models and their empirical evaluation.

D. M. NOWLAN, Ph.D. Toronto 1965. Technical change in models of economic growth.

JOSEPH E. STIGLITZ, Ph.D. Mass. Inst. Technology 1967. Studies in the theory of economic growth and income distribution.

MORRIS F. TEUBAL, Ph.D. Chicago 1967. Inflation, unemployment and economic growth.

The analysis deals with the patterns of growth, inflation and unemployment of a one-sector monetary economy. Money is increased at a constant rate by a monetary authority by means of transfers to the private sector. Particular attention is given to the conditions under which the economy will shift from unemployment to full employment. Alternative assumptions concerning the formation of expectations and the behavior of money wages are postulated.

ADRIAN W. THROOP, Ph.D. Stanford 1967. Sources of inflationary bias in the American economy, 1949-62.

This dissertation analyzes the inflationary bias which has been manifested by the post-war Phillips curve. Alternative hypotheses are tested at several different levels of aggregation. Support is found for the hypothesis that collectively bargained wages fell relative to competitively determined ones during the demand inflation of the 1940's. It is

shown that the ensuing increase in the union-nonunion wage differential was the source of a once and for all cost-push inflation in the 1950's.

TERENCE J. WALES, Ph.D. Mass. Inst. Technology 1967. The effect of accelerated depreciation on investment, an empirical study.

EVANGELOS A. VOLOUDAKIS, Ph.D. Yale 1967. An empirical investigation of the Greek manufacturing investment function.

History of Economic Thought

GHALIB M. A. BAQIR, Ph.D. Saint Louis 1967. The Historical School in economics.

This dissertation has analyzed the rise and the development of the main teachings of the Historical School in economics as they were offered in the writings of its leading members in Germany, Great Britain, and the United States of America. The historical economists in these three countries have rendered a major service not only to historical or institutional economics but also to economic science taken as a whole.

ROBERT B. EKELUND, JR., Ph.D. Louisiana 1967. A critical evaluation of Jules Dupuit's contributions to economic theory and policy.

This study has analyzed in depth the works of the French economist, Jules Dupuit, including major economic works not heretofore available in English translation. Examined in detail are Dupuit's theories of marginal utility, demand and consumers' surplus, monopoly and price discrimination as well as his theory of "marginal cost pricing." In addition to developing original microeconomic tools of great theoretical interest, this research found him to be the first important welfare economist.

JOHN W. MCKINNEY, Ph.D. Columbia 1967. A critique of Frank H. Knight's economic philosophy.

A particular conception of the human mind as creative, the location of free choice and active decision-making, is the foundation of Knight's teaching as an economic theorist, methodologist of social science, and moralist. The study undertakes an appraisal of his ideas in the three fields from the point of view of an alternative conception of the creative mind, one that denies the status of the mental as a separate existence.

ROBIN F. NEILL, Ph.D. Duke 1966. The content and context of the work of Harold Adams Innis.

EDWARD J. POWERS, Ph.D. Boston College 1967. The social economics of John Maurice Clark.

Economic writings of John Maurice Clark are expounded and appraised in three important areas: the theory of overhead cost, business fluctuations, and competition. Clark's work is interpreted in terms of three key analytical concepts he formulated, those of social value, social efficiency and social balance. Clark's emphasis on a broadly conceived and policy-oriented social economics is viewed as his distinctive characteristic, which tends to weaken somewhat the analytic rigor of the Clarkian system.

Economic History; Economic Development; National Economies

GLEN G. ALEXANDRIN, Ph.D. Clark 1967. A study of investment, employment and growth in Newfoundland; with a statistical analysis of the period 1949-1961.

DAVID J. CANTOR, Ph.D. Harvard 1967. Import-replacing industrialization and economic development in Ghana.

Given markets for manufactures, Ghana stresses import-substitution in its development program. The prospects for its success appear doubtful because of the need for Ghana to maintain exports of primary products to finance capital imports in the short run and raw material inputs in the long run. Therefore, the dual structure of Ghana's economy, in which the majority of the population earn a low and stagnant level of income, is likely to be perpetuated.

MARK Z. FABRYCY, Ph.D. City University New York 1967. Determinants of technological advance—twenty countries, 1950 to 1963.

A Cobb-Douglas production function with analysis of covariance was used to measure technological change which was then regressed on four determinant variables. On-the-job-learning was shown to be by far most important. It was then demonstrated that technology may depend to a very important degree on the accumulated effect of capital input and can be expressed in a Cobb-Douglas function by a capital coefficient which is much larger than that of labor.

IRWIN FELLER, Ph.D. Minnesota 1966. Regional variations in the diffusion of innovations: the case of the Draper loom.

Prevailing accounts of the response of New England cotton textile mills to the Draper

loom hold that these mills were slow in responding to the technique and that this hesitation was due to the "conservative" quality of management. The conclusion here is that the response by these mills is explainable in terms of the adjustment behavior expected of firms operating within competitive markets given a new production technique which is a functional rival of installed equipment.

JOSEPH C. FUREY, Ph.D. Maryland 1966. The crisis of feudalism in the fourteenth century in England.

CARL H. GOTSCH, Ph.D. Harvard 1967. Technological change and private investment in agriculture: a case study of the Pakistan Punjab.

The study examines two hypotheses: (1) that peasants in a backward agriculture are poor but efficient, and (2) that the rapid private investment in water resource development observed in recent years in the Punjab is consistent with the idea that peasants are responding to a disequilibrium situation created by the availability of new water producing technology. The investigation was conducted by constructing linear programming models for both "traditional" and "modern" agriculture. Special attention was devoted to incorporating linear approximations of nonlinear water response curves into the programming models.

AHMED S. ISPAHANI, Ph.D. Southern California 1966. The optimization of economic resources for economic growth in Iran.

Findings seem to indicate that the future of Iran looks encouraging. Possessing substantial human and rich productive mineral resources, Iran has one of the best potentials for advancement among the developing countries. Its petroleum industry is one of the largest in the world. The substantial natural gas reserves, which together with oil, will provide the power for new industry is one of the largest in the world. Mining is in its infancy, but there are indications of considerable wealth here too. The rich fishing resources of the Persian Gulf are largely untapped. Iran has no population growth problem, or likelihood of future pressure on the land. Substantial revenue can be obtained from taxes by reforming the tax structure of Iran. Iran has an enlightened, intellectual, democratic, progressive and far-sighted leader in Reza Shah. Under his leadership, Iran can make solid advantages toward its goal of a modern economy.

ABDEL-FATTAH M. KANDEEL, Ph.D. Southern California 1966. The "Surplus" approach for project appraisal (an application to the Aswan High Dam).

The criterion of consumers' and producers' superior to other criteria in going beyond a simple comparison between costs and outcomes. Although the Dam would result in a net gain, stripping from the project its contribution to industry would have serious effects on its contribution to agriculture. To recapture the loss of potential surplus, a deliberate process to increase national income outside the agricultural sector is required.

S. STANLEY KATZ, Ph.D. American 1966. The external assistance contribution to Indian economic growth and development 1951-1961.

Qualitative and quantitative assessment of the contribution made by external economic assistance to the economic growth and development achieved by India during the 1951-1961 decade of the First and Second Indian Five Year Plans.

DOUGLAS H. KEARE, Ph.D. Princeton 1966. Planning and French economic policy: 1958-1965.

The French planners possess virtually no tools for influencing the economy. They must rely upon persuading others, most notably the Minister of Finance, to use their formidable powers to achieve ends desired by the planners. This has been done with limited success. Planning has not exerted a comprehensive influence upon the conduct of policy. Nonetheless, it has succeeded in promoting certain specific goals and the removal of "structural" obstacles to the development of the economy.

DAVID KLINGAMAN, Ph.D. Virginia 1967. The development of Virginia's coastwise trade and grain trade in the late colonial period.

The coastwise trade and the total grain exports of Virginia were quantified, and the development and growth of these two branches of commerce were analyzed in detail. The average annual rate of growth of both branches of trade surpassed that of the population. Total grain exports to world markets grew especially fast over roughly the last 30 years of the colonial period and compensated the economy in part for the sluggish growth of tobacco exports.

LLOYD J. MERCER, Ph.D. Washington 1967. The Central Pacific System: an estimate of social and private rates of return for a land-grant aided railroad system.

This study provides estimates of the private and social rates of return for the Central Pacific Railroad System, 1863-1889. These estimates are used to evaluate some government policies designed to promote growth, particularly the land grant policy. Three rates of return are calculated: (1) Unaided private rate—12.9 per cent; (2) private rate with land grant—14.1 per cent; (3) social rate—28.6 per cent. Even the lowest of the three is much above the market rate of return for the period, 7.5 per cent, indicating that this railroad would have been profitable in the absence of land grants. Still since the social rate of return is much above the private one, to the extent that land grants provided an extra incentive to undertake the railroad construction, it was not an unattractive policy.

MAUNG MYINT, Ph.D. California (Berkeley) 1966. Agriculture in Burmese economic development.

ROBERT T. NEWSOM, Ph.D. Tulane 1966. Changes in the structure of employment in Texas, 1940 to 1960.

The employment shift analysis is the statistical technique utilized to relate the structural changes in the State Economic Areas of Texas to the nationwide structural changes. The goals are: (1) to analyze employment change in each state sub-area in terms of the role of industrial composition and the role of differential growth rates between the sub-area and the nation, and (2) to reveal the patterns of change associated with the economic specialization of sub-areas.

STAHIS S. PANAGIDES, Ph.D. Iowa (Ames) 1967. An econometric study of the Cyprian economy.

RAMANBHAI C. PATEL, Ph.D. Southern California 1966. Applications of stochastic processes to economic development.

This dissertation attempts to develop a theory of economic growth using stochastic processes of the diffusion type. Besides the purpose of the stochastic model of economic

growth to discover and explain the nature of economic growth exhibited by temporally interdependent economic variables, its empirical applications to a wide variety of economies provide a basis of comparison of the growth process for different regions. The empirical results indicate similarity of economic growth although parameter values are different for different situations.

SYED I. RIZVI, Ph.D. Southern California 1967. The evaluation of the Second Five Year Plan of Pakistan.

Mechanization of an optimal piece of and installation of a steel industry sufficient for mechanization are very important. Effective "grass roots" participation is a strategic prerequisite for the impartation of flexibility and mobility of factors of production for a self-sustained rate of growth. Measures have been suggested to infuse elasticity, both in taxation and the money supply, coupled with an optimal demarcation of the allocation of scarce resources between the production of consumers' goods and producers' goods.

DANIEL K. ROYER, Ph.D. Florida 1966. Economic development of El Salvador.

A summary of available income and price level statistics for various sectors of the economy during the postwar years, with particular effort to determine the relationship between income/investment ratios for new and for old investment sectors. Numerous unpublished economic development reports were used, and an effort was made to appraise the value of past and future investment in specific projects as well as in general areas of production.

WILLIAM T. RYAN, D.B.A. Indiana 1966. Planning in Peru: an analysis and strategy for development.

JAMES F. SHEPHERD, Ph.D. Washington 1966. A balance of payments for the thirteen colonies—1768-1772.

The general contours of colonial economic development can be understood only when the essential data are obtained. Up until this time such information has been lacking. A crucial aspect of the colonial economy was its economic relationships with the rest of the world. This study for the first time has estimated the values of exports and imports and invisible items in the balance of payments. As a result we can now precisely determine the importance of tobacco, rice, and shipping services in the credits of the balance of payments, and also get an equally precise breakdown of the relative importance of each of the debts.

SAMIR Y. SIDHOM, Ph.D. Southern California 1967. Developmental planning in the United Arab Republic: an economic analysis and evaluation of the Egyptian experience.

The Egyptian experience in comprehensive planning during the First Five Year Plan indicates that it was significantly successful in promoting economic growth, raising the living standard, and attaining a high degree of equitable income distribution. However, the First Plan was not effective in dealing with some development problems including rapid population growth, decreasing the rate of increase in consumption, curbing inflationary pressures, and solving the efficiency problem. Measures to aid future plans are included in the study.

- MARY B. VANIYAPURAYIL, Ph.D. Boston College 1967. Some aspects of capital formation and its financing in the Indian economy, 1948-49 to 1960-61.

This dissertation analyzes the role of capital formation and its financing in India from 1948-49 to 1960-61. Average and marginal capital-output and saving ratios are analyzed. Investment increased sharply during the period, capital-output ratios rose slightly, and saving ratios fell in the latter years. It is argued that these lower savings ratios in the latter years resulted from lower agricultural production and the shift in the terms of trade against the urban high-saving sector.

- BENSION VARON, Ph.D. Pennsylvania 1967. Export instability and economic development—the Turkish experience 1948-60.

Turkey had one of the lowest foreign trade ratios in the world and her export fluctuations were moderate compared to those of 80 countries. Yet these fluctuations were instrumental in bringing about a slackening in the growth rate of real investment and a deterioration in the productivity of capital. The dissertation analyzes the causes and consequences of export fluctuations with particular emphasis on the major factors which account for their disproportionate repercussions on the Turkish economy.

- JAMES N. VEDDER, Ph.D. Michigan 1966. Improved measurement of state economic growth, its sources, and the impact of state economic development programs.

- BRENDAN M. WALSH, Ph.D. Boston College 1966. An economic model of Ireland 1944-62.

On the basis of historical and institutional material concerning the Irish economy in the years 1944-1962, a model was formulated and statistically tested to study the determination of 21 key macroeconomic variables. Using an industry-agriculture dichotomy, a number of behavioral equations were estimated for each sector. The dependence on external trade was studied and estimates of import and export price elasticities obtained. The model was applied to the simulation of the economy in 1962 and the preparation of forecasts for 1963 and 1964.

- GARY M. WALTON, Ph.D. Washington 1966. A quantitative study of American colonial shipping.

There has been almost no analytical work done exploring the rate of growth or the sources of growth during the first 170 years of colonial existence. This thesis is a study of a major colonial industry—shipping—and provides new information on the volume of shipping, trade routes, and income generated. However, its most important contribution is to provide a rough measure of productivity improvement during that period, and then through an examination of inputs into shipping to explore the sources of that productivity increase. The results of this investigation are twofold: (1) that there was substantial increase in productivity in colonial shipping from the middle of the seventeenth century to the Revolutionary War, and (2) that the decline in piracy and improving economic organization accounts for this growing efficiency. Technological change on the other hand which is usually thought of as the major source of productivity increase plays little or no part.

A. EUGENE ABRASSART, Ph.D. Illinois (Urbana) 1967. Dimensional analysis in economics.

PAUL ALDUNATE, Ph.D. Purdue 1967. Labor and capital sectoral allocation in the Chilean economy: a linear programming macroeconomic model.

An intersectoral macro-economic linear programming model was used to analyze the Chilean economy. The objectives were: (1) a static analysis when additional labor or capital resources were freely allocated to all the sectors of the economy and when these resources were allocated to the agricultural or manufacturing sectors; (2) A dynamic analysis when labor and capital resources were freely allocated to all the sectors of the economy and when additional labor or capital resources were allocated to the agricultural sector. The static analysis indicated that when additional workers were freely allocated among the sectors, the manufacturing and other sectors were most profitable. When additional capital was freely allocated among the sectors of the economy, manufacturing and mining were most profitable. The dynamic analysis indicated that when labor and capital resources were freely allocated, gross domestic product grew at increasing rates. These growth rates were always higher than the rate of increase in population.

ALAIN CEOPPIN DE JANVRY, Ph.D. California (Berkeley) 1966. Measurement of demand parameters under separability.

A number of ways of testing the hypothesis of a separable utility function and of determining a suitable partition of the commodity space are presented. Methods for measuring demand parameters are then systematically developed under various types of separability. Particular use is made of the two-stage maximization hypothesis.

FRANCES D. FERGUSON, Ph.D. Boston College 1967. Survey and analysis of time series econometric studies of U.S. manufacturing investment in plant and equipment.

This study examines the structural stability and predictive ability of the investment equations of deLeeuw, Kareken and Solow, Goldfeld, Bourneuf, and Liu. Although covariance tests suggest that all the equations, except Liu's, are stable over time, the "t" tests indicate that various coefficients within the equations are not. The predicted series lagged or moved simultaneously with the actual series; the differences between the predicted and actual series were seldom more than ten per cent of the actual series and often less.

WILLIAM E. HOEHN, Jr., Ph.D. Northwestern 1966. Simultaneous interpolation and parameter estimation.

This dissertation addresses the problem of maximum-likelihood estimation in models containing lagged endogenous variables when observed values of the dependent variable are obtained less frequently than observations on the independent variables. Two estimation strategies are considered. The first strategy is to obtain parameter estimates only, treating missing observation values essentially as nuisance parameters. The second strategy is to obtain simultaneously both parameter estimates and estimates of missing observations, by a straight-forward maximization of the joint density function. Several estimation procedures are developed and Monte Carlo estimation of some numerical examples is performed. On the basis of two distribution sampling experiments, the second strategy, that of estimating both parameters and missing observations, appears marginally better than the first.

ROGER F. RIEFLER, Ph.D. Washington 1966. Interregional input-output: Washington and California.

For some decades, perhaps beginning with Ohlin in the early 1930's, economists have recognized the feedback relations between two economic regions. In international trade analysis, this is the familiar foreign trade multiplier concept. While it has been recognized that two states can be tied in an interregional network, empirically no one has implemented such a model for two states. This thesis constructs an interregional input-output for the states of California and Washington. Both states have input-output studies and the major task was to link them together empirically. This involved developing a two-region input-output model with 53 sectors.

The thesis has developed some careful measuring techniques to generate interregional

flow data. In addition, it has tested the stability of certain trading coefficients and found them, in general, stable.

Economic Systems; Planning and Reform; Cooperation

JAMES G. ABERT, Ph.D. Duke 1966. The coordination of economic policy in the Netherlands.

ALAN A. BROWN, Ph.D. Harvard 1967. The economics of centrally planned foreign trade: the Hungarian experience.

This study is a theoretical, quantitative, and institutional analysis of Hungarian foreign trade (1949-1960). Its basic purpose is to further our understanding of centrally planned foreign trade, in general. The analysis is polarized around two central themes: the role of foreign trade in a traditional centrally planned economy, and the foreign trade reform movement. The general conclusions are that (a) the economic problems tend to intensify over time in a small centrally planned economy because of foreign trade; and (b) the foreign trade reforms, if they are to be effective, need to be well coordinated. These conclusions, in turn, may be derived from a single proposition, i.e., the dynamic effects of centrally planned foreign trade are functionally interrelated. The study also contains a theoretical model of centrally planned foreign trade, which is used to systemize and generalize the relationships among the variables.

DAVID W. CONKLIN, Ph.D. Mass. Inst. Technology 1967. Essays on Soviet agriculture and decentralization reforms.

PAUL C. ROBERTS III, Ph.D. Virginia 1967. An administrative analysis of Oskar Lange's theory of socialist planning.

The natures of hierarchical and polycentric organization are examined and found fundamentally different. Lange's theory is examined in the context of the Socialist Debate and

found not to reflect the intentions and aspirations of what was meant by central planning, but to be rooted in polycentric organization. The famous refutation of Mises' argument about the impossibility of a planned economy is found to be illusory. Five factors are given that contributed to perpetuating the illusion.

FAUAD E. M. EL TAHER, Ph.D. Pennsylvania 1967. A management perspective on the U.A.R.'s First Five Years of national economic planning.

The specific objectives of this study are: (1) to provide an analytic description of the U.A.R.'s Central Planning experience within the full historical context of the country's cultural, physical, institutional and economic development; (2) to uncover and analyze the areas of relative success and failure in the first five years of the centrally planned economy; (3) to identify the adaptations required of business institutions by the national planning structure and process; (4) to offer insights for alternative adaption patterns for business institutions within the National Planning structure and process.

SALWA A. S. FARGHALI, Ph.D. Southern California 1966. Planning under socialism—and risk.

Data limitations and the clarity of priorities in early stages of development limit the possible uses of the great advantages of the present stochastic analysis; and under conditions of central planning, the "imperfections in the conditions of plan execution" represent the existence of new random elements, inherent in the system, which reflect a situation or uncertainty. Since these elements are inseparable from technical aspects of the allocation policy, the actual situation under which anticipations in a centrally planned system are made is one of uncertainty rather than risk. This, in turn, justifies the acceptance of planners' choice and value-judgement.

WILLIAM L. HOLMES, Ph.D. Illinois (Urbana) 1966. Control aspects of economic planning under information restrictions.

PAUL JONAS, Ph.D. Columbia 1966. A critique of Sovietology: the theory of a centrally planned economic system.

The study shows that the general analytical diagrammatic framework, with modifications, can be applied to centrally planned economies. For these systems, models are developed to represent and analyze (1) price structure; (2) determination of product-mix; (3) distribution of product-mix; (4) trade equilibria; (5) estimation of national income. The study also argues that in the family of special purpose theories a sub-family should be developed to deal with the pure theory of the Soviet type systems.

LEONARD KIRSCH, Ph.D. Harvard 1967. A study of Soviet economics: wage administration and structure in the USSR since 1956.

In broad outline this investigation is divided into seven parts. The chapter following the introduction is devoted to the determination of basic wage rates. Chapters III through V concentrate on incentive wages: the scope and nature of the various incentive systems; the determination of output norms for piece-rate workers; and the effect of incentive wages upon differentiation of earnings. In Chapter VI, Soviet wage theory and proposed reforms are discussed. The final chapter is devoted to an appraisal of the Soviet approach to intra-industrial wage determination.

JOYCE S. PICKERSGILL, Ph.D. Washington 1966. Soviet monetary policy 1914-1937.

The essential contribution of this study is the application of western macro-economic theory to the investigation of monetary policy in the Soviet economy. Traditional demand theory is applied to an analysis of changes in the holdings of cash and non-cash assets of consumers and firms. Several economic variables were chosen to test the stability of the demand function for money in the context of Soviet institutions. By conventional statistical criteria, the demand function was remarkably stable over the long period despite major institutional changes that occurred over the period.

AKRAM SHAKRA, Ph.D. Oklahoma 1966. Land reform in Syria.

ARMAND M. J. VAN NIMMEN, Ph.D. Columbia 1967. French planning: an essay in evaluation.

The dissertation is an attempt to (1) evaluate French planning as a form of economic

forecasting and (2) verify whether there exist any statistically verifiable indications in support of the hypothesis that planning has had a discernible impact on the pattern of French economic growth. The analysis is carried out in terms of a series of statistical tests involving correlation coefficients, inequality coefficients and input-output experiments.

Business Fluctuations

ROSANNE COLE, Ph.D. Columbia 1967. Errors in estimates of Gross National Product and their relation to forecasting accuracy.

Study appraises the accuracy, as indicated by the successful revisions, of the preliminary estimates of GNP and its components and analyzes the effects of errors in these data on the accuracy of short-term forecasts. Estimates are made of the extent to which the accuracy of different types of forecasts was impaired as a consequence of using preliminary rather than final (1965) data.

MOHEB A. GHALI, Ph.D. Washington 1967. Rational models of finished goods inventories.

A review of the literature on inventory holdings reveals a gap between theory and data. This dissertation helps to bridge this gap by combining a theory of inventory holdings predicated on profit maximization and sound statistical analysis of data on finished goods inventories. An empirically verifiable model of inventory holdings in response to predictable seasonal fluctuations in sales is developed.

FAITH HALFTER, Ph.D. Harvard 1967. The cyclical behavior of materials' prices in United States industry, 1947 to 1965.

This is an empirical study of the cyclical behavior of prices of the major crude industrial raw materials in the American economy in the postwar period. Although price equations are estimated for several individual materials, the chief interest is in explaining macro behavior. The hypothesis is neoclassical, namely, changes in domestic materials' prices can be explained by demand pressures in the product market both at home and abroad. The results largely support this hypothesis.

ALLAN E. BERGLAND, Ph.D. Arizona 1967. The response to monetary policy in the Eleventh Federal Reserve District 1954-1963.

This study determined, for the Eleventh Federal Reserve District, the length of the intermediate lag in monetary policy. The intermediate lag was defined as the time lapse occurring between a "dynamic" change in open market operations and the response of selected member bank variables. The study concluded that free reserves, gross reserves, and loans showed relatively little response to monetary policy, while regional demand deposits responded after an approximate lag of eight months.

PETER BERMAN, Ph.D. Johns Hopkins 1967. A theoretical and empirical examination of large bank use of the discount facility in the United States.

A study of the use of the discount facility by 143 large member banks active in the Federal Funds market using weekly data supplied by the Board of Governors suggests that: (1) large banks borrow continuously for long periods from the Fed during tight money thereby denying the "tradition of staying out of the Fed"; (2) significant inter-

District differentials in discount facility administration exist; (3) the facility should be modified and retained solely as a member bank convenience.

JOSEPH M. BURNS, Ph.D. Chicago 1967. The saving-investment process in a theory of finance.

The saving-investment process is shown to be affected by various finance costs. In particular, the costs of effecting transactions and of bearing uncertainty are shown to be factors affecting saving and investment demand. The nature of these costs, together with the ways in which savers and investors seek to minimize them, are examined. Financial innovations are shown to reduce the finance costs. Evidence on financial developments in the United States is presented.

ARTHUR R. DORSCH, Ph.D. Florida 1966. Consumer installment sales credit in the United States economy and its relationship to monetary policy, 1946-1963.

PETER A. FROST, Ph.D. California (Los Angeles) 1966. Banks' demand for excess reserves.

An inventory model is developed for an individual bank as a basis for deriving a demand function for excess reserves. The major implication of the model is that the demand function is sharply kinked, being inelastic above some critical short-term interest rate (approximately two-thirds of one per cent) and elastic below this rate. The theory is used simultaneously to explain the behavior of excess reserves and the short-term interest rates during the 1930's.

B. V. GESTRIN, Ph.D. Toronto 1966. The structure of interest rates in Canada.

JAGDISH HANDA, Ph.D. Johns Hopkins 1967. A new approach to the theory of portfolio selection.

The thesis generalizes the concepts of motives inherited from Keynes and of characteristics from existing portfolio selection theories. It argues that assets possess quantifiable characteristics which satisfy quantifiable uses or motive. Any number of assets, characteristics and motives can thus be easily treated. Two characteristics are expected returns and variance (for risk). The individual has a preference ordering over motives and maximizes utility subject to a wealth constraint. The concept of the Efficiency Substitution Effect is then used to explore problems in portfolio selection.

THOMAS M. HAVRILESKY, Ph.D. Illinois (Urbana) 1966. An investigation of monetary policy action, 1952-1965.

ALBERT G. HEEBNER, Ph.D. Pennsylvania 1967. Negotiable certificates of deposits: the development of a money market instrument.

This dissertation examines the development of negotiable certificates of deposit (CDs). The primary and secondary markets are investigated, as well as the structure and behavior of interest rates. It is suggested that influences on CD outstandings include bank reserve positions, anticipated loan demand, the volume of short-term investment funds, corporate tax and dividend payments, and interest rate differentials, and these hypotheses are largely supported by multiple regressions. Also, the implications of CDs for monetary policy are considered.

C. ELTON HINSHAW, Ph.D. Vanderbilt 1967. The recognition pattern of the federal open market committee: a study of the inside lag of monetary policy, 1947-1960.

BERISLAV KARČIĆ, Ph.D. Columbia 1966. The role of money, credit, and related institutions in postwar Yugoslavia till 1960.

A discussion of the Yugoslav economic system precedes the detailed analysis of the financial institutions. Flow-of-funds analysis is employed; monetary and real flows are carefully scrutinized. It is suggested that in spite of a very favorable overall economic record, excessive monetary and credit expansion did occur. The view is advanced that the shortcomings of overall planning, rather than those of the financial institutions proper, were responsible. The appendix contains extensive statistical information.

JOONG-KOON LEE, Ph.D. Columbia 1967. Behavior of money and prices in the Korean inflation, 1953-1964.

An attempt to explain the time distribution of the rate of price change in Korea between 1953 and 1964. Done by first investigating the factors determining the demand for real money assets à la Gurley-Patrick-Shaw Mission study; then, by investigating the price changes, using three alternative models. Agricultural component of GNP seems to have most significantly influenced the demand for money and, in turn, the time rate of price changes.

PETER LINDERT, Ph.D. Cornell 1967. Key currencies and gold exchange standard.

DAVID L. MCKEE, Ph.D. Notre Dame 1966. An economic analysis of credit unions in Michigan.

ANTHONY MACH, Ph.D. Boston College 1967. The institutional, statistical, and analytical importance of Federal Reserve check collections.

This thesis analyzes and compares bank debits and Federal Reserve check collections as alternative series for the study of expenditure flows. A monthly series on check collections for the period 1946-1964 was developed from the operational data of the Reserve Banks. Check collections were more closely associated with GNP and industrial output than were bank debits. Check collections data may be used in velocity and regional economic studies.

DONALD MARKET, Ph.D. Louisiana 1967. The theory of 100 per cent reserve banking: historical development and critical analysis.

This study traces historically the development of the 100 per cent reserve banking plans up to and including the proposals of Milton Friedman. Included in the study are the plans developed by John R. Cummings, Frederick Soddy, Irving Fisher, and Henry Simons. The theoretical and policy issues are examined in their historical contexts and re-examined in the context of contemporary monetary and banking theory.

MELVYN MEER, Ph.D. Minnesota 1966. Securities, intermediaries, and consumer theory.

A financial model postulating community demands for assets, one of which is a financial intermediary liability, is presented. Theorem I establishes necessary conditions for the intermediary to affect monetary policy in a specified manner. Theorem 2 assumes the integrability of the demand functions and demonstrates that with specified security forms, restrictions on the operations of financial intermediaries affect monetary policy in a way which runs counter to some of the prominent intermediary literature.

CHARLES T. NISBET, Ph.D. Oregon 1967. The informal credit market in rural Chile: its nature, significance and relationship to the institutional credit market.

MORRIS PERLMAN, Ph.D. Chicago 1966. International differences in liquid asset portfolios.

An international cross-section study of the holdings by the private nonbanking sector of the economy of currency and various types of deposits. Forty seven countries are included in the sample. The main explanatory variables used in the study are income, urbanization, the rate of interest and the expected rate of inflation. The currency-deposits ratio and its determinants are also examined.

SAMUEL H. PHILLIPS, JR., Ph.D. Virginia 1966. The Radcliffe Report: its implications for United States monetary policy.

A critical review and summary of the *Radcliffe Report* is presented. The purpose is to defend the uniqueness of the supply of money in monetary policy and to show that control of the cash base of the banking system will provide control of general liquidity. It shows that the *Radcliffe Report* does not give support to the Gurley-Shaw thesis since the problem of liquidity in the United Kingdom is not one created by non-bank financial intermediaries.

PAUL J. L. SCHATZ, Ph.D. Alabama 1967. The development of credit unions in Alabama.

EDWARD B. SELBY, JR., Ph.D. Louisiana 1967. Response of the Federal Open Market Committee to economic changes 1951-1966.

The publication of the minutes of the Federal Open Market Committee (FOMC), provides information heretofore unavailable to "outside" economists. This study, utilizing the minutes, considers the following topic areas: FOMC meeting procedure; goals, indicators, and targets of the FOMC; and the FOMC's response to economic changes, 1951-1960. Conclusions—the FOMC has been flexible in its use and refinement of targets and it has usually responded to economic changes within three months after their occurrence.

MIGUEL SIDRAUSKI, Ph.D. Chicago 1967. Rational choice and patterns of growth in a monetary economy.

An attempt to introduce monetary factors in the theory of economic growth. It analyzes the effects of different rates of inflation on short-run capital accumulation and on the long-run capital intensity of an economy in which money can be held in the portfolio of wealth owners as an alternative asset to real capital. It concludes that while under certain assumptions the long-run capital intensity is independent of the rate in inflation, an increase in the rate of monetary expansion lowers capital accumulation in the short run.

WILLIAM L. SILBER, Ph.D. Princeton 1966. Monetary policy, debt management and capital allocation: the implications of behavior in the financial sector and the substitutability between securities.

A disaggregated quarterly econometric model of the United States with major emphasis on the financial sector is specified and estimated, with the initial objective of examining the substitute-complement relationships between securities in financial-intermediary portfolios. After estimating the demand equations for securities (disaggregated according to each intermediary), an entire model is estimated from which the reduced-form equations are calculated. The impact multipliers provide insight into the relationship between monetary (and debt) policy and substitutability between securities.

ANDREW STERN, Ph.D. Columbia 1967. The neutralization of foreign assets; a study of eleven countries: 1955 to 1964.

Quarterly data for the countries in the "Group of Ten" and Switzerland support the

hypothesis that central bank domestic assets are a negative function of foreign assets and a positive function of industrial output. A stock adjustment model is specified, and the time shape of central bank adjustment to changes in the independent variables is estimated. In addition, the short- and long-run effects of neutralization on high-powered money and on the money stock are measured.

RICHARD E. TOWEY, Ph.D. California (Berkeley) 1967. Commercial bank time deposits and some of their implications for Federal Reserve policy.

ROBERT C. VOGEL, Ph.D. Stanford 1967. The demand for cash and liquid assets by manufacturing corporations: estimates and implications.

This dissertation investigates the cash and government security holdings of manufacturing corporations during the postwar period, using both cross-section and time-series regressions. The principal findings are: (1) a transactions model appears more adequate than a wealth model; (2) interest rates have a significant influence, and there is evidence of substitution between liquid assets and trade credit and inventories; (3) adjustment lags are shorter, but more complex, than those found in most other studies. Some implications of these results for monetary economics are also discussed.

CHARLES W. WALTON, Ph.D. Georgetown 1967. The determinants of member bank free reserves—some demand considerations.

The Meigsian hypotheses concerning the determinants of member-bank free reserves are retested for the period 1960-1966. Interest rate spreads continue to be a more important determinant of free reserves than open market operations. However, the influence of the discount rate is inconsistent with the earlier period and the profit motive. Substituting the federal funds rate for the Treasury bill rate improves the explanatory power of the equations. Attempts to measure the influence of loan demand were inconclusive.

DONALD C. WELLINGTON, Ph.D. Chicago 1966. Inflation during the French Revolution.

The study is concerned with the paper currencies, the assignats and the mandats, that were issued during the French Revolution, 1789-1797. It attempts to measure the depreciation of the assignats and mandats, and explain the depreciation in terms of monetary theory.

MARK H. WILLES, Ph.D. Columbia 1967. The inside lags of monetary policy.

OLIVER G. WOOD, JR., Ph.D. Florida 1966. The Federal Reserve System's "Operation Nudge."

LOUIS H. ZINCONI, JR., Ph.D. Virginia 1967. The real-balance effect: aspects and evidence.

The purpose of this dissertation is to discuss different aspects of the real-balance effect (RBE) to show how it can be used to resolve the paradox of the predominant macro-wealth effect and the micro-income effect. It finds three aspects of the RBE (the net wealth aspect, the portfolio balance aspect, and the Cambridge aspect), each of which affects consumption directly or by increasing investment, incomes, and, finally, consumption. In the light of these aspects, the dissertation analyzes several empirical studies and finds that (1) due to the indirect operation of the RBE, some influence of wealth on consumption is shown through the income variable and (2) that demand-for-money studies also reflect the presence of the RBE.

Public Finance; Fiscal Policy

HENRY F. ANDERSSON, Ph.D. Southern California 1966. Effects of Swedish fiscal policy and planning on economic growth and stability, 1930-1964.

The success of economic policies can be attributed to the following factors: (1) Invest-

ment was the strategic factor in attaining growth. (2) Public investment supplemented private investment during economic downturns. (3) Private investment was encouraged by allocation and release of investment reserve funds, accelerated depreciation rates, and a tax policy which induced plant and equipment expansion. (4) Planning became the principal instrument for integrating fiscal and monetary policies with anticipated private investment. (5) Partnership between government and private business was realized by encouraging private enterprise to participate in the planning and determination of the course of action for realization of the economic objectives. (6) Responsible labor unions co-operated with government and business to attain economic objectives without interruptions.

DAVID F. BRADFORD, Ph.D. Stanford 1967. Public finance: aspects of public goods.

To elucidate the notion of "draft uncertainty" a model of the individual's choice of enlistment age (the main variable under his control) is developed, using a simple non-stationary Markov process representation of the situation. A variety of implications of an expected-utility maximization assumption are derived. Uncertainty costs are seen to arise from individuals' preferences about the age of entering military service. A final chapter sketches out the nature of production costs due to draft uncertainty.

MARVIN BRAMS, Ph.D. Clark 1967. State assessments and shared taxes in Massachusetts, with special attention to Boston.

EDWARD W. BRENNAN, Ph.D. Pennsylvania 1966. The personal property tax on intangibles in Pennsylvania.

In Pennsylvania, intangibles are subject to a county property tax of four mills. The thesis had three objectives: (1) a study of the evolution of the tax, and related concepts; (2) a survey of present administration of the tax by the counties; (3) an analysis of the tax's effect on relative yields of taxable and exempt investments. The major part, the administrative study, disclosed more vigorous enforcement than is popularly supposed, at modest cost. This, plus exchange of data with the Internal Revenue Service, leads to the expectation of more vigorous enforcement in the future.

THOMAS W. CALMUS, Ph.D. California (Berkeley) 1966. Depreciation for tax purposes.

DONALD C. CELL, Ph.D. Columbia 1966. Federal-local fiscal relations through 1935: an economic interpretation of Federal aid decisions.

This study develops hypotheses toward explaining why the states have been by-passed in some Federal aid programs while permitted to participate in others. Downs' vote maximizing decision rule is applied to a multi-part system of interdependent governments in which administrative channels—Federal, state, and local—are responsive to different sets of political demands. The study analyzes some pre-Depression attempts by rural governments to by-pass the states and the city-state struggles of the early 1930's.

DEAN T. CHEN, Ph.D. Minnesota 1966. An analysis of inter-community expenditure differentials in the provision of public services to rural communities in Southwestern Minnesota.

PAUL L. CHEN-YOUNG, Ph.D. Pittsburgh 1966. An economic evaluation of the tax incentive program in Jamaica.

JOHN P. COOKE, Ph.D. Colorado 1967. Determinants of the variation in local public expenditures in Colorado.

JOHN R. COOPER, Ph.D. Virginia 1967. Institutional factors affecting the outcome of school bond referenda.

This paper is an attempt to determine whether or not alternative voting rules have any influence on the outcome of school bond elections. The voting requirements in the various states were grouped according to the size of majority required for passage and the existence of a property qualification for voting in the election. The initial hypothesis was that as the voting requirement became more restrictive and the majority necessary for approval increased, fewer bond proposals would be passed. The total number and total value of bond proposals voted upon were considered in relation to the voting rule. There is no indication that the property qualification alone decreases the chance for approval of a bond proposal. The evidence does indicate that as the size of majority necessary for approval increases, there is a greater chance for the defeat of a school bond proposal.

STUART R. CRANE, D.B.A. Indiana 1967. Federal financing for toll projects incorporated in the interstate highway system.

JAMES CUTT, Ph.D. Toronto 1966. Taxation and economic development in India.

ANTAL DEUTSCH, Ph.D. McGill 1967. Income redistribution through Canadian federal family allowances and old age benefits.

This thesis measures the immediate net effects on the distribution of disposable income of the operations of the Canadian government's family allowance and old age benefit programs. The basic information used originates largely with the Dominion Bureau of Statistics. Results are presented by income group, family type and geographic region. The old age benefit program acts as a more progressive income redistributor than family allowances. Family allowances redistribute income from unattached individuals to farm and non-farm families. Unattached individuals and institutional residents gain from non-farm families through old age benefits. Residents of Ontario and British Columbia lose to those of Quebec and the Atlantic Provinces through family allowances. Old age benefits favor residents of the Prairies, the Atlantic Provinces and British Columbia at the expense of Quebec residents.

VIJAYA G. DUGGAL, Ph.D. Harvard 1967. Fiscal policy and economic stabilization: simulations with the Brookings Quarterly Econometric Model of the United States.

This thesis studies the effectiveness of expansionary fiscal policies. The results are examined in the context of the structure of the model that generates them. In coping with recessions, the expenditure increase policy is found to be most effective, and the increased balanced budget the next best alternative. The tax reduction policy, being less efficient, is feasible only in raising stagnantly low activity levels in the long run. Automatic stabilization schemes to reduce fluctuations are experimented with and found successful.

JOSEPH R. FAHEY, Ph.D. Mass. Inst. Technology 1967. The advisability and probable economic effects of a local income or local sales tax in Boston.

ROBERT S. FELL, Ph.D. Brown 1967. Tax incentives and investment growth.

An analysis of empirical studies determines areas in which tax incentives could prove effective. The type of tax incentive used depends upon its purpose, economic conditions, future expectations, the prevailing tax system and characteristics of the government. The author recommends federal tax incentive aids for area development, allowance of direct costing and lower of LIFO or market inventory valuation, congressional elimination of reserve-ratio tests and permanent reinstatement of the investment credit and accelerated depreciation.

RICHARD F. FRYMAN, Ph.D. Illinois (Urbana) 1967. The extent and effects of sales taxation of producers' goods.

DAVID F. GATES, Ph.D. Princeton 1967. The effect of population growth on the fiscal strength of residential suburbs.

This study is an empirical analysis of the effects of variations in growth rate upon the public needs, public resources, and the ratio of public needs to public resources in 56 New Jersey residential suburbs.

BRUCE L. GENSEMER, Ph.D. Michigan 1966. Determinants of the fiscal policy decision of local government in urban areas: public safety and public education.

RONALD B. GOLD, Ph.D. Princeton 1966. Subsidies to industry and alternative policies to reduce regional unemployment.

This study consists of two parts. In the first, benefits and costs of alternative policies to reduce regional unemployment are analyzed from the viewpoint of an individual community and from a national viewpoint. In the second part, the efficacy of one policy, subsidies to attract new industry, is investigated through a case study of subsidies given by communities in Pennsylvania. It is demonstrated that the subsidizing communities and the state experienced significant employment gains.

WILLIAM R. HENDLEY, Ph.D. Duke 1966. Swedish fiscal measures to stabilize investment and analysis of the investment-reserve system and the temporary investment tax.

WALTER J. HERMAN, Ph.D. Florida 1965. Federal debt management; an analysis of its objectives and application from 1953 through 1962.

DAVID H. KOPF, Ph.D. Princeton 1967. Government debt, intergeneration welfare and economic activity.

This study examines the proposition that government debt can have an effect on the distribution of economic welfare among generations. Individual utility from amount and distribution of lifetime consumption can be altered by government debt operations, and the impact of such operations on consumption and capital stock are examined. The effect of inherited wealth and international trade are considered, and a general model incorporating money and government debt is developed.

JOHN B. LEGLER, Ph.D. Purdue 1967. Regional trends in federal receipts and expenditures, 1815-1900.

HENRY M. LEVIN, Ph.D. Rutgers 1967. Estimating the municipal demand for public recreational land.

Land is considered as an input into the production function for municipal recreation. On the basis of a model of revealed preference in the public sector, the parameters of derived demand for local recreational land are specified and estimated for a "public-goods" region. The cross-sectional estimates yield the expected results. Finally, some insights into the allocation of recreational land are deduced from the findings.

PETER B. LUND, Ph.D. California (Berkeley) 1967. Municipal costs arising from business and industry: a case study of San Leandro, California.

WILMA S. MAYERS, Ph.D. California (Berkeley) 1966. The real property transfer tax.

WILLIAM E. MITCHELL, Ph.D. Duke 1967. State and local government legal debt limitations.

JOHN M. C. OLSON, JR., Ph.D. Southern California 1966. An analysis of fiscal policy during the Truman Administration (1945-1953).

The art of practicing fiscal policy does not appear to have been sufficiently developed at the time of the Truman Administration to cope with the problem of inflation. Easy money and credit, tax reduction, liquid assets and inadequate supply combined in such a manner that the purchasing power of the dollar declined 33 per cent during the period. The Administration failed to achieve voluntary or restrictive action to curb the inflationary pressures.

LARRY L. ORR, Ph.D. Mass. Inst. Technology 1967. Municipal governmental policy and the location of population and industry in a metropolitan area: an econometric study.

JACK W. OSMAN, Ph.D. Rutgers 1966. The determinants of interstate variations in state and local government expenditures in the United States.

Multivariate regression analysis was used to find the determinants of state-local government outlay by function. Federal aid was found to have a dual impact on expenditures, "stimulating" those functions to which it was directed, while federal aid to *all other* functions was also found to have increased outlay for particular functions. Other variables included were income, urbanization, state's share of tax revenue, the rate of population growth and variables "specific" to the function under investigation.

ANNETTE PINCKNEY, Ph.D. Clark 1967. State and local government industrial aid bond finance: a critique.

JESSE E. RAINE, Ph.D. Kentucky 1967. The tax status of religious property in the United States, with special emphasis on Nashville and Tennessee.

This is a study of the gradual narrowing, over time, of the scope of the tax exemption granted to real property owned by religious institutions in the United States. It considers in depth the statutes and case decisions marking this narrowing in Tennessee, and

a random sample was taken to estimate the total value of such exempt property in Nashville.

DAVID D. RAMSEY, Ph.D. Minnesota 1967. Optimal financing of local government capital projects.

ROY W. RICHARDS, D.B.A. Indiana 1967. The federal income tax: 1872 to 1913.

JEAN Y. RIVARD, Ph.D. Michigan 1967. Determinants of city expenditures in Canada.

JEFFREY M. SCHAEFER, Ph.D. Columbia 1966. Charitable transfers at death under the Federal Estate Tax.

Data cited in this study indicate that upper income and wealth groups give proportionately larger amounts of their contributions for educational and social welfare purposes than lower income and wealth groups do. Therefore, it may not be entirely unsound for the public sector to share a greater cost of contributions by wealthier individuals, since such contributions are fairly good substitutes for government expenditures on civilian goods and services.

PHILIP A. SHADE, D.B.A. Indiana 1967. Municipal capital budgeting: a case study of Indianapolis, Indiana.

BERNARD SOBIN, Ph.D. Columbia 1967. Shadow prices for money in government expenditure policy.

The paper discusses the current practices of U.S. government agencies and the evolution of thought in professional literature with respect to interest rate criteria for government investment. It goes on to a more general analysis of the concept of shadow prices for government funds, which are marginal exchange rates between particular kinds of funds and money of other kinds or dates of availability; and it discusses uses of the concept in government expenditure policy.

BYRON G. SPENCER, Ph.D. Rice 1967. The shifting of the corporation income tax: the Canadian experience.

The dissertation is an econometric study of short-run shifting of the Canadian corporation income tax using the Krzyzaniak-Musgrave model. The author finds in the open Canadian economy there is less shifting of corporation income tax than in the U.S. economy.

VITO TANZI, Ph.D. Harvard 1967. The structure of the individual income tax in the major industrial countries: an international comparison.

The main objective of this study is an analysis of the structure of the individual income taxes in the six major industrial countries (France, Germany, Italy, Japan, United Kingdom, and United States). The study is concerned with the question of "sacrifice" connected with these taxes; with the relationship between individual income tax and the propensity to save of the household sector; and with the relationship of the individual income tax of each country to the growth of the economy.

GEORGE M. VON FURSTENBERG, Ph.D. Princeton 1967. The impact of tax and credit incentives and political risks on industrial growth in West Berlin over the period 1952 to 1964.

The pattern of industrial investment in West Berlin has been primarily determined by the changing impact of political threats and tax and credit preferences. Income statement simulations for Berlin based on West German input structures reveal the factor compositions and operating characteristics favored. An econometric model standardizing the conditions of sale other than location allows quantification of the political risk discount by interpreting the relation between selling price and annual yield of certain immobile assets.

HUBERT D. WHITE, Ph.D. Southern California 1967. A dynamic model for predicting the effects of fiscal policy measures.

Using a block recursive model, the following are among the conclusions supported by the study. First, the form of the model has limited usefulness as a tool for evaluating fiscal policy measures. Second, the most significant fiscal policy variable was the govern-

ment deficit. Finally, fiscal policy measures were not of sufficient intensity to appreciably diminish the recessions of the period.

JAMES WIGHTMAN, Ph.D. Clark 1967. The impact of state and local fiscal policies on redevelopment areas in the northeast.

JOHN O. WILSON, Ph.D. Michigan 1967. Capital budgeting and local government investment decision-making.

MUHAMMAD YAQUB, Ph.D. Princeton 1966. The tax structure of a developing country: a case study of Pakistan.

The study contains a quantitative analysis of the elasticity of taxes in Pakistan. Its results broadly support the hypothesis that, in an underdeveloped country, tax structure may be inelastic with respect to money national income. It, however, contradicts the generally held view that income taxes are more elastic than commodity taxes. It has four sections. A discussion of the statistical approach in Section I is followed by an analysis of the elasticity of income taxes in Section II and of commodity taxes in Section III. Section IV contains an exercise in projections.

International Economics

HERMAN E. DALY, Ph.D. Vanderbilt 1967. Trade control and Uruguayan economy.

ROBERT M. DUNN, JR., Ph.D. Stanford 1957. Flexible exchange rates and the prices of traded goods: a study of Canadian markets.

Internal prices of traded goods may not fluctuate with an exchange rate; oligopolists with strong preferences for stable prices may maintain local currency prices in each market as the exchange rate varies within some range. Such pricing reverses the normal relationship between the exchange rate and the terms of trade, and has effects on the reactions of the trade account. Regressions and questionnaires are used to study seven markets, and the results support these hypotheses.

WILLIAM O. FREITHALER, Ph.D. Michigan 1966. The contribution of the export sector to Mexico's balance of payments and economic growth.

PAUL GRAESER, Ph.D. Columbia 1967. Money, growth and the balance of payments.

Open growth models, after the work of George Borts, were constructed to test the following proposition: permitting a long-term balance of payments disequilibrium will alter the response of the model economy to policy and other exogenous variables, from what it would be if payments equilibrium were maintained. Conclusion: the response to fiscal and exchange rate policy, and especially to monetary policy, is very much altered.

ABDESSATAR R. GRISSA, Ph.D. Brown 1967. The stability of flexible exchange rates: the case of the French and the British experience in the 1920's.

The dissertation is primarily an empirical study whose main object is to determine whether changes in the values of the franc and of the pound in the foreign exchange market were the result of destabilizing speculation against these currencies or due to shifts in their equilibrium levels. Another question this study is designed to investigate is the relation between fluctuations in the external value of the franc, the French money stock, and the demand for pegged government securities.

DOROTHY HODGES, Ph.D. Wisconsin 1966. An international comparison of industry production functions: implications for international trade theory.

JAMES M. HOLMES, Ph.D. Chicago 1967. An econometric test of some modern international trade theories: Canada 1870-1960.

The modern theory of the balance of payments and the purchasing power parity theory are formulated in a five equation, sixteen variable model. These theories imply ten statistical tests in one reduced form equation. One identifiability test can also be made from this equation. Yearly data is used for Canada and the U.S. for 1870-1960. Both of these theories are acceptable on the basis of the tests made. This thesis has been reprinted in the "Krannert Paper Series" and is available through the Department of Economics at Purdue University.

JOHN IRON, Ph.D. Johns Hopkins 1967. Economic development and the external sector (with reference to post-war Brazil).

An attempt to study the Brazilian economy's vulnerability to export real earnings fluctuations. Reduced-form relationships for real gross product, real total gross investment, and total real consumption are derived from a model in which the real value of merchandise export earnings is an exogenous variable. The conclusion is that during the sample period export real earnings instability destabilized real total gross investment and real consumption and very slightly stabilized real gross product.

GEORGE J. KALAMOTOUSAKIS, Ph.D. New York 1966. Economic integration and economic development: a case study of Greece and the Common Market.

GENE E. LABER, Ph.D. Maryland 1967. International travel in the Canadian balance of payments, 1949-1964.

The objectives of this study are to (1) explain the determinants of Canadian travel transactions and (2) to explain the secular behavior of Canadian travel receipts and payments between 1949 and 1964. A conceptual framework for analyzing travel receipts is developed theoretically and statistically tested on a cross-section group of U.S. automobile travellers. Canadian receipts from state *i* are found to be significantly affected by income in state *i*, past migration, and distance. Regression estimates reveal that over

the 1949-1964 period, Canadian travel transactions were generally elastic with respect to prices and income. Canadian receipts from the OECD area were substantially depressed by exchange restrictions prevailing in the early 1950's.

CHUNG H. LEE, Ph.D. California (Berkeley) 1966. The demand for foreign securities and long-term capital movements: the United States-Canadian case.

KIE B. LEE, Ph.D. Virginia 1967. Measure of and factors affecting "the level of trade dependence" with special application to Great Britain, Japan and Taiwan.

The dissertation is concerned with the empirical study and conceptual problems of Werner Sombart's alleged law of the declining dependence on trade. There is a discussion concerning factors that have the effects of raising or reducing such a "trade dependence" measured in the ratio of commodity trade to aggregate income. The relationships between the changes in such trade ratios and the standard of living for Great Britain, Japan, and Taiwan are examined in detail.

RAYMOND LUBITZ, Ph.D. Harvard 1967. United States direct investment in Canada and Canadian capital formation, 1950-1962.

The study tries to estimate the net contribution (on aggregate and sectoral levels) to capital formation of United States direct investment in Canada. It employs a statistical model in which Canadian capital formation is made a function of domestic Canadian determinants of capital formation (accelerator and residual funds variables) and direct investment. The size and significance of the direct investment variable showed that the direct investment did make a net contribution.

JOHN LYNCH, Ph.D. Georgetown 1967. The voluntary export quota as a modern type of quantitative restriction—a case study of Japanese voluntary controls on cotton, textile, exports.

The voluntary quotas that the Japanese placed on their cotton textile exports to the United States and later to other parts of the world marked a major step away from the avowed spirit of trade liberalization embraced by developed countries after Breton Woods. After a consideration of the history of the Japanese textile industry, a detailed account of American pressures for controls and of Japanese conditions leading to controls is presented. The final chapter features an attempt to analyze what is meant by the frequently used term "orderly market."

SHAH MAHMOUD, Ph.D. Columbia 1967. The balance of payments problem in underdeveloped nations: a case study of Afghanistan.

ROBERT H. MASON, Ph.D. Stanford 1967. Joint international business ventures in less-developed countries.

VICHITVONG NA POMBHEJARA, Ph.D. Harvard 1967. Monetary management under the gold-exchange standard: a study of Thailand's experience, 1902-1941.

This dissertation examines the gold-exchange standard from the standpoint of a small developing country, using Thailand during 1902-41 as a case study. The holding of foreign exchange as monetary reserve is considered a logical practice, whereas the need

for a large reserve is imperative. Arguments in favor of a system of fixed exchange rate are also presented.

SYED N. H. NAQVI, Ph.D. Princeton 1966. Commercial policy and resource allocation in Pakistan.

This study attempted an empirical analysis of changes in the "allocative bias" of Pakistan's commercial policy during 1953-63. It revealed that, contrary to prevalent views in Pakistan, these policy changes were broadly consistent with overall development strategy. This empirical analysis was supplemented by a theoretical examination of the question of the "efficiency" of commercial policy in promoting the "desired" pattern of investment. The discussion of "structure" of Pakistan's commercial policy provided the necessary institutional background.

YOON B. OUI, D.P.A. New York 1966. An analysis of the Kennedy Administration's 1961 proposal for a new economic aid policy and aid organization.

JOHN PIPPENGER, Ph.D. California (Los Angeles) 1966. The behavior of flexible exchange rates: theory and evidence.

The type of exchange rate behavior implied by theories used to explain flexible rates, e.g., destabilizing speculation, is developed. Autocorrelation, spectral analysis, and analysis of runs are used to analyze behavior of flexible rates (daily) for six countries during the 1920's, and Canada during the 1950's. The conclusions based on a comparison of implied and observed behavior are: (1) speculation is not destabilizing; (2) stabilization funds have stabilized exchange rates; and (3) devaluation does not lead to inflation.

HARL E. RYDER, JR., Ph.D. Stanford 1967. Optimal accumulation and trade in an open economy.

Optimal accumulation is considered in two neoclassical two-sector two-factor models. We seek to maximize discounted per-capita consumption. In the first model, the terms of trade depend on the amount offered. Departures from competitive trade result not from dynamic considerations, but from static monopoly power. The second model has endogenous technical change in the investment good sector. There may be specialization in the investment good despite a (temporary) comparative advantage in the consumption good.

MERLE I. YAHR, Ph.D. Columbia 1967. Estimating the elasticity of substitution from international manufacturing census data.

This empirical work suggests that the point estimate of the elasticity of substitution for all-manufacturing industry is slightly less than unity, but for many individual industries, the estimates of the elasticities are not significantly different from unity. The all-manufacturing elasticity is significantly different from zero, as are the elasticities for the detailed industries. Furthermore, it is shown that differences in the quality of the labor input affect the elasticity of substitution.

CHARLES B. FRANKLIN, JR., Ph.D. Florida 1965. The treatment of security holders under the absolute priority rule in Chapter X reorganizations.

Possible inequities and means of minimizing them are examined. The valuation required by the absolute priority rule results in some degree of unfairness. The capitalization of expected earnings method is inexact when applied. No provision is made for error. Greater participation in the reorganized corporation may be provided by hierarchical capital structures with different rates of capitalization for each stratum of new securities. Warrants should be allowed as a stratum for maximum valuation and equity.

THOMAS J. COURCHENE, Ph.D. Princeton 1967. Inventory behavior and the stock-order distinction: an analysis by industry and by stage of fabrication with empirical applications to the Canadian manufacturing sector.

The central hypothesis (confirmed) of the thesis is that full understanding of inventory behavior requires disaggregation both by industry and by stage of fabrication. At the base of the theoretical argument leading toward the development of this hypothesis is the distinction between those industries producing to stock and those producing to order. The empirical work (quarterly, 1955-1962) deals separately with raw materials, goods in process, finished products, and total inventories, and for each maintains a disaggregation by industry.

W. DAVID DOWNEY, Ph.D. Purdue 1967. Customer services and promotions in supermarkets.

This study was designed (1) to explain the combinations of services and promotions of supermarkets in terms of external and internal environment of the firm; (2) to measure and evaluate the effects of these services and promotions on operating and financial characteristics of the firm. Results indicated that some services have been so widely accepted that they have become a necessary cost of doing business. Sales, expenses, and gross margins were influenced to varying degrees by customer services such as parking lots, number of hours open, etc.

SIERT E. DE JONG, Ph.D. Rice 1967. An analysis of capital budgeting models under various assumptions of non-profit maximizing behavior.

The dissertation investigates capital budgeting decisions by the firm operating under either sales maximization goals (Baumol) or maximization of managers' utilities (Williamson). The differences between these rules under these goals and the profit maximization goals are then investigated.

ROGER A. DICKINSON, Ph.D. Columbia 1967. Models of department store buying behavior.

MARY F. DUNSTAN, Ph.D. Alabama 1966. Marketing scientists in the United States: a study of mobility and relative achievement.

An investigation of the extent and nature of socioeconomic, educational, geographic and occupational mobility of marketing scientists—defined individuals listed in *American Men of Science* whose academic discipline is marketing. The relationship of mobility to measures of achievement—income, job title, and an achievement index based on earned doctorates, publications, activity in professional associations, and professional honors is examined. The findings evidence no important differences when compared to those reported for other elite groups.

ARNOLD F. HASELEY, Ph.D. Purdue 1966. Information and decision-making in a management game.

This study examines managerial behavior in a computer programmed simulated business environment and the relationship between information feedback and firm performance. The study also explores the use of management games as tools for teaching aspects of managerial planning and control.

MURRAY HAWKINS, Ph.D. Ohio State 1967. An analysis of the structure and conduct in the wholesale meat industry.

The presentation is based upon analysis of data received from 24 retail grocery firms in Ohio. The text is concerned with formula pricing, procurement techniques, product specifications, advertising and promotional budgets and many other facets of retail meat operations. Current measures of market power do not utilize subjective criteria in evaluating market performance. The text presents a theoretical index in an attempt to remedy that and other deficiencies inherent in the market share concept.

LONNIE JONES, Ph.D. Ohio State 1967. Short-term forecasting models for average monthly prices of wholesale beef.

This study developed and tested short-term forecasting equations which may be applied to forecast monthly prices and price changes for wholesale beef. The technique used for generating forecasts from current data was to select indicators of future supply-demand conditions whose influence on price would be exerted during the forecast month. Coefficients of the forecasting equations were estimated by relating lagged values of these indicators to wholesale prices during the 1960-1965 period.

IRVING LEVESON, Ph.D. Columbia 1967. Nonfarm self-employment in the U.S.

The number, incomes and characteristics of nonfarm proprietors are examined. Opportunities for disadvantaged groups are considered. Declines in the relative importance of small businesses did not contribute perceptibly to productivity growth in the economy. Earnings of proprietors are surprisingly consistent with information on demographic characteristics. Labor's share is found to be high, supporting the notion of constancy of labor's share of national income over time. Secular declines in the relative number of self-employed have been mainly due to a movement along a supply curve.

VASANT NADKARNI, Ph.D. New York 1966. A study of the new managers in India.

ROGER G. NOLL, Ph.D. Harvard 1967. An economic analysis of network operations research techniques.

Network operations research techniques have become an important analytical tool for attacking certain kinds of production management problems. Some network techniques, such as PERT and the Critical-Path Method, are designed to be applied to production processes with technological and organizational characteristics that differ from those assumed in conventional microeconomic theory. This dissertation examines the connection of network or techniques to the conventional theory of production, and the contribution that each field can make to the other.

MITCHELL S. NOVIT, Ph.D. Michigan 1966. A field study of role conflict and ambiguity among managers in a modern department store.

ALLAN L. PENNINGTON, D.B.A. Indiana 1967. Bargaining processes in retail appliance transactions.

RICHARD B. PETERSON, Ph.D. Wisconsin 1966. The status of managerial rights in Swedish collective bargaining.

The purposes of this study were to trace the development of the management rights issue in Swedish collective bargaining and to determine if the Swedish experience has relevance for other industrial nations. In the analysis the legal, social and demographic, economic, political, institutional, and contractual factors which have influenced the status of managerial rights in Sweden were considered. It was determined through this analysis, that the Swedish experience does have some relevancy to other western industrial nations.

JOSEPH D. PHILLIPS, Ph.D. Alabama 1966. Normal volume costing: a specialized costing technique for decision making and control.

WALTER J. PRIMEAUX, JR., Ph.D. Houston 1967. An analysis of the structure-conduct relationship of firms in a selected retail market.

This is an in-depth study to ascertain how satisfactorily received economic doctrine explains the structure-conduct relationship in a particular retail household consumer market. The hypothesis tested is whether received economic doctrine, eclectically applied, satisfactorily explains structure-conduct relationships with regard to the following variables: store location, competitive goals, advertising, pricing policy, price discrimination, and product-line policy. The findings are that received economic theory explains such structure-conduct relationships rather well although certain exceptions are noted.

FREDRIC RAINES, Ph.D. Wisconsin 1967. A decision rule approach to dynamic cost estimation.

RONALD SAVITT, Ph.D. Pennsylvania 1967. Dual distribution and market competition: the ethical drug industry.

The dissertation explores the development of dual distribution in the ethical drug industry and examines the nature of competition at the wholesale level. The basic conclusions are: (1) the market share of drug wholesalers has declined; (2) competition among general line drug wholesalers and direct selling manufacturers has increased to the benefit of retail pharmacists; (3) new legislation for the control of this practice in the ethical drug industry is not warranted at this time.

LEE J. SEIDLER, Ph.D. Columbia 1967. Accounting and economic development.

ZALMAN A. SHAPELL, Ph.D. Maryland 1967. Modifications of budgeting procedures and performance measures for use by department stores.

MARTIN B. SOLOMON, JR., Ph.D. Kentucky 1967. Investment decisions in small business.

Little attention has been given to the small business man in the area of investment decisions. This study attempts to examine existing theory, current empirical study in large corporations, and then contrast these with actual practice in small firms. The conclusions indicate that small business investment problems are somewhat different from their big brothers'. In particular, the search function so vital in productive capital budgeting may require greater attention in the small firm. Case studies of actual decisions in the making are included.

GENE L. SWACKHAMER, Ph.D. Purdue 1966. A management control system for processed meat firms.

This study brings together in a management control system as much relevant decision information as is practical. Two models form the core of the system: (1) the allocative linear programming model, and (2) the sales forecasting model. The integration of these models with appropriate solution sensitivity analysis, performance analysis, and management review constitutes the management control system. The total systems approach to management problems as developed with the case firm has resulted in significant advances in control production and marketing.

CHARLES E. TREAS, Ph.D. Alabama 1966. Selected ordinal measures of travel-related information cues and choices affecting automobile motorist travel behavior: a case study.

A psychometric technique (Thurstone paired comparisons) was used to construct rank interval scales of importance for selected information sources to motorists in choosing motels. A sample of 133 respondents interviewed in 15 Birmingham lodging establishments ranked non-media-oriented cues above media-oriented ones. "Previous experience" and "appearance of the establishment" were highest. Others, in order were as follows: advice of individuals, referral services, reservation services, billboards, credit card directories, official signs, broadcast media, print media and novelties.

MARVIN W. TUCKER, JR., Ph.D. Alabama 1966. A probabilistic approach to the measurement of current assets under uncertainty.

This dissertation explores the measurement of current assets within a framework of (1) asset recognition according to the going-concern concept, and (2) the assumption of uncertainty of the asset amount. The various uncertain variables for each current asset are identified, and probabilistic models are used in their evaluation. The assets accorded treatment as random variables include marketable securities, accounts receivable, and inventories.

ANTONIE VAN SEVENTER, Ph.D. Michigan 1966. The theory of the dualistic balance sheet.

JOSEPH B. WASHINGTON, Ph.D. Alabama 1966. Matrix analysis of an accounting system, an empirical study.

In this empirical study a conventional accounting system is translated into matrix formulation in accordance with input-output analysis framework. The model developed is a flow system indicating the interdependence of flows between respective accounts. Testing indicated insufficient stability to justify use of the model for predictive purposes. The methods utilized might alternatively be used to focus attention on changes occurring between ac-

counting periods, thereby facilitating increased understanding of an accounting system that is being analyzed.

RICHARD F. WENDEL, Ph.D. Pennsylvania 1966. Occupational differentiation as the basis of market segmentation.

HARDOL C. WHITE, Ph.D. Florida 1966. A concept of management development: applications for a health center.

The philosophy of management recognizes the dignity of man in an ordered universe. The individual possessing an equalitarian personality is the most effective group worker and leader. Learning theory is directed toward the development of the adequate personality. The design of a program for management development is based on the conclusion that the most effective learning situations also provide experiences of the manner in which the manager is being encouraged to perform.

YORAM WEND, Ph.D. Stanford 1967. Organizational factors as motivating factors in the decision to purchase industrial products.

BILL VASTINE, Ph.D. Ohio State 1967. An analysis of present and future roles of store managers and supervisors in the retail and wholesale food industry.

Based upon questionnaires completed by 145 management personnel, the study findings suggest as more decisions and functions are transferred from retail store level to computer supported headquarters, the managers of chains and independent retailers will become more similar and will become increasingly customer and employee oriented. Supervisors will become more highly trained specialists capable of quasi-research and small group instruction. The implications of these trends in selecting and developing managerial talent are proposed.

KENNETH E. WING, Ph.D. Cornell 1966. Central market quotation pricing of eggs.

Industrial Organization; Government and Business; Industry Studies

DOROTHY COHEN, Ph.D. Columbia 1967. The Federal Trade Commission and the regulation of advertising in the consumer market.

THOMAS C. COMMITTE, Ph.D. Alabama 1966. An analysis of the economic philosophy followed by the Federal Power Commission in administering Section 1 (b) of the Natural Gas Act.

PETER J. CASSIMATIS, Ph.D. New School 1967. The performance of the contract construction industry, 1946-1965.

This study has surveyed some of the most important aspects of the economics of construction which can be used to assess the performance of the industry and review its prospects. The central finding of this analysis is that potential economies of large scale are not realized. This accounts in part for lagging productivity and increasing construction costs. Following the analysis a number of recommendations are offered toward the im-

provement of the industry's performance, including some suggestions for economic policy with regard to construction activity.

ELISEO DA ROSA, Ph.D. Kentucky 1967. Planning highway investment in Argentina.

An analytical framework to support applications of benefit-cost analysis in planning highway investment in Argentina is developed from conventional principles of capital investment, public expenditure theory, welfare economics, and interregional programming methods. The model is applied to Argentina's highway data to estimate rates of return to representative highway projects, to appraise the extent of regional imbalances in fund allocation, to evaluate shortcomings in pricing and financing practices, and to identify some urban transportation problems.

MARTIN J. DAVIDSON, Ph.D. Houston 1967. Economic rationale of science policy in the federal establishment.

The dissertation focuses upon rationale in the federal government's increasing allocation of resources to research and development. The role of cost-benefit analysis is considered and an attempt is made to determine if research and development allocations are internally consistent with values made manifest through the democratic political process. It is concluded that such resource allocations are increasingly rational. A model suggests the federal government's more effective pursuit of the goal of economic growth through allocation of resources to civilian research and development.

EDWARD N. DODSON, Ph.D. Stanford 1966. An evaluation of component product flows within the electronics industry.

ROBERT W. DOEDE, Ph.D. Chicago 1967. The monopoly power of the New York Stock Exchange.

The thesis illustrates that the New York Stock Exchange is one of the most effective monopolies in the United States. It shows that the monopoly is based on economies of scale in exchange organization. Finally the fluctuation in monopoly profits over the last forty years is analyzed by means of a variable weight adaptive expectations model.

JOSEPH J. FINK, Ph.D. New York 1966. The economics of entry into the petrochemical-plastics industry.

RENATE T. FLEMING, Ph.D. Alabama 1967. Changing aspects of private property concepts—a case study of the vested property: the American Potash and Chemical Corporation under the management of the alien property custodian.

FRANCIS M. FLETCHER, Ph.D. Pennsylvania 1966. Free market restrictions in the retail drug industry.

Each state has established a Board of Pharmacy to serve as an occupation licensure board for pharmacists and to regulate drugstores. Because the Board is usually controlled by independent drugstore owners through the State Pharmaceutical Association, many laws and regulations are in force that restrict the activities of chain drugstores, department stores, supermarkets and discount stores. The dissertation focusses upon an analysis of these restrictive practices, mechanisms that perpetuate the devices and the economic and managerial implications of the restrictions.

HAROLD W. FOX, Ph. D. Rutgers 1967. The economics of distributing merchandise through the trading-stamp channel.

A stratified random sample of Sperry & Hutchinson redemption merchandise was priced in department stores and discount houses in six cities; average retail value was 21% above the Company's average proceeds from retailers for the corresponding number of Green Stamps.

MAHSOUN B. GALAL, Ph.D. Rutgers 1967. An equilibrium analysis of the American crude oil industry.

The equilibrium analysis is of a short- and a long-run dimension. An analysis of the market equilibrium when "concentrated oligopoly-oligopsony with leadership"; vertical integration; and percentage depletion allowance characterize the industry. An analysis of the allocation of resources between this industry, where crude production is argued to be externality creating, and the rest of the economy. The relevant tax provisions would correct the resources allocation if the "rationality hypothesis," that in the long run ad-

dition to proved reserves at year t is equal to expected production at a future year $t + e$, was accepted.

HOWARD A. GILBERT, Ph.D. Oregon State 1967. An integration of market structure theory and decision making in selected agricultural industries.

This research tested the applicability of commonly accepted market structure theory to firm behavior within agricultural processing industries. It was primarily concerned with testing the influence of relative firm size or discretionary management decisions. Three firms of differing relative size in each of five industries provided data indicating actual behavior. Findings did not substantiate a close relationship between firm size and decision discretions in product prices, investment and technical innovation. Consequently, alternative hypotheses for future research were identified.

HENRY G. GRABOWSKI, Ph.D. Princeton 1967. The determinants and effects of industrial research and development.

Several hypotheses on the determinants and effects of industrial research and development expenditures are formulated, and then tested on firms in the chemical, drug, and petroleum industries. The empirical results indicate a significant relation between R&D and various other technological, financial, and marketing variables of the firm. The implications for government antitrust and fiscal policy are considered, and some theoretical models which incorporate the main empirical findings are developed to analyze various policy questions.

IRWIN GRAY, Ph.D. Columbia 1967. Employment considerations in the award of public contracts.

RICHARD E. HAMILTON, Ph.D. Duke 1966. The Damodar Valley Corporation: India's experiment with the T.V.A. idea.

RICHARD HELLMAN, Ph.D. Columbia 1967. Government competition in the electric utility industry of the United States: case studies of origins and results.

This empirical and historical analysis covers some 1,500 cases, 100 individually and others mainly in aggregates. A statistical definition of government competition—threatened, by example, and duplicative—is developed. Through comparisons of rates, usage and financial results with and without competition, the theories of a natural monopoly and of regulation as “the law’s substitute for competition” are demonstrated to be incompatible with the real world. A theory of government competition as a regulatory form is developed. Chapters include individual city case studies, the Power Authority of New York State, the Tennessee Valley Authority, and the Rural Electrification Cooperatives.

HENRIK HELMERS, Ph.D. Michigan 1967. Some effects of the United States-Canadian Automobile Agreement.

SEIKO HIGA, Ph.D. Northwestern 1966. Effect of motor carrier competition on railroad rates: theoretical and statistical analyses.

RAYMOND JACKSON, Ph.D. Boston 1967. An empirical evaluation of electric utility regulation.

Regulation is intended to provide lower electric rates, prevent undue discrimination and limit rates of return. Using econometric methods this study examines various aspects of regulation to see whether they significantly affect the achievement of these goals. The results indicate the only effect of regulation is to reduce the level of rate increases when prices are rising. When electricity prices are falling regulation is ineffective since commissions do not aggressively pursue greater price reductions.

HENRY D. JACOBY, Ph.D. Harvard 1967. Analysis of investment in electric power.

This dissertation is devoted to the development of an improved method for analyzing alternative investments in electric power generation and transmission. The result is a new planning model based upon digital computer simulation of the long-run capacity expansion and short-run operation of electric power systems. Use of the model is demonstrated in sample applications to two distinctly different electric power markets, one in Argentina and the other in Pakistan.

JAMES H. JORDAN, Ph.D. Pennsylvania 1956. Contracting out the maintenance function in the chemical and oil refining industries.

Evaluation of "contract maintenance," the utilization of outside maintenance workers in the chemical and oil refining industries from the viewpoints of flexibility, labor relations, cost, and quality of service. Includes a cost analysis for computing optimum workforce size. Conclusions: the chief advantage of contract maintenance is flexibility; it is used most economically to supplement an in-plant force; fear of labor relations difficulties is unfounded; the quality of service equals or exceeds that of in-plant workers.

SUNG-WOO KIM, Ph.D. California (Berkeley) 1967. Capital appropriations and investment behavior, U.S. manufacturing industries, 1953-1964.

LINDA KLEIGER, Ph.D. California (Los Angeles) 1967. Maximization of industry profits: the case of United States air transportation.

The economic theory used in this study to explain the market behavior of United States airlines states that firms act to increase industry profits. Two necessary conditions for this action are satisfied: entry is controlled by the Civil Aeronautics Board, and behavioral controls on existing firms take the form of industry trade association agreements. The study conjectures that these agreements are viable because the fixed route system limits the expansion possibilities of any firm which decides to leave.

WESLEY R. KRIEBEL, Ph.D. Missouri 1965. A managerial-economics analysis of selected Midwestern class I motor common carriers of refrigerated commodities.

RICARDO LAGOS, Ph.D. Duke 1966. Industry in Chile: some structural factors.

ROBERT C. LIND, Ph.D. Stanford 1967. The nature of flood control benefits and the economics of flood protection.

This paper deals with the problem of assessing the benefits from various types of flood protection. The first chapter contains a discussion of the nature of the benefits from flood protection and relates the various types of benefits to five different measures for coping with flood losses. The second chapter develops a theory of land use as it relates to the structure of rents. This theoretical framework is used in Chapter III to develop the proper measure of benefits from "land enhancement." The final chapter deals with the effects of alternative programs of insurance on the cost of risk-bearing associated with flooding.

RICHARD E. LOW, Ph.D. Harvard 1967. Economic defenses under the revised Section 7 of the Clayton Act.

There are eight groups of possible economic defenses against a Section 7, Clayton Act, complaint—the failing company doctrine, the against-giants defense, the investment exception, ease of entry into the postmerger industry, the natural monopoly defense, the greater efficiency of the postmerger firm, lack of market power in the postmerger firm and the competitive level of the postmerger industry. The first five have varying degrees of judicial support; the last three do not. All eight are analyzed in the light of economic theory; all but the failing company doctrine are judged to be, when correctly defined, economically sound.

JOSEPH R. MASON, Ph.D. Boston College, 1967. The financing of research and development projects contracted to private firms: an economic study of the patent policy of the National Aeronautics and Space Administration.

An analysis of the patent policy of NASA with respect to the market structure of the industries in which recipients of patents operate. The economic issue involved is whether NASA's increasing willingness to grant patents unnecessarily contributes to monopoly power in that the invention would be forthcoming without NASA's waiver of patent rights. The author concludes that NASA's waiver policy should be reexamined.

JAMES W. MEEHAN, JR., Ph.D. Boston College 1967. Market structure and excess capacity: a theoretical and empirical analysis: an abstract.

This dissertation investigates how different market structures adjust capacity to a permanent increase in demand. Competitive industries are expected to over-adjust capacity when faced with a permanent increase in demand. Oligopolistic industries are expected to behave similarly. A single-firm monopoly is expected to perform much better in adjust-

ing capacity. The empirical investigation examined five industries and found that all, except the monopoly, overexpanded capacity when faced with an increase in demand.

DAVID MERMELSTEIN, Ph.D. Columbia 1967. Large industrial corporations and asset share maintenance, 1909-1964.

This dissertation is a decade by decade statistical analysis of the changing shares of various corporate "survivors" (firms ranked among the largest 100 in both of the two years of the several decades studied) between the years 1909-1964. Using regression analysis, this study takes into account changes in industrial structure, mergers, and anti-trust dissolutions and concludes that the largest firms are increasingly able to maintain their share of assets.

ROBERT R. MILLER, Ph.D. Stanford 1967. The steel industry and U.S. antidumping policy.

JOHN H. MOORE, Ph.D. Virginia 1966. Economics of research and development and the NASA program.

A probabilistic model of investment by firms in R&D was proposed. The model placed emphasis on the externality and uncertainty aspects of R&D. After testing, some of the model's implications regarding the effects of funding of R&D by NASA were investigated. Stimulation of private effort in R&D was found to be most likely in three industries, all of which are and have been important private funders of R&D.

BERNARD A. MORIN, Ph.D. Duke 1966. An analysis of the variation in liquor consumption and prices among states.

E. WAYNE NAFZIGER, Ph.D. Illinois (Urbana) 1967. Entrepreneurship in the footwear industry in Nigeria.

KIT G. NARODICK, Ph.D. Columbia 1967. The domestic air cargo industry.

HENRY ORION, Ph.D. Columbia 1967. Domestic air cargo, 1945-1965. A study of competition in a regulated industry.

An evaluation of the competitive market performance of the industry during the first twenty years of its existence under public regulation. Emphasis is placed on the relationship between the trunk airlines, who utilize both specialized equipment and the belly-compartments of their passenger planes, and the all-cargo carriers. Costs and rates are investigated in detail, since they are assumed to be the basic determinants of industry behavior.

D. JEANNE PATTERSON, D.B.A. Indiana 1967. Local industrial development corporation in Indiana.

JOSEPH MCG. PERRY, Ph.D. Northwestern 1966. The impact of immigration on three American industries 1865-1914.

This study measures the impact of immigration on the New England cotton goods industry, the crude iron and steel industry, and iron ore mining between 1865 and 1914. Results indicate that immigration contributed strongly to growth of output, stimulated an existing trend toward relative capital-intensity, and probably hindered rises in wage rates.

CHARLOTTE A. PRICE, Ph.D. Columbia 1967. The helium industry: a study of a federal government monopoly.

The economic history of the helium industry from its beginnings in World War I through the development of a government monopoly and its decline with the present long-term conservation program is described and analyzed. Benefit-cost estimates of the planned investment in that storage program are made and possible expansions of recovery from natural gas for storage are considered and judged a net social benefit. These calculations appear to contradict the Preston-Brooks study for the CEA.

WILLIAM A. REYNOLDS, Ph.D. Columbia 1967. Innovation in the United States carpet industry 1947-63.

The dissertation is an empirical analysis of the diffusion of technological innovation in an industry. After a review of the problem, the capital saving innovations of the tufting process and man-made fibers are shown to have lowered the barriers to entry into the established industry, resulting in substantially reduced concentration and in lower

carpet prices. The demand for carpet and the nature of the factor market affecting the supply are analyzed in detail.

FRANCIS H. ROCHE, Ph.D. Notre Dame 1966. The public interest and economic regulation of educational television.

JAMES M. ROCK, Ph.D. Northwestern 1966. The Wisconsin aluminum cookware industry prior to World War II.

This study encompasses the period from the 1893 Columbia Exposition to March of 1941, when aluminum was restricted to military use. The major objectives were to apply the economic theories of location, entrepreneurship and industrial organization to this industry. It was concluded that 1) Wisconsin had no locational advantages relative to other states in the Midwest; 2) the location was basically a function of the initial entrepreneur; and 3) the structure of the industry conformed to theory.

JAMES N. ROSSE, Ph.D. Minnesota 1966. Daily newspapers, monopolistic competition and economies of scale.

Chamberlin-like econometric models are used to test whether scale economies necessary (but not sufficient) for explaining the structure of the U.S. daily newspaper industry exist. Using multiple equation methods and an assumption of profit maximizing behavior, cost function parameter estimates are inferred from cross-section observations of price and output data. The evidence indicates that such scale economies exist. Other evidence suggests that scale economies have not changed over time.

HARVEY SCHWARTZ, Ph.D. Illinois (Urbana) 1966. The changes in the location of the American agricultural implement industry, 1850-1900.

THOMAS J. SHANLEY, Ph.D. Notre Dame 1966. The public interest and the struggle for the New England natural gas market 1950-53.

DAVID L. SHAPIRO, Ph.D. California (Berkeley) 1966. Statistical appraisal of the economic efficiency of the Trinity River Division of the Central Valley Project of the United States Bureau of Reclamation.

W. PAUL SMITH, Ph.D. Northwestern 1966. The American small arms industry, 1870-1890.

This description and analysis of the industry's development revealed two distinctive aspects of the industry's operations: improvements in ammunition permitted innovations in firearms and, as a result, significantly affected the rivalry within and, in turn, the structure of the firearms industry; and, demand segmentation provided the opportunities for smaller firms to develop market niches and thereby survive. It was also shown how the varying product lines, integration, size and entrepreneurial perspectives of individual firms affected the industry's operation and performance.

FRED A. TARPLEY, JR., Ph.D. Tulane 1967. The economics of combined utility and transit operations.

This study investigates the provision of electric, gas, and transit service by a single firm. Relevant pricing models are developed for the electric and gas industries and for urban transport these models are viewed in relation to the operations of New Orleans Public Service, the only firm in the United States providing all three services. Of special interest are the pricing and welfare implications of the subsidization of transit service from electric and gas revenue.

JUDITH D. TENDLER, Ph.D. Columbia 1966. The rise of public power in Brazil.

This is a study of the breaking of a bottleneck in the electric power sector of south-central, industrialized Brazil. The author explores the technological configuration of the industry, and its effect on three major aspects of the breaking of the bottleneck: the successful introduction of state enterprise in the power sector, the remarkable degree of coexistence that prevailed between state and foreign utility, and the protracted stay of a foreign utility dissatisfied with its rates and uncertain of its future.

Economic Geography; Housing**

MARCELLE V. ARAK, Ph.D. Mass. Inst. Technology 1967. The supply of Brazilian coffee.
BRUNO BALDINI, Ph.D. California (Berkeley) 1966. Reversibility and demand functions for agricultural products.

JERE R. BEHRMAN, Ph.D. Mass. Inst. Technology 1967. Supply response in underdeveloped agriculture: a case study of the four major Thai annual crops, 1937-1963.

RUSSELL L. BERRY, Ph.D. Ohio State 1967. The Scully Estate and its cash-leasing system in the Midwest.

This study indicates that major farm tenure goals are fixity or security of tenure, freedom of improvement. A survey of 103 Scully cash tenants and crop-share tenants in Marion County, Kansas, indicates that the Scully tenants has been more successful in achieving these goals due largely to the cash rents, the size of the Estate, and tenant ownership of improvements. The public relations problems of large estates are also discussed.

JOHN H. BOYD, Ph.D. Minnesota 1967. The problem of external diseconomies with special emphasis on river water pollution.

This study postulates that a technological externality arises because some asset, yielding service flows to economic units, is not subject to the laws of property ownership. The case of river water pollution is examined, and formal conditions for efficient allocation of the services of the river basin are derived. The "water quality" service satisfies a generalized definition of a public good. It is also shown that costless negotiation among affected parties cannot lead to efficiency.

BOYD M. BUXTON, Ph.D. Minnesota 1967. Economies of size in Minnesota dairy farming.

The synthetic approach is used to estimate economies of size on dairy farms. In total, sixty farm situations are synthesized from (1) specified supplies of labor and (2) selected machinery, housing, milking and feeding technologies. For each farm situation, a short-run cost curve is determined by minimizing the cost of producing several levels of output (standard linear programming techniques are used). The long-run unit cost curve is derived from the short-run unit cost curves.

JU C. CHAI, Ph.D. Minnesota 1967. An economic analysis of the demand and price structure of wheat for food by classes in the United States.

The purpose of this study is to investigate the nature of the underlying economic and physical relationships that tend to determine the domestic food consumption of each of the five major classes of wheat in the United States. Results of statistical estimation were generally satisfactory. The price elasticity of demand for hard red winter was—1.37, hard red spring—1.41, durum—1.36, soft red winter—0.36, and white—0.22.

HSING-YIU CHEN, Ph.D. Ohio State 1967. Structure and productivity of capital in the agriculture of Taiwan and their policy implications to agricultural finance.

An empirical determination of the characteristics of the capital structure and tests of the productivities of capital at the micro-level of Taiwan agriculture. It employs a cross-sectional approach on 1963 farm record data for a sample of 277 farms. The marginal revenue productivities of the disaggregated components of both farm assets and operating expenses are determined for various sub-groups of farms. Policy implications are suggested at the farm, institutional, and national levels.

NG-SHEONG CHEUNG, Ph.D. California (Los Angeles) 1967. The theory of share tenancy—with special application to the first phase of Taiwan land reform.

The theory shows that resource use under various contractual arrangements is the same as long as these arrangements are aspects of private property rights. However, a legal reduction of rental share leads to increased farming intensity and marginal inequalities of resource use. Observations from Asia not only confirm the implications of standard economic theory, but they also deny other existing hypotheses of disguised unemployment, of rental share restriction, and of tax-equivalent analyses of share tenancy.

WILLIAM J. CRADDOCK, Ph.D. Iowa (Ames) 1966. The effect of grain price on the profitability of livestock production—an econometric simulation.

JAMES E. CRISWELL, Ph.D. Minnesota 1966. Insurance strategies of West Kentucky farmers.

The three major objectives of this study were to: (1) identify some of the elements of risk and uncertainty as they appear to the farmer; (2) determine the quantity of resources allocated by farmers for protection against elements of risk and uncertainty; and (3) study the degree of relationship of such factors as age of farmer, number of dependents, education, total assets, family income, acres in operating unit, etc., to the quantity of resources allocated to formal insurance.

CORTLANDT D. DITWILER, Ph.D. California (Berkeley) 1966. Political economy of water use transfer and integrated water resource management in the Salinas Valley, California.

The analysis focuses on a problem of ground water overdraft which stems primarily from a divergence between private and social cost. A criterion encompassing community or social optimality is outlined and an optimal water management rationale for a water district is developed within the composite structure of the water economy. The study emphasizes the evaluation of political-institutional processes, legal structures and administrative techniques insofar as they influence water allocation and transfer.

MOHAMMED R. EL-AMIR, Ph.D. California (Berkeley) 1967. Location models for the world rice industry.

An attempt has been made to answer certain questions related to the world rice industry quantitatively through use of a spatial equilibrium analysis applied to international trade in rice. The major components required to implement various short-run and long-run spatial equilibrium models are developed. These components include regional demand functions and long-run forecasts (for 1970 and 1975) of consumption; regional supply functions and estimates of future production (in 1970 and 1975); and transfer cost functions for rice, both ocean and rail.

GARY H. ELSNER, Ph.D. California (Berkeley) 1966. A multi-variate analysis of California's agricultural income.

This dissertation develops and furnishes exemplification of alternative methodological approaches to regional economic analysis. Defines an approach to spatial analysis mapping. Using this approach, presents static spatial analyses for 1950 and 1960 California county patterns. Develops and discusses an efficient technique for solving the generalized Weber problem. Example applications employ California data. Suggests a new approach to income distribution analysis. This involves the formulation and estimation of a multivariate income distribution determination model.

ARNOLD M. FADEN, Ph.D. Columbia 1967. Essays in spatial economics.

This is a fairly comprehensive and rigorous development of location theory. The topics treated include: (1) the determination of optimal personal movement patterns, which yield (2) a "maximizing" explanation for gravity models. Some contributions are made to (3) the industry location problem, and, in particular, to (4) the problem of optimal scale and spacing of urban facilities. (5) The Wingo-Alonso theory is extended, and applied to income-residence patterns, land values, and transportation demand.

JOHN D. FARQUHAR, Ph.D. Southern Illinois 1966. An approach to the economic allocation and use of resources for forestry and allied purposes.

BARRY C. FIELD, Ph.D. California (Berkeley) 1967. The impact of changing economic structure on the strategy of agricultural policy: the case of cotton.

Examination of U.S. cotton price and income policy, 1964-65, to determine how policy changes developed because of structural changes in cotton economy. Included are investigations of bargaining in Congress between east and west on acreage allotments, cohesion among cotton-state legislators on policy matters, and the lagged response of producer support programs to cotton market developments. The effects of increasingly heterogeneous production conditions over the cotton belt, and the difficulties of policy "feed-back" are also discussed.

C. LYNN FIFE, Ph.D. Purdue 1967. The decision-making process in large fluid milk firms in the Midwest.

Economic goals and objectives seemed unclear to management and often changed to reflect past accomplishments of the firm. Goals were usually limited by self-imposed restrictions on credit usage and by arbitrary decisions to limit sales to local territories. Firms applied rather sophisticated economic analysis to minor and routine decisions but made many major decisions on the basis of hunches and rules of thumb. Major decisions were often prescribed by prior commitments to minor decisions.

JAMES R. GARRETT, Ph.D. Washington State 1967. A cost analysis of Northwest livestock auctions.

The main hypothesis of this study was that Northwest livestock auctions can be constructed and operated more efficiently. The hypothesis was generally accepted, based upon synthesized requirements. Fixed costs were derived from construction requirements. Variable costs were divided into two categories, labor and non-labor, and obtained farm regression equations applied to data of sampled auctions. The number of men required was found to be a function of construction design rather than volume. Two other factors were examined for their effect on average costs: (1) average size of lot and (2) fluctuations in weekly volume.

GEORGE R. GEBHART, Ph.D. Michigan State 1966. A test of the economic relevancy of the Holdridge Life Zone System.

The Holdridge Life Zone System is a system of climatic determinism under which certain ranges of three climatic factors—heat, precipitation and moisture—are thought to significantly influence economic variables. Two "life zones" were compared statistically, for variations in productivity, technology, cost of production, and land use. Corn, rice and beans were analyzed for productivity differences. The results showed no significant differences by life zones. This study was carried out in Costa Rica.

GLENN A. GILLESPIE, Ph.D. Missouri 1966. An evaluation of the factors affecting the demand for water oriented outdoor recreation.

ANTONIO GUCCIONE, Ph.D. California (Berkeley) 1967. Productivity indexes and economic theory.

Various methods for ranking farmers are discussed: (1) statistically estimated production functions; (2) Farrell's linear programming method; (3) different types of elementary indexes. The foregoing methods are applied to a sample of Italian farms and compared.

J. WILLIAM HANLON, Ph.D. Minnesota 1966. An analysis of processing costs in plants that manufacture butter and nonfat dry milk.

The short- and long-run cost structures of the Minnesota butter and nonfat dry milk manufacturing industry were estimated. Long-run costs were interpolated from short-run costs which were estimated through intensive study of four of Minnesota's most efficient plants covering the industry's plant size range. Regression analysis using historical data was used to estimate production functions for plant processes. Engineering coefficients were used where data were not available. Cost economies to size have been exhausted in the size range of Minnesota's larger plants.

MARVIN L. HAYENGA, Ph.D. California (Berkeley) 1967. Sweetener substitution in food processing industries.

The primary technological, legal, and economic factors were studied which affect the substitutability among sweeteners in five major sweetener-using (food processing) industries. Supporting econometric analyses related the market share occupied by each sweetener (in each industry) to the relative sweetener prices observed during 1949-1963. Substantial differences in the ease of sweetener substitution were noted in these industries. The dominance of sucrose (cane and beet sugar) is being eroded, requiring renewed sugar policy analysis.

DOUGLAS L. HEEREMA, Ph.D. Iowa 1966. A benefit-cost analysis of Pakistan fertilizer plants.

ROBIN G. HENNING, Ph.D. Cornell 1967. California grapes—an economic allocation problem.

EITHAN HOCHMAN, Ph.D. California (Berkeley) 1967. A problem of growing inventory with particular reference to the broiler producing firm.

The idea that factors like weight, feed, and quality are functions of age of the broiler is adopted to incorporate the growth functions into a production model. The economic theory relevant to such a production model is then applied within a static framework. A dynamic decision model is developed, based on a sequential stochastic decision process. The solution is based on the assumption of stochastic distribution of prices.

JACK HOPPER, Ph.D. Texas 1966. A study of tin: with special emphasis on the problem of the years since World War II.

AARON C. JOHNSON, Jr., Ph.D. California (Berkeley) 1967. Structural characteristics of the demand for milk in California: a quantitative analysis.

Major interest centers on the role of socio-economic variables in structuring the consumption relation for fluid milk and on the usefulness of census data in such an analysis. Analyses of both California and United States data are conducted. Questions of methodological interest focus on several problems of estimation frequently encountered in empirical analysis. An appendix is devoted to a development of the technique of principal components within the framework of regression analysis.

GERALD L. KARR, Ph.D. Southern Illinois 1966. Economic models of the feeder-swine market.

ORVAL KERCHNER, Ph.D. Minnesota 1966. Economic comparisons of flexible and specialized plants in the Minnesota dairy manufacturing industry.

This study deals with the problem of flexibility versus specialization in dairy manufacturing plants. Synthesized model plants were the bases for analyzing costs and returns. Monthly data were developed for the years 1959 thru 1964. The specialized butter plant yielded higher average yearly net returns than a flexible plant producing both butter and cheese and their associated by-products. On the other hand, the flexible plant yielded higher net returns than the specialized cheese plants.

JONGBIN KIM, Ph.D. California (Berkeley) 1966. The Korean cotton manufacturing industry, 1954-1963.

The Korean cotton manufacturing industry is analyzed in the framework of industrial organization. In terms of market performance of the industry there has been no substantial excess capacity; most of the firms have operated on small scales; the industry has earned a high profit rate; product quality has considerably improved; selling cost has been negligible. Barriers to entry, especially large capital requirement, distinctively influenced the market performance. Other dimensions of market structure and market conduct have had little effect on the industry.

SETH LAANYANE, Ph.D. Stanford 1966. The oil palm industries of western tropical Africa.

The oil palm in western African economies—geographical distribution, systems of farming, land tenure and local diets. Characteristics and agronomy of oil palm—red and white oil, palm kernel cake and palm wine. Growth and development of oil palm industries in eastern, western and central sectors. Supply of oil palm products, substitutes and economic organization. Export trade—export, import and price trends. Prospects for development of oil palm industries.

THOMAS E. LISCO, Ph.D. Chicago 1967. The value of commuters' travel time: a study in urban transportation.

A study of the marginal value of commuters' travel time and comfort. Values for time and comfort are imputed from modal choice decisions made by commuters' traveling between Skokie, Illinois and downtown Chicago. The binary choice statistical tool used is multiple profit analysis.

JOHN S. LYTLE, Ph.D. Ohio State 1967. An optimal pattern of shipment for grain in Ohio with projections to 1970.

This study delineated the areas of surplus and deficit grain production in Ohio and determined the expected changes in the relative surplus-deficit position of each county by making projections of the production and consumption of grain on a county basis for the year, 1970. Optimum flows were developed for corn, oats, wheat, and soybeans

using the net surplus—deficit position and the appropriate transfer costs as inputs for a transportation model.

JULIUS MALDUTIS, JR., Ph.D. Columbia 1967. Lithuanian land reforms 1919-1939.

ALEXANDER F. MCCALLA, Ph.D. Minnesota 1966. An analysis of the possibilities for international arrangements for temperate zone, grain-livestock trade.

Proposals for international arrangements to reduce conflicts between freer trade and agricultural protectionism are analyzed historically and in a politico-economic framework. Pricing models for wheat, feed grain and meat trade are constructed individually and then are integrated for the total sector and are used to analyze the following proposals: free trade, commodity agreements, fixed price schemes and the international negotiation of domestic policies. The latter seems most likely to succeed.

ROBERT A. MCILWAIN, Ph.D. American 1967. An investigation of resource combinations leading to intrastate differentials in agricultural income in selected southern areas in the United States.

Agricultural data from the five high average farm centers were contrasted with similar data from the five low average farm sales centers in each of the six southern states of Alabama, Arkansas, Georgia, Mississippi, Louisiana and South Carolina, to develop clues as to the factors underlying the low income farm problem in the South.

CARMEN F. MENEZES, Ph.D. Northwestern 1966. Agricultural migration and rural development in Ghana.

MAX MOSZER, Ph.D. Pennsylvania 1966. American wheat farmer and agricultural programs 1939-1964, a quantitative analysis.

JOHN M. MUNRO, D.B.A. Indiana 1966. Transportation investment and depressed regions: the case of Appalachia.

ALBERT J. ORTEGO, JR., Ph.D. California (Berkeley) 1967. Impact of California contract and pool procedures on procurement practices of milk processing firms.

Blend average prices for Grade A milk were investigated and were found to vary widely among producers delivering milk to the same plants, among plants in the same area and between areas in California. The variance in prices was separated into two components, that are attributable to producer-processor contracts and to the pooling procedures. The relationship between selected producer characteristics and price was evaluated. The impact of certain modifications of the market regulations was also considered.

KENT O. SIMS, Ph.D. Colorado 1966. An evaluation of cost-benefit analysis applied to the proposed urban redevelopment of the Platte River Valley.

QUIRINO PARIS, Ph.D. California (Berkeley) 1966. Estimation of individual firm production functions.

The study is an econometric analysis of the California dairy industry located in the San Joaquin Valley. Two samples of 65 and 21 Grade A and B farms, respectively (for which an average of 25 monthly observations were available), have been analyzed in an econometric framework which allows for the estimation of production functions with variable coefficients both with respect to firms and time. Results obtained verify the hypothesis that production functions vary among farms in the San Joaquin Valley. Furthermore, due mainly to institutional restrictions imposed by the milk price control program, a substantial number of farmers (30 per cent) operate under conditions of increasing returns to scale.

ANTHONY H. PASCAL, Ph.D. Columbia 1967. The economics of housing segregation.

This study is an attempt to explain the residential segregation of non-whites in U.S. metropolitan areas by means of various econometric techniques. Using data from Chicago and Detroit, it analyzes the roles played by economic maximizing behavior of non-white households, voluntary self-segregation, and prejudicial attitudes on the part of whites in the process of observed housing segregation. It concludes that the phenomenon cannot be explained except by the inclusion of attitudinal factors.

JOHN F. PEARCE, Ph.D. Alabama 1966. Human resources in transition: rural Alabama since World War II.

WILLIAM E. PHILLIPS, Ph.D. California (Berkeley) 1967. Regional development of the Owens Valley, California: an economic base study of natural resources.

This study constituted an examination of current and alternative use patterns of land, water and associated natural resources of the Owens Valley region in an economic and institutional framework. It serves as a basis for decision making concerning some crucial issues of resource policy. Evaluation procedure involves the use of benefit-cost analysis to interrelated problems dealing with recreation resource use, wildlife management, agricultural land and water utilization, and water export for municipal and industrial uses.

MALCOLM J. PURVIS, Ph.D. Cornell 1966. Evaluation and use of underdeveloped agricultural statistics: the food economy of Malaysia.

BERTRAND RENAUD, Ph.D. California (Berkeley) 1966. The allocation of the California grape production; an econometric study.

This is an analysis of the production and marketing strategy of an agricultural industry facing non-controllable variations of its output. The structure of the industry is analyzed in terms of production and marketing sectors. Sectorial demand functions are estimated by simultaneous equation methods. A linear theory of monopolistic discrimination with multiple outlets is formulated. The industry utility function is computed by quadratic programming under technological and economic constraints. The optimum allocation strategy under fluctuations is obtained concurrently.

JOHN E. REYNOLDS, Ph.D. Iowa (Ames) 1966. An econometric investigation of farmland values in the United States.

SURA SANITTANONT, Ph.D. Wisconsin 1967. Thailand's rice export tax: its effect on the rice economy.

JUAN F. SCOTT, Ph.D. California (Berkeley) 1967. Socio-economic performance of alternative tenure systems in Mexico.

Since the conquest of Mexico, private landownership has been favored in governmental policy-making over communal landownership at most times. The private farms were the leading tenure system in the high income region of Hermosillo, while the *ejidos* led in the low income region of Balsas. Thus, neither system is intrinsically backward. The socio-economic performance of the farmers in these regions was ascribable mainly to factors other than their systems of land tenure themselves.

BISTOK L. STORUS, Ph.D. California (Berkeley) 1967. Productive efficiency in agriculture: with special reference to the farm sector of Luzon of the Republic of the Philippines.

The method proposed by M. J. Farrell for measuring technical efficiency of production was applied to agricultural data from Pakistan and the Philippines. In the latter application, by far the more extensive of the two, the level of efficiency, using nine categories of inputs, was found to range down to 30 per cent, with an average of about 87 per cent. Estimates were made of the quantity of productive factors that could be released from farm activities presumably without reducing output. The study concludes with an attempt to relate efficiency measures to a variety of socio-economic factors.

LEON SHASHOUA, Ph.D. Cornell 1967. Long-range projections of investment in dairy housing in New York State.

WALTER A. SMITH, Ph.D. Oklahoma 1967. Water use in hotels and motels in Oklahoma.

The extent, pattern, and determinants of water withdrawal and consumption in 312 hotels and 471 motels in Oklahoma from September 1963 to September 1964 are measured in this study. Withdrawal patterns are not clearly defined. They are diffused by the number and extent of functional services other than lodging. The main determinant of withdrawal is the number of clients. The variation in total withdrawal by establishment characteristics is a function of services other than lodging.

ADAM SOKOLOSKI, Ph.D. Oregon State 1967. Welfare and institutional economics as tools in the analysis of an area water resource management problem.

This study has combined results of engineering, biological and economic investigations as a preliminary step in evaluating the economic consequences of effluent disposal alternatives. Management and governing institutions are investigated to determine institutional forms for future resource administration. Results suggest the need for (1) some form of

a dynamic, multilevel input-output model; (2) knowledge of the pulp mill's investment patterns; (3) measurement of ownership uncertainties; (4) inclusion of activities complementary to the sports fishery; (5) more precise measures of flexibility needs; and (6) further evaluation of local government forms.

KARL E. STARCH, Ph.D. Colorado 1966. A practitioner's guide to regional economic analysis.

SAM SYDNEYSMITH, Ph.D. Duke 1966. The economics of outdoor recreation: a study of the market area for Cape Hatteras.

AZRIEL TELLER, Ph.D. Johns Hopkins 1967. Air pollution abatement: an economic study into the cost of control.

The dissertation demonstrates that theoretically it is more costly to society to satisfy air quality standards through emission standards than with selective abatement. The empirical results show that it is relatively cheaper to use selective abatement rather than emission standards and if air pollution problem days are forecasted accurately, the costs decrease drastically. In addition, a method is presented and demonstrated for obtaining a schedule of equipment costs for different levels of efficiency of abatement for different industries.

PAUL R. THOMAS, Ph.D. Ohio State 1967. Comparisons between buyer estimates of live cattle yield grades and actual carcass performance.

This presentation is concerned with the factors effecting pricing accuracy and operational efficiency in the marketing process of slaughter cattle. The accuracy of cattle buyers in estimating dressing percentage, quality grade, cutability grade and rail cost, as they purchase cattle from auction markets, feed lots and terminal markets is analyzed through comparisons with actual carcass measurements. Procurement costs involved in purchasing cattle from alternative sources are also delineated and accuracy in price determination is emphasized.

SAMUEL L. THORNDIKE, JR., Ph.D. Columbia 1967. Problems in appraising the economic impact of a transportation improvement: a theoretical exploration.

Models were developed permitting theoretical determination of the true value of a transportation improvement, taking into account migration of establishments (unspecified by type) from elsewhere in the region into the affected sector. Selected situations were systematically explored. Even with simplifying assumptions (including that of homogeneous, CBD oriented establishments), the true value and impact of an improvement was seen to vary, depending on specified conditions. Some general rules for project evaluation were formulated.

NICKOLAS S. TRYPHONPOULOS, Ph.D. California (Berkeley) 1967. An investigation of the economic structure of a small urban area: Napa County, California.

This study investigates the structure and workings of the Napa County economy. The first part consists of an overview of the local economy drawing on published data and attempting to establish magnitudes for major economic variables. The second, and main part, is devoted to the construction and application of input-output tables for the county. Thirteen endogenous and four exogenous sectors are identified. A number of forecasts are made.

EDWARD W. TYRCHNIEWICZ, Ph.D. Purdue 1967. An econometric study of the agricultural labor market.

An inter-dependent six-equation model was developed for the market for agricultural labor. The model contains supply and demand equations for each of the three components of the labor force: hired, unpaid family, and operator. Distributed lag models are introduced into each equation. Time series data from the period 1929-61 are used in estimation, and Theil-Basman estimating procedures are used. The estimated models and their reduced form transformations are used to evaluate various policy alternatives and situations.

ARNOLD R. WELLS, Ph.D. Minnesota 1966. The economies of beef cow herds in North-eastern Minnesota.

BILL WESTERHOLD, Ph.D. Ohio State 1967. An optimal grain storage system for the State of Ohio.

This study first determined the capacity, type of construction, age and location of grain and storage facilities in Ohio in 1954 and 1964. Second, a series of graphic transportation problems were used to determine where additional grain storage should be located to most effectively and economically utilize existing storage facilities and to minimize transport costs.

RUSSELL C. YOUNG, Ph.D. Purdue 1967. An empirical study of underemployed agricultural labor in selected areas of Minas Gerais, Brazil.

The objective of the study was to test the hypothesis of zero marginal product for agricultural labor in Brazilian agriculture. The hypothesis was tested by fitting production functions with sample data from 5 regions of the state of Minas Gerais. The MVP, evaluated at the geometric mean, was tested against zero, against the wage rate, against the MVP in other agricultural regions, and against the MVP of labor in the nonfarm sector. The hypothesis of zero MVP was rejected in three of the five regions, and a serious regional imbalance in labor allocation was found.

TERRY YU-HSIEN YU, Ph.D. Purdue 1967. Analysis of factors affecting the optimum size and number of country elevators in Indiana.

This study had the objective of determining the optimum size and number of country elevators in Indiana from an aggregate and firm standpoint. Least-cost volumes, herein defined as optimum sizes, of grain, feed and fertilizer sales were jointly determined by a cost model incorporating an internal plant cost function and an assembly or distribution cost function. Findings from this study indicated that potential cost-savings to be gained from expansions of size of business appeared to be substantial.

Labor Economics

JOHN W. ALLEN, Ph.D. Cornell 1966. A study in the nature of collective bargaining in the retail food industry.

JAMES F. ANDERSON, Ph.D. Colorado 1967. Radiation hazards and United States workmen's compensation and occupational disease laws.

YORAM BEN-PORATH, Ph.D. Harvard 1967. Some aspects of the life cycle of earnings.

Part I (Chapter 1). A production function of human capital is introduced in a model of investment in man and is used to derive the optimal path of investment in human capital, the implied allocation of time and the life cycle of earnings. Part II (Chapters 2 and 3). An empirical analysis of the cross-section earning profiles by detailed occupation and level of education. A tentative attempt to identify "depreciation" of human productive capacity, followed by a discussion of the limitations of occupational earning profiles due to mobility.

BHALCHANDRA BHATT, Ph.D. Wisconsin 1966. A case study in the emerging industrial labor force in four factories in Bombay.

The study was based on a sample of 515 male workers selected at random from four "heavy-industry" factories in Bombay, India. The purpose of the study was to present an analytical description of the labor market behavior and characteristics of the newly emerging factory work force. A majority of workers in our sample had migrated from rural areas and for most workers the present factory employment marked their first experience in urban industrial life. The findings cover the workers' employment, training,

mobility and earnings before and after their move to the industrial factory; and attempts to arrive at cause-and-effect relationships between these variables.

MALCOLM S. COHEN, Ph.D. Mass. Inst. Technology 1967. Determinants of the relative supply and demand for unskilled workers.

CHARLES CRAYPO, Ph.D. Michigan State 1966. The national union convention as an internal appeal tribunal.

An empirical examination and evaluation of the national union convention as a final, internal appeal body for individual members and groups. Surveys nearly 2,000 separate appeals in 100 national and international unions between 1945-65. Shows how the national convention is dominated by the leadership and, as a result, appeals cannot be reviewed in the impartial manner we expect of judicial tribunals. Independent review boards are seen as desirable final appeal agencies.

EDGAR CZARNECKI, Ph.D. Georgetown 1967. Factors affecting the growth of the American labor movement.

A critical evaluation of membership statistics, particularly from 1950 to 1966, confirmed the lack of current union growth. Academic and pragmatic writing in the field led to the establishment of exogenous and internal union variables, which were analyzed to determine if they explained any of the recent change in union membership. The conclusion was that external variables, particularly governmental assistance, were primary to union organizing, while internal union variables, such as structure, administration and organizing techniques, were secondary.

WILLIAM E. CULLISON, Ph.D. Oklahoma 1967. An examination of union membership in Arkansas, Louisiana, and Oklahoma, 1960-1963.

This dissertation examines union membership data for Arkansas, Louisiana, and Oklahoma and presents new information derived from financial reports filed by local unions under the Landrum-Griffin Act. The new information is compared to extant data, differences are analyzed, and problems encountered in evaluating financial reports are enumerated. After examining area membership trends, it is argued that area union growth during the next decade may be relatively larger than national union growth.

ROBERT D. DEAN, Ph.D. Pittsburgh 1966. A case study in the residential distribution of selected occupation groups in the Pittsburgh metropolitan area, 1960.

LAWRENCE A. DE LUCIA, Ph.D. Arizona (Tucson) 1967. The secondary boycott and the federal law.

This dissertation gives an account of the developing public policy and the law on the national level in response to organized labor's utilization of the secondary boycott. The emergent policy developments are reflected in an examination and analysis of common and statutory law decisions prior to 1947 and in a synthesis of the decisions of the National Labor Relations Board and the federal courts from 1947 through mid-1966.

DENNIS J. DUGAN, Ph.D. Brown 1967. A dynamic model of the regional education market: an econometric analysis.

A dynamic import model for human capital (heterogenous labor groups embodying the technical progress of their formal education) is presented. The demand functions are combined with dynamic supply functions, based upon optimal decision-making under uncertainty criteria, and empirically tested. The statistical results demonstrate a high degree of substitution among the educated labor groups and the significance of risk factors in determining the rate of participation of educated labor groups.

EDWIN F. ESTLE, Ph.D. Princeton 1966. On-the-job training: a theoretical and empirical analysis.

The dissertation presents a theory of on-the-job training which holds that the supply of trainees is inelastic, and that the demand for trainees depends upon the type of

skill and the firm's turnover of trained workers. Hypotheses were tested in the Boston area by means of questionnaires and personal interviews. Concludes that training is related to replacement and growth needs in a skill. Specific-type training, however, fails to keep those trained in the firm.

HELEN GINSBURG, Ph.D. New School 1967. Wage differentials in nongovernment hospitals, 1956-1963: a study emphasizing the wages of nurses and unskilled workers in non-government hospitals.

Hospitals and other industries are compared: a) occupational and geographical wage differentials are wider in hospitals; b) hospital workers' wages are more related than other workers' wages to certain economic and demographic characteristics of SMSA's (i.e. racial composition); c) confirming Dunlop's hypothesis, nongovernment hospitals and other services but not government hospitals, form a low-wage contour for unskilled workers; d) the nursing shortage and other critical problems are related to the hospital industry's low wages and special legal status.

JUDITH C. GLASS, Ph.D. California (Los Angeles) 1966. Conditions which facilitate unionization of agricultural workers: a case study of the Salinas Valley lettuce industry.

This study encompasses an economic, historical, and sociological analysis of unionization of agricultural workers in the Salinas Valley. The changing technology of harvesting and the supply conditions of harvest labor are not independent; the interrelation of vacuum cooling, labor intensive field packing, and the bracero program is discussed. Vertical and horizontal unionization are related to market power, market structure, and mechanization. A domestic work force will reintroduce unionization via institutional and technological changes.

CECIL G. GOUKE, Ph.D. New York 1967. The Amalgamated Clothing Workers of America, 1940-1960.

DAVID H. GREENBERG, Ph.D. Mass. Inst. Technology 1967. Some industry characteristics as determinants of the structure of collective bargaining.

GEORGE S. HAGGLUND, Ph.D. Wisconsin 1966. Some factors contributing to Wisconsin occupational injuries.

In this study analyses of the factors suspected of being related to occupational work injuries were conducted utilizing approximately 80,000 work injury cases settled by the Wisconsin Industrial Commission from 1950 to 1963. In addition, California injury data were analyzed to corroborate findings derived from the original study. The most significant finding was that older workers, contrary to earlier studies, had the highest injury frequency rate in Wisconsin.

PAUL T. HARTMAN, Ph.D. California (Berkeley) 1966. Work rules and productivity in the Pacific Coast longshore industry.

WILLIAM D. HERMANN, Ph.D. Washington (St. Louis) 1967. Adjustments to shortage occupations.

Research encompasses the adjustments made by hospitals in St. Louis and Chicago towards overcoming two types of labor shortages, those for licensed practical nurses and certified medical technologists. It was found that in the Chicago labor market, adjustments such as the increase in training positions, job dilution with nurses aid and substantial increases in salary, enabled the Chicago hospitals to function without apparent LPN shortages. In St. Louis, hospitals were unwilling to make the above adjustments to as great a degree, while probably because of the very high proportion of Negroes on the waiting lists, the number of training posts was not increased. Thus, the St. Louis hospitals were unable to adjust to the LPN shortage which increased in intensity during the period of study. For medical technologists, the shortage and labor markets are nationwide and very little could be done in the local labor market area to rectify the shortage.

JOSEPH A. HILL, Ph.D. Florida 1966. The economic implications for management of the Manpower Development and Training Act of 1962.

The impact of the MDTA of 1962, as amended in 1963 and 1965, has been shown to be both direct and indirect. Indirectly, the MDTA will alter the general business environment, modifying the market projections of the firm; directly, it will change the

supply and demand of labor. The MDTA will appease some of labor's demands and augment others. The MDTA will also increase the supply of skilled workers. The provisions and operations of the act are examined, as well as causes and cures of unemployment. Different types of programs, i.e., institutional vs. OJT, are compared and results evaluated. The recent shift in emphasis from providing skilled workers to training the especially disadvantaged is reviewed.

WILLIAM A. HOWARD, Ph.D. Cornell 1966. Money wage changes in U.S. manufacturing industry: a statistical model based on an analysis of the variables involved in the Eckstein-Wilson wage determination model.

CHONG C. HU, Ph.D. Saint Louis 1967. Interstate differences in insured unemployment and their implications for a recession period extended benefit program.

The two approaches to unemployment compensation extended benefits are examined—the Federal approach to begin and end payments at the same time in all states according to the condition of the economy and the state approach permitting each state to determine eligibility and qualification. The approaches are examined in thirteen different states to determine what results would have been in the 1957-58 and 1960-61 recessions.

NORMAN S. HUBBARD, Ph.D. Yale 1967. Short-run changes in labor productivity in United States manufacturing, 1954-59.

GORDON C. INSKEEP, Ph.D. Columbia 1967. An analysis of productivity and turnover among women garment workers as related to criteria used in employee selection.

GEORGE E. JOHNSON, Ph.D. California (Berkeley) 1966. The theory of labor market equilibrium.

THOMAS M. JOHNSON, Ph.D. Columbia 1967. Some aspects of the economics of minimum wages.

The theory of adverse employment effects from the minimum wage is restated and previous empirical studies are criticized. New measurements of effects on average hourly earnings are developed by use of BLS industry statistics. Adverse effects on employment are shown by observing trend changes at times of minimum wage increases, and by regressions using ratio of minimum wage to average hourly earnings. The appropriateness of the minimum wage as an anti-poverty policy is considered.

ROBERT E. JONES, Ph.D. Colorado 1966. A resource allocation model of man-hour and work load relationships in a non-market setting.

GEORGE F. LEAMING, Ph.D. Arizona (Tucson) 1967. Changes in the composition of the labor force in the primary copper industry.

The dissertation analyzes in detail changes in the relative pay structure, skill level composition, and type of work performed by the work force in the primary copper industry of the United States from 1947 to 1963. The separate analyses find significant positive trends in relative pay and skill levels and in the proportion of workers operating and maintaining capital equipment but not in the proportion of maintenance workers as compared to production workers.

ALLEN J. LENZ, Ph.D. Stanford 1966. Military retirement and income maximization: an examination of the economic incentives to extended military service.

MILDRED B. LEVY, Ph.D. Northwestern 1966. Interregional labor migration in Ghana. Interregional labor migration in Ghana is estimated in an econometric model which includes income, distance, education, urbanization and population size as explanatory variables. Migration data are from the 1960 Census. Rural to urban migration is examined within the context of the regression model and on the basis of other data.

DAVID B. LIPSKY, Ph.D. Mass. Inst. Technology 1967. The labor market experience of workers displaced and relocated by plant shutdowns: the General Foods case.

HAROLD I. LUNDE, Ph.D. Minnesota 1966. The prediction of occupational labor demand in the United States.

GRAEME MCKECHNIE, Ph.D. Wisconsin 1966. Retraining and geographic mobility: an evaluation.

This dissertation focuses on two methods of alleviating unemployment caused by

structural changes—retraining and relocation. One of the hypotheses tested was that retrained and relocated workers would have more success in the labor market in terms of increased earnings than workers who did not retrain or relocate. A major conclusion reached from data collected in West Virginia was that retrained men who relocated enjoyed a higher rate of return on the cost-investment than groups who did not combine retraining and relocation.

JOHN H. NORTON, Ph.D. Pennsylvania 1966. Studies in the measurement, analysis and projection of metropolitan area employment and unemployment.

The dissertation consists of a series of related studies of the uses of and requirements for data in metropolitan area manpower analysis, the nature and quality of the available statistics, and the problems encountered when small-area manpower data are employed in the construction of economic models. Emphasis is placed on economic base and labor market analyses, on models and methods of forecasting, and on procedures for improved inference.

DENNIS J. O'CONNOR, Ph.D. New School 1967. Fixed employment cost and wage rigidity.

The fixed employment cost hypothesis is offered as an explanation of wage rigidity. The hypothesis asserts that when the firm invests in employees, it is encouraged to maintain wages in order to minimize labor turnover. The hypothesis was tested in a number of ways and the results suggest that wage rigidity is partially explained by the hypothesis. It is concluded that profit maximizing behavior contributes to wage rigidity.

NEIL A. PALOMBA, Ph.D. Minnesota 1966. A measure of the stabilizing effect of the unemployment compensation program—with emphasis on the experience rating controversy.

The author examines the unemployment compensation program literature with special emphasis on the experience rating controversy. Then the author devises a Variance Measure, which can be altered to use different estimates of the multiplier, to test the stabilizing-destabilizing argument concerning experience rating. The measure reveals that experience rating has not been destabilizing during 1948-I to 1964-IV, but it also reveals that a non-experience rating tax rate would have achieved the same stabilizing results.

MICHAEL J. PIORE, Ph.D. Harvard 1967. Technological change and structural adjustment in the labor market.

The study investigated the manner in which the relative costs of different types of blue-collar workers influence the selection of new technology in the manufacturing sector. The investigation was conducted through interviews with managerial officials in 17 plants. The findings imply that relative costs of different types of labor are largely ignored in selecting technology. Structural bottlenecks, however, appear to be avoided through the process of on-the-job training. Several other implications of this process for labor market analysis are explored.

ROBERT PIRON, Ph.D. Northwestern 1966. Two essays on human capital and its relation to changing patterns of employment and technological change.

DENNIS F. RAY, Ph.D. Florida 1966. Automation, unemployment, retraining and a theory of retraining effectiveness.

The thesis of this study asserted that retraining programs would be considerably more effective if they were conducted prior to the unemployment of the individual. Based upon the findings presented in the study and the criterion of "retraining completions," the writer found that the experience of both public and private retraining programs supported the thesis. It was therefore concluded that the hypothesis was correct.

JAMES ROBINSON, Ph.D. Duke 1967. Labor education in Britain and the United States.

JAMES R. ROCHA, JR., Ph.D. Iowa 1966. The different impact of an urban labor market upon the mobility of white and Negro potentially skilled workers.

PAUL D. ROMAN, Ph.D. Saint Louis 1967. An analysis of the effectiveness of the reporting and disclosure provisions of Sections 202 and 203 of the Labor-Management Reporting and Disclosure Act of 1959.

The purpose of this study is to evaluate, in the light of congressional intent, the effec-

tiveness of the reporting and disclosure provisions contained in Sections 202 and 203 of the Labor-Management Reporting and Disclosure Act of 1959. The LMRDA evolved in direct response to the public concern caused by the disclosures of the Senate Select Committee on Improper Activities in the labor or management field.

MURRAY A. TUCKER, Ph.D. Pittsburgh 1966. The effects of three unions on wage and employment structure.

FRANK E. WAGNER, Ph.D. Syracuse 1966. Female employment in developing countries.

RODNEY F. WEIHER, Ph.D. Virginia 1966. The union as a monopoly: an empirical view.

JEFFREY H. WEISS, Ph.D. Harvard 1967. The changing job structure of health manpower.

Previous studies dealing with health manpower shortages have focused on specific health care jobs. As such, they have tended to ignore questions pertaining to the utilization of health care personnel. In this study, a job classification scheme for health care jobs was developed. Changes in the structure of employment among health care jobs were analyzed. The technological and market factors underlying changes in the structure of employment in several "health care job families" were explored in detail.

THOMAS D. WILLIAMS, Ph.D. Mass. Inst. Technology 1967. Labor and education in Ghana.

JACK C. WIMBERLY, Ph.D. Louisiana (Baton Rouge) 1967. Private industrial pension plans in the United States: a comparative analysis.

This study is a comparative analysis of pension plans in the automobile, steel, rubber, and petroleum refining industries. The analysis is based upon detailed examination of pension plan provisions as they appear in current pension agreements. Pension benefits for normal, early, special early, and disability retirement are computed with several hypothetical age, service, and earnings combinations. Special attention is given to the problems associated with vesting provisions as they appear in contemporary pension plans.

JOHN C. WINFREY, Ph.D. Duke 1965. The appropriate bargaining unit decisions of the National Labor Relations Board.

Population; Welfare Programs; Consumer Economics

ERNEST J. BARTELL, Ph.D. Princeton 1967. Catholic elementary and secondary education: a study of costs and benefits in selected areas.

This study examines questions of efficiency and equity raised by operation of Roman Catholic elementary and secondary schools in the dioceses of Youngstown, Ohio and San Francisco, California. Resource costs of school operation were measured by adding to accounting costs imputed values of services contributed by Church teachers and property. Allocation of contributed services of teachers was examined according to economic criteria. Returns to Church investment in religious teachers were measured, and incidence of school revenues was examined.

EILEEN M. BEYDA, D.B.A. Indiana 1967. Employee economic education programs by business firms.

BARRY R. CHISWICK, Ph.D. Columbia 1967. Human capital and the distribution of personal income.

A model is developed to facilitate the study of the effect of human capital on the inequality in, and the skewness of, the distribution of personal income across regions. Due to data limitations, the empirical analyses are for years of schooling. The analyses are performed for adult males in the states and regions of the United States (white and all), Canada, Great Britain, Israel, Mexico, the Netherlands and Puerto Rico.

ARTHUR J. CORAZZINI, Ph.D. Princeton 1967. Vocational education: an analysis of costs and benefits (a case study of Worcester, Massachusetts).

The goal of this study is to measure the economic benefits of the vocational-technical school to the individual graduate and to the local community and to compare these benefits with the economic costs of maintaining the school. To this end, current and capital direct and implicit costs of a community high school system are calculated and compared with direct income benefits and external social benefits.

RAYMOND S. FRANKLIN, Ph.D. California (Berkeley) 1966. The relative economic status of the Negro male: an econometric study.

CHARLES S. FRIEDMAN, Ph.D. Columbia 1967. The size, value and distribution of postwar automobile stocks in the United States.

This study presents newly developed estimates of size and/or value of automobile stocks in the United States on a national basis for 1946-1964, by states for 1962 and by households for 1960 and 1964. The household estimates are based on samples of more than 15,000 observations. Regressions are used to relate the alternative measures of per capita auto stocks by state and probabilities of auto ownership by households to economic, social and demographic explanatory variables.

WALTER P. HETTICH, Ph.D. Yale 1967. Equalization grants, minimum standards and unit cost differences in education.

MELVIN E. HORTON, Ph.D. Washington 1966. An economic analysis of progress in the medical care of the United States Navy and Marine Corps personnel.

In this study the output of the medical industry is measured in terms of the value of man-days saved from disease due to medical effort. Output series for the last three decades are constructed for the U.S. Navy. When compared with the corresponding inputs, a rate of productivity advance of 5 to 7 per cent per year is obtained. This high rate indicates that this service industry differs from manufacturing not in its proneness to progress, but in the ability of the economist to appropriately evaluate the rate of progress.

CASWELL L. JOHNSON, Ph.D. Columbia 1967. The structure of immigration and the labour force: an enquiry into the economic characteristics of Canada's postwar immigration 1946-1962.

The study explores in detail the hypothesis that the economic characteristics of the immigrant population and the pattern of postwar population movement to Canada indicate that immigration in Canada is effectively utilized to supplement and complement manpower needs in the national economy at various stages of the country's industrial transformation along lines consistent with a "classical selectivity" policy or limited classical internationalism. The scope of the study covers the employment, demographic, educational, occupational and mobility aspects of immigrant relative to native labour force characteristics.

NANDINI U. JOSHI, Ph.D. Harvard 1967. The efficient allocation of resources in higher education.

The planning model for higher education, involving input-output analysis, deals with optimum investment requirements for different kinds of skilled personnel in different sectors of the economy, considering choices among educational as well as production technologies. The input-output structure of labor force, factors affecting it, shortages and surpluses of skilled personnel arising from its disequilibrium, and its educational implications are analyzed. The model is applied to India.

MARTIN T. KATZMAN, Ph.D. Yale 1967. Distribution and production in a big city elementary school system.

DEMETRIOS KOULOURIANOS, Ph.D. California (Berkeley) 1967. Educational planning for economic growth.

RICHARD A. MALT, Ph.D. Princeton 1967. Population and the fisc: the effect of demographic change on public expenditures and revenues.

This thesis explores the proposition that demographic change does significantly affect some components of public expenditures and revenues. Theoretically, an approach to age-selective expenditures is set out. Empirically, fiscs and population of the United States are chosen for study. Changes in age composition are found to significantly affect expenditures on public education and welfare, and revenue lost through age-selective exemp-

tion provisions of the U.S. personal income tax. Demographic variables are found useful in regressions of state and local expenditures.

ALEXANDER R. MAURIZI, Ph.D. Stanford 1967. Economics of the dental profession.

We have endeavored to use some of the tools of economic analysis to understand the dental profession in this country. We have examined internal rates of return to training, explored inter-state relocation patterns of established dentists, examined the slope of the short-run supply curve of labor, and constructed a Cobb-Douglas production function for the dental service industry. This application of economic reasoning proved to be rather fruitful.

JOHN R. MCKEAN, Ph.D. Washington 1967. Regional disaggregation of rates of return to educational investment.

This dissertation extends the previous studies on the rate of return from investment in formal education in three directions. First, the author estimates the rates of return from the most recent data compiled in the 1960 Population Census. Second, he provides a more detailed analysis of the costs of education, thereby allowing for further disaggregation in the profile of rates of return. Finally, he estimates the rates of return for each of the four census regions as well as a separate estimate of the rate of return to education for non-whites in the South.

WILLIAM B. NEENAN, Ph.D. Michigan 1966. Normative evaluation of a public health program.

ARTHUR J. O'NEAL, JR., Ph.D. Rutgers 1967. The demand for vocational rehabilitation services: a statistical analysis.

An analysis of economic and demographic factors underlying the demand for public vocational rehabilitation services. Hypotheses that demand would be a decreasing function of community income levels and an increasing function of the rate of unemployment received support, and there was some evidence of an inverse relationship between demand and urbanization and a direct relationship between demand and labor force participation rates. Results for other variables tested were negative or inconclusive.

URBAN B. OZANNE, JR., D.B.A. Indiana 1967. Family decision-making processes and the degree of innovativeness among Scottish central-heating.

HAROLD R. PHILLIPS, Ph.D. Florida 1966. An investigation of some aspects of the prices and costs of hospital care.

THOMAS I. RIBICH, Ph.D. Princeton 1967. Education and poverty.

This dissertation attempts to measure and interpret the income gains resulting from the improved education of the poor. These gains are then compared with costs as a measure of program efficiency. Comparable measurements are derived for several varieties of education. For most of the changes examined it is estimated that the earnings gains are not as large as the dollar costs of making the changes, though some notable exceptions occur.

ENRIQUE A. ROLDAN, Ph.D. Minnesota 1966. Education and income distribution: an empirical study.

T. J. SAMUEL, Ph.D. Toronto 1965. Population control in India.

PINHAS SHWINGER, Ph.D. Pittsburgh 1966. The timing of births and the business cycle.

VACANCIES AND APPLICATIONS

The Association is glad to render service to applicants who wish to make known their availability for positions in the field of economics and to administrative officers of colleges and universities and to others who are seeking to fill vacancies.

The officers of the Association take no responsibility for making a selection among the applicants or following up the results. The Secretary's office will merely afford a central point for clearing inquiries; and the *Review* will publish in this section a brief description of vacancies announced and of applications submitted (with necessary editorial changes). Since the Association has no other way of knowing whether or not this section is performing a real service, the Secretary would appreciate receiving notification of appointments made as a result of these announcements. It is optional with those submitting such announcements to publish name and address or to use a key number. Deadlines for the four issues of the *Review* are February 1, May 1, August 1, and November 1.

Communications should be addressed to: The Secretary, American Economic Association, 629 Noyes Street, Evanston, Illinois 60201.

Vacancies

Economists, mathematicians, statisticians, operations analysts: Needed by the Research Analysis Corporation to participate in defense-related studies of resource allocation techniques and applications. Areas of interest include systems analysis of defense forces, weapon systems, and manpower and material resources, and its constituent elements of cost-effectiveness analysis and military cost analysis. A strong capability is maintained in computer-assisted model building. Staff members are assisted in acquiring a working knowledge of computer techniques if they do not already have it. Candidates should have at least a master's degree. For additional information, send résumé to Mr. John G. Burke, Supervisor of Professional Staffing, Research Analysis Corporation, McLean, Virginia 22101.

Economist: September, 1967. Principles and advanced course to be selected. Twelve-hour load. Assistant or associate. Ph.D. required. Small college of about 2,000 enrollment where emphasis is placed on teaching. Write to: O. A. Grant, Head, Department of Social Science, Tarleton State College, Stephenville, Texas 76402.

Teaching opportunities abroad: University positions, instructor to professor level, in the developing nations of Asia, Latin America, and primarily Africa. Two-year contracts. Salary dependent on level and location; transportation provided. Write to: Overseas Educational Service, 522 Fifth Avenue, New York, New York 10036. An equal opportunity employer.

Accountants: With continued growth and expanding academic programs, the Accounting Department, Texas A. and M. University has openings for two additional staff members. One, an outstanding tax and auditing specialist with a capability in computers as related to accounting in general and auditing in particular. Applicants should possess terminal degree and preferably be in mid-career and interested in a balanced program of teaching, research, and publications. Salary to \$16,500 for nine months with opportunity for additional summer term teaching at a comparable rate. Second, an assistant professor interested in principles and theory, cost, and computer applications in accounting. Applicant should possess terminal degree. Salary to \$10,750 for nine months with opportunity for additional summer term teaching. Applicants for both positions may send credentials to: Dr. Jack W. Coleman, Head, Accounting Department, School of Business, Texas A. and M. University, College Station, Texas 77843.

Transportation economist or transportation specialist: U.S. Army Corps of Engineers, Civil Works Directorate, requires several transportation economics or transportation specialists to fill staff positions in division and district offices in various parts of the country. Positions are from grade level GS-5 (\$5,331) to GS-13 (\$12,873) and are a part of the federal Civil Service program. Basic requirements are a degree in economics or business administration and appropriate experience or training for performing the following duties: supervises or produces economic evaluation studies of proposed waterway or harbor improvements; structures potential area of influence of proposed improvement, determines movements of commodities in area of influence, and assesses economic efficiencies of moving these commodities by various carrier modes—water, rail, road, and pipeline. Should be familiar with cost and rate structures of these carrier modes as well as evolving technologic changes affecting their interrelationships in an overall transportation system for a region and for the entire nation. Applicants should apply to: Mr. N. A. Back, Chief, Economics and Evaluation Branch, Civil Works Directorate, Office, Chief of Engineers, Washington, D.C. 20315.

Economic statistician: Under direction of chief, Research and Analysis Division, conducts research and prepares analyses of economic conditions and trends and statistical indicators relevant to the planning and development programs of the state. Requires master's degree in economics or economic statistics and four years of progressively responsible experience in economic research involving collecting, manipulating, and analyzing economic data. Salary range, \$9,840-\$12,552 per year. File applications with: State of Hawaii, Department of Planning and Economic Development, 426 Queen Street, Honolulu, Hawaii 96813.

Economist I: Under direction of chief, Research and Analysis Division, conducts research and prepares analyses and reports on macro- and microeconomic conditions relevant to the planning and development programs of the state. Requires four years of responsible professional experience involving work in economics and a master's degree in economics or business administration. Specialization in regional economics, econometrics, or statistics helpful. Salary range, \$9,840-\$12,552 per year. File applications with: State of Hawaii, Department of Planning and Economic Development, 426 Queen Street, Honolulu, Hawaii 96813.

Economics: Assistant dean, College of Business, Ph.D. or D.B.A. in business or economics required. Three to 5 years of full-time teaching experience in college or university. Administrative experience given special consideration. Limited teaching opportunity. Initial annual salary \$17,000-\$18,000. Effective date September 1, 1967. Contact: Dean Earl A. Roth, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Economists: The state of Virginia has recently established a Division of Planning with broad research responsibilities. Opportunities are open for original work in state and local finances, regional economics, and operations research. The work is particularly challenging for young men wishing to gain research experience in an organization with few bureaucratic restraints and good facilities and financing. Positions are open for persons with training in economics at the M.A., near-Ph.D., or Ph.D. level. Salary range fairly close to federal GS-9 through GS-12. For additional information, send résumé to: Chief, Research Section, Division of Planning, 805 State Office Building, Richmond, Virginia 23219.

Economist: For one- or two-year teaching assignment in economics and/or business administration at one of the most progressing international universities. All lectures are in English. Ph.D. or D.B.A. and some teaching experience are required. Salary depends on qualifications, present rank, and experiences. The position may be permanent for Iranian citizens who meet the above qualifications. Contact: Dr. Manuchehr Vessal, Provost, Pahlavi University, Shiraz, Iran.

International economist: Westinghouse Electric Corporation, advanced studies group. Located in Cambridge, Massachusetts, consisting of senior political scientists, systems and operations analysts and specialists in strategic intelligence, psychology and engineering who seek the services of an international economist. Duties are to provide economic inputs to international and corporate political and strategic studies conducted for federal agencies. Though studies are often broad, conceptual, or long range, conclusions regarding problems examined are usually stated in as specific and policy-oriented a manner as possible. Some knowledge of economic development

desirable. Typical contributions: projection of national capabilities and resource allocations for various countries; role of economic aid and military assistance in U.S. foreign policy; gross order of magnitude costing of required U.S. military forces and facilities; contribution of economic planning measures to political and economic modernization in a specific environment; and influence of blockade on a nation's economy and military capabilities. Master or doctorate with experience in mathematics. Security or strategic studies, international economics, comparative economics and economic development. Write to: R. H. Lence, Director, 545 Technology Square, Cambridge, Massachusetts.

Visiting professorship in China (Taiwan): Requirements are a graduate degree with ability to teach one or more of the following courses: business administration; electronic data processing; marketing, statistics, quantitative methods, economics and related fields. A four-month up to two-year contract can be arranged to suit individual preference. Round trip air expenses paid. Retired professors and businessmen are also welcomed. Write to: Professor Kenneth K. Fan, Utah State University, Logan, Utah 84321.

Foreign service: The government of Jamaica has vacant posts in the Economic and Commercial Branches of its Foreign Service. Graduates (citizens of Jamaica) in economics, commerce or international law are invited to apply. Send applications to: Permanent Mission of Jamaica to the United Nations, 235 East 42nd Street, New York, New York 10017.

Principal economist: The Aerospace Division of Westinghouse Electric Corporation has a unique opening for an economist specializing in the determination of the cost elements of cost/effectiveness analyses of advanced military and nonmilitary aerospace systems, and in the analysis of relationships between specific defense program budget requirements and overall DOD objectives. Objective: to establish, and recommend to management, actions which will maintain a proper relationship between company new business proposal actions and government fiscal budget cycle operation. Basic requirements are Ph.D. (preferred) or master's (minimum) in economics plus three to five years of experience in Department of Defense, preferably in the Comptroller's or Systems Analysis areas of OSD. Equivalent experience in the aerospace industry will be considered. Salary open. Write to: Mr. M. J. Frank, Westinghouse Electric Corporation, Defense and Space Center, Friendship International Airport, Box 746, Baltimore, Maryland 21203.

Economist: Firm of consultants in economics and statistics in Berkeley, California, is seeking an economist to help meet the demands of an expanding practice. This is a fulltime, career position with unusual potential in the largest practice of its kind in the United States. The work involves the application of econometric techniques to a broad variety of appraisal problems, including present value of life-time earning capacity of persons, future expenses of persons, future losses of businesses, and future income of property. The work requires the preparation of appraisals and reports and their presentation in court as an independent expert witness. The minimum requirement is a Ph.D. in economics, preferably labor economics, and a good working knowledge of statistics and the mathematics of finance. Starting salary depends on qualifications and experience. Send full résumé to: Philip Eden, 1303 Walnut Street, Berkeley, California 94709.

Economists: Positions available with TVA's Regional Studies Staff in Knoxville, Tennessee, for candidates interested in regional economic development and economic planning. Duties involved are: To assist in formulation of a regional growth simulation model in program evaluation particularly with respect to waste management systems; to test and evaluate results. To analyze problems in corporate planning of regional development programs; to assist in evaluating research problems submitted by line divisions; to analyze program functions and suggest procedures for evaluating program contributions to regional economic development. Candidates should have at least a master's degree. Salary \$9,000 to \$14,225. Send résumé or write to: Chief, Employment Branch (AER), Tennessee Valley Authority, Knoxville, Tennessee 37902.

Economists: The United Nations needs economists for challenging research and operational posts at Headquarters, New York, in Geneva, Vienna, and in many of the developing countries throughout the world. These posts are in various fields of specialization (development, econometrics, fiscal policy, foreign trade, international finance, industrial management, transportation, agriculture, mining, water resources, urban planning), at all levels of responsibility and of varying duration—permanent

or short term. Candidates with an M.A. or Ph.D. and experience in these fields are invited to contact for additional information: Office of International Organization Recruitment, Department of State, Washington, D.C. 20520.

Economists: Opportunity for participation in original and meaningful research in regional economic studies, industry studies, human resource analysis and state and local finance as part of a continuing state-wide planning function. Requirements include training in economics at the M.A., near Ph.D., or Ph.D. level. Positions can be filled at salary ranges of up to \$12,000, depending upon qualifications. Please send résumé to: James J. O'Donnell, Director, Maryland State Planning Department, 301 West Preston Street, Baltimore, Maryland 21201.

Economists: General Electric's Center for Advanced Studies has openings for economists who are interested in solving problems of government and industry. Preferred training and background will include experience in operations research and a Ph.D. in economics. Offices are in Santa Barbara, California, and Washington, D.C. Write to: Dr. Stephen Enke, P.O. Box QQ, Santa Barbara, California 93102.

Accounting and marketing: Applications are requested for a one-year appointment, effective September 1, 1968, with the possibility of appointment for a second year (1969-70), to replace a Department member on leave of absence. The teaching load of twelve hours each semester will consist of one section of principles of marketing and three sections of elementary accounting. Applicants with the master's degree and no experience will be considered for appointment at the rank of instructor. Further graduate work and experience may qualify an applicant for appointment at the rank of assistant professor. Write to: Dr. William F. Railing, Chairman, Department of Economics and Business Administration, Gettysburg College, Gettysburg, Pennsylvania 17325.

Economist: U.S. Army Corps of Engineers in Huntington, West Virginia, requires an economist in the Planning Branch. Positions are from grade level GS-5 (\$5,331-\$6,915) to GS-9 (\$7,696-\$10,045) and are part of the federal civil service program. Basic requirements are degree in economics or business administration, appropriate experience or training, and the ability to write well. The duties to be performed are: conduct and participate in the coordination of economic studies of river basins, apply professional techniques and principles of economics in formulating water resource investments, determine the potential effects of water resource investments upon the regional and national economy, develop data sources, develop and maintain contacts with specialists in the field. Limited travel and opportunity for additional education are available. Applicants for this position should apply to: Chief, Planning Branch, Huntington District, Corps of Engineers, P.O. Box 2127, Huntington, West Virginia 25721.

Economist: February, 1968. Ph.D. preferred; doctoral candidates and those with master's degree will be considered. Rank and salary dependent on advanced degree, business and/or teaching experience. Principles and advanced courses to be selected from money and banking, public finance, growth and development, labor economics, business and government and international economics. Twelve-hour teaching assignment. Three classes per semester; three or four courses per year. Liberal fringe benefits, including TIAA. Millikin University is coeducational with an enrollment of 1,400. It is affiliated with the United Presbyterian Church (U.S.A.). The school offers undergraduate majors in economics, accounting, marketing, and industrial engineering. Opportunities for teaching at additional compensation are present in both Evening School and Summer Session. Please send résumé and names and addresses of three references to: Dean James R. G. Olson, School of Business and Industrial Management, Millikin University, Decatur, Illinois 62522.

Economists: With continued growth and a new M.A. program in economics, the Department of Economics, California State College at Fullerton will have openings in September, 1968, for several additional staff members at the junior level, Ph.D. or near Ph.D. Although the particular areas of specialization in economics are open, we are interested in persons with strong fundamental grounding in economic theory. In general, the Department seeks persons with a high degree of technical economic competence, dedicated to teaching, and devoted to continuing professional activity and development. The College, 8 years old and rapidly expanding, is located on the fringe of the Los Angeles metropolitan area. For further details, write (enclosing detailed résumé): Dr. Levern F. Graves, Department of Economics, California State College, 800 North State College Boulevard, Fullerton, California 92631.

Labor economists and statisticians: Attorneys have discovered that expert economists and statisticians can provide valuable assistance in determining the extent of monetary losses suffered because of wrongful injury of death. Qualifications required to engage in this highly rewarding activity include faculty status of associate professor and above, an interest in human capital analysis, and located near a major city. Our economic consulting organization has several prime markets open. Write to: D. Carl Deiter, President, Economic and Statistical Consultants, Inc., Box 17184, Tampa, Florida 33612.

Economist, chairman of department: California State College at Fullerton is seeking a qualified economist to fill the position of chairman of its Department of Economics. The position requires a Ph.D. degree from a major university and evidence of scholarly writing, leadership, and administrative ability. The approximate salary range is \$11,000 to \$17,000, depending upon experience and qualifications. The Department of Economics is in the School of Business Administration and Economics. Major interest is directed toward the bachelor and master of arts programs in economics. In addition, the department offers undergraduate service courses for various majors in the college and provides graduate courses for the master of arts in social science and the master of business administration programs. The undergraduate program of the School of Business Administration and Economics is fully accredited by the American Association of Collegiate Schools of Business. California State College is a rapidly growing, eight-year old institution, located on the fringe of Los Angeles, 25 minutes from Newport Beach, an hour from the mountains, and within easy driving distance of the University of California at Irvine. The position of department chairman under growth conditions such as the college is experiencing, provides ample opportunity for innovation, dynamic leadership, and professional development. Please address inquiries to: Paul T. Kinney, Dean, School of Business Administration and Economics, California State College at Fullerton, Fullerton, California 92631.

International economist: The U.S. Arms Control and Disarmament Agency has a Career Civil Service position for an international economist, grade GS-12 (\$10,927) or GS-13 (\$12,873), to perform research on the economic impact of defense and disarmament. Nondiscrimination in employment. Basic requirements are for a degree in economics and a minimum of 3 years of professional experience which includes the specialized fields of designing, monitoring, and evaluating sponsored research projects and performing in-house research. Work involves considerable contact with the academic community, nonprofit and profit institutions, and economic policy officials of other agencies of government. Position provides opportunity for use of economic background in very broad scope. Call Mr. Henry Wyner, Area Code 202, DUDley 3-7755, for further information or mail SF-57, Application for Federal Employment, or résumé to: Economics Bureau, U.S. Arms Control and Disarmament Agency, Room 4666, State Department Building, Washington, D.C. 20451.

Economists: Office of International Operations, Internal Revenue Service, has unique and intellectually challenging career opportunities for economists in Washington, D.C. Nature of work is primarily concerned with applying economic analysis to intercorporate activities between related corporations to ascertain whether they reflect competitive arm's length standards. Basic function is to examine and analyze transactions involving goods and services flowing between related corporations to determine whether the intercorporate transfer prices meet the arm's length standard. Conclusions are then drawn as to whether the corporation has clearly reflected its true taxable income. These economic analyses cover the entire spectrum of business activity and will have an important bearing on the development of tax law guidelines and precedents involving intercorporate pricing in the expanding area of international commerce. Positions are available at entrance salaries ranging from \$10,000 to \$15,000. Position and starting salary will depend upon educational background and professional experience. For further details, write to: Director of International Operations, attention, Chief, Economic Advisory Branch, Internal Revenue Service, Washington, D.C. 20225.

Economists: January, 1968. Ph.D. preferred. Teaching positions open in the areas of micro economic theory, macro economic theory, public finance, comparative economic systems, business cycles, statistics, and principles. Rank and salary appropriate to education and teaching experience. Write to: Dr. J. C. Pogue, Acting Chairman, Department of Social Science, University of Missouri at Rolla, Rolla, Missouri 65401.

Economics and department head: Opening for Ph.D. in growing economics department. Teaching assignments open, but prefer experience in statistics and quantitative methods. College located ideally in rural community, but close to metropolitan centers. Available beginning spring term or fall term, 1968. Send résumé to: Robert N. Ford, Dean of Social Studies, Millersville State College, Millersville, Pennsylvania 17551.

Economics: February or September, 1968. Ph.D. preferred; doctoral candidates with master's degree will be considered. Teaching assignment flexible, including range from elementary to advanced undergraduate courses and/or graduate courses. Rank and salary commensurate with qualifications. T.I.A.A., life insurance, major medical, other fringe benefits. Please send résumé to: Dr. Charles L. Kraemer, Chairman, Department of Economics and Business Administration, Wagner College, Staten Island, New York 10301.

Economists and econometricians: Abt Associates, Inc., a small research firm in Cambridge, Massachusetts, desires to expand its staff of economists and econometricians. The company is young, vital and growing rapidly. The firm offers unlimited opportunities for independent and creative research in a wide range of areas, management of contracts and research studies, and contact with professionals on the staffs of numerous universities. Abt Associates is presently working with many branches of the U.S. government, private companies, foreign governments and international institutions. Present work includes economic development and planning, transportation, economics, economics of education, urban development, the industrialization of rural areas, and the design of information systems for regional development. Staff members are either social scientists or engineers and mathematicians, and many are both. Abt Associates emphasizes an inter-disciplinary approach to economic and social questions and seeks creative operational answers to today's urgent problems. Highly qualified, young and dynamic Ph.D. holders or doctoral candidates are required. Salary open and depends on qualifications. Applicants should apply to: Dr. Clark C. Abt, President, Abt Associates, Inc., 55 Wheeler Street, Cambridge, Massachusetts 02138.

Dean: Dean of the College, spring, 1963. Community college in its tenth year needs replacement for retiring dean. Teaching experience at college level required. Administrative experience desired. Doctor's degree strongly preferred. The College has become the focal point of a nationally unique and significant health education complex. Communicate with: Dr. Moses S. Koch, President, Essex Community College, Baltimore, Maryland 21221. Area 301, Mu 6-1200.

Accounting: Two assistant or associate professorships in accounting. Rapidly expanding department located in state university in Greater Detroit Metropolitan Area. Ph.D. or D.B.A. with specialization in accounting theory. C.P.A. given special consideration. Salary \$11,000 and up. Summer teaching and consulting available. Contact: Dr. Emerson C. Erb, Jr., Head, Department of Accounting and Finance, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Finance: Assistant or associate professorship in finance and banking. Rapidly expanding department located in state university in Greater Detroit Metropolitan Area. Ph.D. or D.B.A. with specialization in capital structure, capital investment and financial theory of the firm. Salary \$11,000 and up. February or September, 1968. Summer teaching and consulting available. Contact: Dr. Emerson C. Erb, Jr., Head, Department of Accounting and Finance, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Business education: Instructor with ability to teach courses in office education. Must have master's degree. Man with plans for higher education preferred, but all applications are invited. Rank and salary open. September, 1968. Contact: Dr. Charles H. Duncan, Head, Department of Business Education, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Business economics: Associate professor to teach courses in managerial economics, business conditions, and related areas at the graduate level. Ph.D. or D.B.A. in economics and/or business administration. College teaching experience preferred. Salary \$11,000-\$13,000, depending on qualifications and experience. Additional stipend for teaching summer school. September, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Data processing: Assistant professor to teach undergraduate and graduate courses in data processing. Opportunity to teach at least one course in another area such as business statistics or introduction to business. Ph.D., D.B.A., or M.B.A. plus. Business experience in data processing required. Salary \$10,600-\$12,000, depending on qualifications and experience. Additional stipend for teaching summer school. September, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Insurance: Assistant or associate professor to teach undergraduate and graduate courses in insurance. Ph.D. or D.B.A. in insurance and related fields. College teaching and business experience in insurance desirable. Salary \$11,000-\$13,000, depending on qualifications and experience. Additional stipend for teaching summer school. September, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Introduction to business: Assistant professor to teach introductory course in business at freshman level. Ph.D., D.B.A., or M.B.A. plus in business administration, with college experience teaching introduction to business. Opportunity to teach at least one course in area of specialization at undergraduate or graduate level. Salary \$10,000-\$12,000, depending on qualifications and experience. Additional stipend for summer teaching. September, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Research and statistics: Associate professor to teach graduate courses in business research, qualitative analysis, and statistics, and undergraduate course in statistics. Ph.D. or D.B.A. in business administration with work in research and quantitative areas. Teaching experience at graduate level desirable. Salary \$11,000-\$13,000, depending on qualifications and experience. Additional stipend for teaching summer school. September, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, Eastern Michigan University, College of Business, Ypsilanti, Michigan 48197.

Management: Two assistant or associate professorships, one in industrial relations and one in management systems or production management, in rapidly expanding department. Greater Detroit Metropolitan Area. Salary \$11,000-plus for academic year. Summer teaching available. September, 1968. Contact: Dr. Claude I. Shell, Head, Department of Management, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Marketing: Assistant or associate professor. Teaching position in an expanding marketing department located in state university in the Greater Metropolitan Detroit Area. Ph.D. or D.B.A. in business or economics required. Training in behavioral sciences, international marketing and/or quantitative methods helpful. Undergraduate and graduate programs. Salary \$11,000 and up for academic year. February or September, 1968. Contact: Dr. Robert J. Williams, Head, Department of Marketing, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Economist (micro and macro), statisticians: A nonprofit economic research organization in Washington, D.C., is seeking several professional economists and statisticians to participate in a study of regional growth and regional planning. Economic studies will focus on labor force requirements and demographic characteristics of regional populations, on problems of industrial structure and location, on issues of public finance and fiscal policy, and on projecting economic activity. Salary is commensurate with education and experience.

P338

MEASURES OF TECHNOLOGICAL PROGRESS IN THE LIGHT OF RECENT GROWTH THEORIES

By WILLIAM FELLNER¹

I. *Preview of Concepts, Symbols, and Propositions*²

The behavior of relative income shares ($wL/r\bar{K}$), profit rates (r), and of output-capital ratios (Q/\bar{K}), along the growth paths of Western economies has stimulated interest in a concept of dynamic equilibrium which the authoress of [22] named a Golden Age. This is a state of growth in *observable* Harrod-neutrality: a growth path of which it is possible to say not only that it is Harrod-neutral in the sense that Q/\bar{K} will remain constant *if* there takes place just enough investment to keep r constant, but also that there does in fact continuously accrue this particular amount of investment. In other words, in a Golden Age we actually have simultaneous constancy of r and of Q/\bar{K} , hence also of $wL/r\bar{K}$.

If the elasticity of substitution (σ) is unitary, then Hicks-neutrality of innovations—expressing itself in unchanging post-innovation values of the $wL/r\bar{K}$ ratio for the given pre-innovation macroeconomic inputs of L and K^2 —logically implies Harrod-neutrality in the sense that it takes the same amount of new investment to keep r constant as to keep Q/\bar{K} and thus also $wL/r\bar{K}$ constant. This is true only for $\sigma=1$ and Hicks-neutral innovations. But not even on these assumptions are we in a state of Golden Age—i.e., directly observable Harrod-neutrality on the growth path—*unless* the amount of new investment which actually takes place along with innovating activity keeps both r and Q/\bar{K} , hence also $wL/r\bar{K}$, constant in fact. If $\sigma < 1$, and if K/L is rising, then innovations need to be Hicks-labor-saving—they must reduce

¹ The author is professor of economics at Yale University. He expresses his sincere thanks to Craig E. Swan for valuable assistance in the work that led to this article, and he acknowledges his indebtedness also to his colleague Henry C. Wallich for very helpful suggestions.

² On the micro-level Hicks-neutrality means that individual firms, to which w and r are given, adopt innovations that leave the K/L ratio of each firm unchanged. Consequently, macroeconomic adoption leads to no change of $wL/r\bar{K}$ for the initial K/L ratio. (The symbol K relates to current capital input, while \bar{K} relates to the stock.)

$wL/r\bar{K}$ for the pre-innovation macroeconomic inputs of L and K^3 —to be consistent with Harrod-neutrality, since aside from innovation the actual amount of investment would raise $wL/r\bar{K}$.

The observed behavior of the relevant variables does indeed suggest that the concept of Golden Ages has significance, though the American economy should not be interpreted as actually having settled down in such a state. In various phases of development, the American economy, and possibly other economies too, may have been approaching Golden Age conditions from "different sides," that is, from states deviating from Golden Ages in different ways.

Until recently it was nearly universal practice to base interpretations of macroeconomic trends on Cobb-Douglas production functions (C-D) and on Hicks-neutrality of innovations (*as if* Hicks-neutrality, and perhaps even $\sigma=1$, followed from a convincing application of the Principle of Insufficient Reason!). Even on these assumptions it could be established that with a constant saving ratio (s), and a constant proportionate growth rate of the labor input (G_L), systems would tend toward a Golden Age, hence toward a constant G_Q and a constant G_K , where $G_Q=G_K$. More recently the authors of [24], [2] and many followers have made good use of linear-homogeneous production functions which have a *constant but not unitary*—usually less than unitary—elasticity of substitution (CES with $\sigma<1$). Given a constant s and a constant G_L , the Golden Age tendency can be established in this framework too, and here it is possible to build on the new and important concept of the innovation possibility frontier, and on the hypothesis of an *induced* Hicks-labor-saving bias by which distributive-shares equilibrium becomes established. Moreover, in the CES framework—in contrast to the C-D—use can be made of the concept of factor-augmenting innovations which leave the form of the production function unchanged *as if* simply more L and/or more K had been fed into the system. Such innovations may of course be said to raise the factor inputs *in efficiency units*, though it must be remembered that the productivity of each input depends not only on its own size in "efficiency units" but also on that of the complementary input. Relatively L -augmenting innovations—innovations that raise the L input in efficiency units in a higher proportion than the K input—are Hicks-labor-saving if, and only if, $\sigma<1$. In this case relatively K -augmenting innovations are Hicks-capital-saving.

³ On the micro-level this means that individual firms, to which w and r are given, adopt innovations that increase the K/L ratio of each firm. But macroeconomic adoption restores the initial K/L for the economy as a whole, with the result that $wL/r\bar{K}$ is reduced.

The present article will explain the meaning of an approach to Golden Age conditions "from one or the other of two sides"; it will make a case for interpreting American data as relating to an economy which is moving toward Golden Age conditions but, as a result of parametric shifts, is always at some distance (probably not a great distance) from these conditions; and the article will examine the appropriateness of alternative measures of technological progress for an economy moving toward a Golden Age. With respect to states of Golden Age, it will also be suggested that those economists who try to avoid the use of production functions involving "real" capital inputs (K) should be able to agree with the rest of us on the meaning of the distinction between output growth via technological progress and output growth via increased inputs (for this Golden Bridge see particularly V, 3 and 4, below). Our own analysis *will* make use of production functions with current K inputs, and it will be assumed that the long-run rate of growth of K inputs equals the rate of growth of the capital stock (\bar{K}). Along our trend lines these two growth rates will be considered equal even for very short, representative unit periods.

Throughout the paper we shall denote proportionate (instantaneous) rates of growth per unit of time by G with appropriate subscripts. On the other hand, subscripts under Q —i.e., under "output"—will express partial derivatives (e.g. $Q_K \equiv \partial Q / \partial K$). In the CES model which we shall formulate, E with a subscript—such as E_L and E_K —will express the augmentation terms by which L and K need to be multiplied to give us these inputs in efficiency units. This explains also symbols such as $G_{E_L} \equiv \dot{E}_L / E_L$, and $G_{E_{LL}} \equiv$ instantaneous growth rate of E_{LL} , etc. By w we shall always mean the *real* wage rate.

All items listed in the bibliography were found very helpful, though not all are referred to in the article itself. Still, it should be mentioned that our point of departure here will be provided by Samuelson's recent growth-theoretical contributions which their author rightly describes as extensions of the Kennedy-Weizsäcker line of approach [23]. The present writer's [9] was a product of the immediately preceding stage of development of this theory.⁴ We regard Chapter 6 of Hicks's [14] as the pioneering achievement, despite the fact that Hicks did not implement his fruitful conjecture by any discussion of mechanisms that could

⁴ In his [9] and earlier writings on the subject the present author was comparing merely two discrete points of what in the hands of Kennedy-v. Weizsäcker-Samuelson became a continuous innovation possibility frontier. In [9] we also assumed that the changes of variables which induce the L -saving or K -saving character of innovations (in Hicks's sense) were anticipated by the innovators but we showed awareness of the fact that past changes of the variables can also induce these biases.

"direct" the character of innovations. With good reason, Samuelson refers back to older authors too: in particular to Wicksell, but also to Marx and Ricardo.

II. *Golden-Age Tendency from the Left and from the Right*

For net output assume the dynamic *C-D* production function

$$(1) \quad Q(t) = e^{\lambda t} L(t)^{\alpha} K(t)^{1-\alpha}$$

The function involves unitary elasticity of substitution ($\sigma=1$), and it involves Hicks-neutrality of innovations that have a *constant* proportionate product-raising effect per period (λ). The exponents too remain constant ($0 < \alpha < 1$). Hicks-neutrality and $\sigma=1$ assure constancy of relative shares, even if both marginal products and both average products change. Furthermore, as a result of $\sigma=1$ and Hicks-neutrality, the assumed progress is also Harrod-neutral in the sense that the amount of investment which would keep the marginal product of capital (Q_K), and thus r , constant would also lead to an unchanging Q/\bar{K} . Directly observable Harrod-neutrality—i.e., Golden Age equilibrium with actually constant r and Q/\bar{K} —is not a *definitional* property, but can be derived from the assumptions underlying Figure 1 (essentially the same graph as is found in [13]). The demonstration assumes a constant s and a constant G_L , and it builds on two relations that follow from these assumptions and from (1). Remembering that K and L are current inputs while \bar{K} is a stock, and treating the right-hand side of (2) for very short periods as an "instantaneous" growth-rate, we obtain:

$$(2) \quad G_K = sQ/\bar{K}$$

$$(3) \quad G_Q = \lambda + \alpha G_L + (1 - \alpha)sQ/\bar{K}$$

Given constancy of λ , of G_L and of s , the intersection of G_K with G_Q must be stable, because G_Q has a positive intercept on the left and its slope falls short of that of G_K everywhere. The intersection marks a state of Golden Age with the following definitional properties: $G_K = G_Q$; hence Q/\bar{K} remains constant; also, in view of $\sigma=1$ and the assumed Hicks-neutrality, Q_K remains constant (note that here and in what follows $Q_K=r$). Approach to the Golden Age is asymptotic from either side, because the driving force toward the growth equilibrium is generated by a discrepancy between G_Q and G_K —a discrepancy which raises Q/\bar{K} if we come from the left and diminishes it if we come from the right—and because the fact that G_K is steeper than G_Q continually diminishes the discrepancy between these two growth rates with the result that the time rate of change of Q/\bar{K} also diminishes.

Starring all symbols that express Golden Age growth rates, we find

FIGURE 1. GROWTH RATE OF K AND Q IN THE EVENT OF C-D AND HICKS-NEUTRALITY.

(Income-distribution constant throughout the analysis)

Legend. "Realism" would require drawing G_K with a slope of about 0.10, and G_Q with a slope of about 0.025. For the sake of visual convenience the slopes were made larger in the graph.

At the origin, on the left-hand side, G_Q and G_K have the values shown in the graph; the value of Q/\bar{K} there should be interpreted not as zero but as negligibly small. Whether the process starts on the ordinate at the left or at the right-hand vertical line, we may think of it as being started by a sudden rise of s from zero to the value expressed by the slope of G_K . Just prior to the start G_Q had the value shown on the vertical line from which we take off. The G_Q intercept on the ordinate is $\lambda + \alpha G_L$.

$$(4) \quad G_Q^* = \frac{\lambda}{\alpha} + G_L^*$$

The Golden Age value of Q/\bar{K} is

$$(5) \quad (Q/\bar{K})^* = \frac{G_Q^*}{s}$$

Note that a change in s leaves G_Q unaltered, but that a transition from a Golden Age with a lower to one with a higher s will of course nevertheless increase Q in relation to the contemporaneous Q of the initial Golden Age.

The conventional model so far discussed—cf. equations (1) through (5)—has the disadvantage of *postulating* Hicks-neutrality, a conceptual construct the empirical importance of which cannot be made plausible

by any convincing application of the Principle of Insufficient Reason, because the underlying partitioning of the set of all possible innovations is highly unconvincing. The CES innovation-frontier model, to which we now turn—cf. equations (6) through (11) in the following pages and (12) in Section V—postulates neither Hicks- nor Harrod-neutrality. It derives a tendency toward Harrod-neutrality, coupled with Hicks-labor-saving bias, from a reasonable maximization postulate.

In the CES innovation-frontier model we assume $\sigma < 1$, which in the formulation appearing below implies $\rho < 0$, since $\sigma = 1/1 - \rho$. We shall assume also that innovations are of the factor-augmenting variety.⁵ Noting that all terms of (6) with the only exception of ρ are functions of time, we write the linear-homogeneous production function

$$(6) \quad Q = [(E_L L)^\rho + (E_K K)^\rho]^{1/\rho}$$

L and K are the inputs in natural units; $E_L L$ and $E_K K$ the inputs in efficiency units; $G_{E_L} \equiv \dot{E}_L/E_L$ is the (new or additional) L -augmentation per period; $G_{E_K} \equiv \dot{E}_K/E_K$ the corresponding term for K . Equation (6) can be written also as

$$(6a) \quad Q = \left[(E_L L)^\rho \left(1 + \left(\frac{E_K K}{E_L L} \right)^\rho \right) \right]^{1/\rho}$$

Equation (2) for G_K holds in this framework too in unmodified form. As for G_Q , we note that (6a) leads to

$$(7) \quad \log Q = \log E_L L + \frac{1}{\rho} \log \left[1 + \left(\frac{E_K K}{E_L L} \right)^\rho \right]$$

We use the notation $1 + (E_K K/E_L L)^\rho \equiv \gamma$, and we denote the proportionate rate of change per period of γ by the symbol G_γ . Then,

$$(8) \quad G_Q = G_{E_L L} + \frac{1}{\rho} G_\gamma$$

In any state of Golden Age that may be reached $G_\gamma = 0$. This is because *in efficiency units* the ratio of the two inputs must remain constant once the Golden Age path is reached, to keep $wL/r\bar{K}$ constant with $\sigma < 1$. Therefore the Golden Age growth rate may be written as

$$(9) \quad G_Q^* = G_{E_L L}^*$$

It follows that along a Golden Age path the instantaneous rate of increase of the real wage rate (w) equals $G_{E_L L}^*$. The last of these terms,

⁵ The most general form of factor-augmenting functions is $Q(t) = F[g(t) L(t), h(t) K(t)]$, where g and h are the augmentation terms applicable to L and K , respectively. The new (or additional) augmentation per period is $G_g \equiv \dot{g}/g$ for L , and $G_h \equiv \dot{h}/h$ for K .

which differs from the Golden Age growth rate G_Q^* only by the constant G_L , is the abscissa intercept of the innovation possibility frontier. This is why it was more revealing to carry out the operations leading from (6) through (6a) to (9) the way in which they were presented rather than to have them result in $G_Q^* = G_{EK}^* = G_K^*$, though these equations too are valid, and an obvious alternative to (6a) would have landed us in these.

FIGURE 2. INNOVATION POSSIBILITY FRONTIER

Legend. Abscissa: Proportionate rate of new (or additional) L -augmentation per period (G_{EL}).

Ordinate: Proportionate rate of new (additional) K -augmentation per period (G_{EK}).

For this function: $G_{EK} = f(G_{EL})$, we assume $f' < 0, f'' < 0$.

For explanation of the frontier and of tangencies, see footnote 6.

As for the behavior of E_L and of E_K , given ρ , we rely on the theory of induced inventions, see [9] [1] [16] [23], and we make use of the very fruitful concept of the innovation possibility frontier. The apparatus is graphed in Figure 2, the relevant equation

$$(10) \quad G_{EK} = f(G_{EL})$$

and its significance are explained in the legend and in a footnote.⁶

⁶ The frontier implies a specific—presumably optimized—cost (or effort) of inducing *inventions* which can be put into effect as industrial *innovations*. The abscissa values of the frontier

FIGURE 3. GROWTH RATE OF K AND Q IN CES INNOVATION-FRONTIER MODEL WITH FACTOR-AUGMENTATION

(Temporary shifts of G_Q associated with changes of income-distribution are disregarded in graph; intersection-point not shifting.)

Legend: Here, as in Figure 1, G_L and s are assumed to be constants. Maximization along innovation frontier is assumed.

The graph corresponding to Figure 1 may be drawn as in Figure 3.

The following considerations justify giving the G_Q curve in this model the shape it has in Figure 3. It may be seen from equation (8) that G_Q is uniquely determined by $G_{E_L L}$ if $E_K K / E_L L$ remains unchanged, regardless of the value of $E_K K / E_L L$ at which this ratio is stabilized. Thus, for any unchanging value of this ratio (for any unchanging income distribution), $(1/\rho)G_\gamma = 0$. It follows that if we draw G_Q in relation to Q/\bar{K} on the assumption $(1/\rho)G_\gamma = 0$, as we have done in Figure 3, then we do indeed obtain the correct G_Q point for the Golden Age intersection of G_Q with G_K , i.e., for $(Q/\bar{K})^*$. At this point $(1/\rho)G_\gamma = 0$ in actual fact. That such a point *exists* follows from the last paragraph of footnote 6, because there it was shown that the system tends to P_H in Figure 2, a point at which $E_K K / E_L L$ remains constant, and at which therefore income distribution too remains constant in actual fact (despite $\sigma < 1$). To P_H in Figure 2 there corresponds the intersection point with abscissa $(Q/\bar{K})^*$ in Figure 3.

To the left of this point in Figure 3, i.e., to the northwest of P_H in

show the maximum possible $G_{E_L L} = \dot{E}_L / E_L$ given any feasible value of $G_{E_K K} = \dot{E}_K / E_K$; this statement contains also a valid definition of the ordinates if in the statement $G_{E_K K}$ and $G_{E_L L}$ are interchanged. The numerical value of the frontier's slope is a marginal trade-off ratio, expressing the

Figure 2, we have a rising labor share, that is, a rising $E_K K/E_L L$ with $(1/\rho)G_\gamma > 0$;⁷ on the other side of Golden Age we have a declining labor share, that is, a declining $E_K K/E_L L$ with $(1/\rho)G_\gamma < 0$. Consequently, Figure 3, which neglects the $(1/\rho)G_\gamma$ term across the board, does not strictly speaking associate the "correct" values of G_Q with the Q/\bar{K} values, except that it does associate the "correct" G_Q value with the intersection abscissa $(Q/\bar{K})^*$. But once we take it for granted that, given $\sigma < 1$, all shares-equilibrium tangencies through which the system passes would be stable and viable for *some* given G_K (and thus for *some* given $G_{K/L}$),⁸ neglecting the $(1/\rho)G_\gamma$ term across the board merely means neglecting a term of transitory importance outside the intersection point in Figure 3, and of no importance at all at the intersection point itself. Differently expressed: even left and right of the intersection, Figure 3 associates with Q/\bar{K} those values of G_Q which correspond to the successive shares-equilibrium tangencies at the successive levels of $E_K K/E_L L$, though the G_Q curve of the figure does not show the temporary shifts

marginal opportunity cost (m.o.c.) of acquiring a higher G_{EL} , where m.o.c. is expressed in terms of the G_{EK} which is being sacrificed. Firms maximize profits by equating this m.o.c. with the marginal advantage of G_{EL} in terms of G_{EK} , i.e., by moving to the point of the frontier where the numerical value of its slope ($-f'$) equals that of the slope of a straight line such as any of the three lines in the graph. The numerical value of the slope of any such line is by *definition* equal to the ratio of factor costs, i.e., to $wL/r\bar{K}$. Thus maximization involves moving to a tangency position.

Given any $G_{K/L}$, hence given any G_K , the system settles down in distributive shares equilibrium, by the profit-maximizing tangency's becoming a *specific* tangency position. At this specific tangency point the factor-augmenting (factor-saving) properties of the innovations are so adjusted that shares will cease to change. As long as this *shares-equilibrium tangency* is not yet reached, the slope of the straight line will change because the joint effect of current changes in K/L and of the factor-saving properties of the innovations does not yet stabilize the shares. Stability of such shares-equilibrium tangencies requires $\sigma < 1$ in which case innovations with $G_{EL} > G_{EK}$ —i.e., "relatively L -augmenting" innovations—are Hicks-labor-saving, and vice versa. Only if $G_{K/L}$ remains unchanged—i.e., given a constant G_L , only if G_K remains unchanged—is the corresponding shares-equilibrium tangency *viable*. Changes in G_K alter $wL/r\bar{K}$ and they call forth further adjustments of the relationship between the augmentation terms (i.e., these changes deprive any previous tangency of its shares-equilibrium character).

Assuming a constant s as well as a constant G_L we arrive at the conclusion that G_K and $G_{K/L}$ will indeed go on changing until the Harrod-neutral Golden Age point P_H is reached. Only at this point is the shares-equilibrium tangency viable, because only at this point does that tangency involve $G_{EL} = G_K = G_Q$ (in view of $G_{EK} = 0$), and hence only at this point does Q/\bar{K} remain unchanged with the result that $sQ/\bar{K} = G_K$ also remains unchanged. At P_H income distribution is uniquely determined by the slope of the frontier on the abscissa, and G_{EL} by the abscissa intercept of the frontier. The point is Harrod-neutral but, given $\sigma < 1$, it is Hicks-labor-saving (indeed, *purely* L -augmenting). The Hicks-neutral point is P_N . Only if K/L remained unchanged, i.e., if $G_{K/L} = 0$, would the system settle down at P_N . All points southeast of P_N are Hicks-labor-saving; they become shares-equilibrium tangencies for positive values of $G_{K/L}$ (for increasingly high values of G_K and of $G_{K/L}$ as we move downward on the frontier).

⁷ Considering that $\rho < 0$ (a condition conveniently illustrated with $\rho = -1$), a rising $E_K K/E_L L$ means $G_\gamma < 0$, hence $(1/\rho)G_\gamma > 0$.

⁸ For this see the second paragraph of footnote 6; and for a detailed demonstration see [23].

of the G_Q points brought about during the Golden Age approach by movement of $E_K K/E_L L$ from one nonviable level to the next. This "distortion" would gradually disappear at any level of $E_K K/E_L L$ (at any level of income-distribution) if the system settled down at any one of these levels, since $G_Q = G_{E_L L}$ —i.e., $(1/\rho)G_\gamma = 0$ —unless $E_K K/E_L L$ changes. At the intersection point the "distortion" disappears in actual fact.

Let us now briefly trace the G_Q curve of Figure 3, remembering that it implies $(1/\rho)G_\gamma = 0$, $G_Q = G_{E_L L}$. Starting in Figure 2 from high up in the positive quadrant, i.e., in Figure 3 from the left, the intercept of G_Q in this last figure is located at a value of $G_{E_L L}$ which is not much greater than the constant G_L , since the region in question in Figure 3 corresponds in Figure 2 to the region with low G_{E_L} and high G_{E_K} . As we move to the right along the abscissa of Figure 3, and move down in the first quadrant of Figure 2, $G_{E_L L}$ is increasing for successive values of Q/\bar{K} because for these successive values the rate of new L augmentation per period (G_{E_L}) is increasing. The increase is proceeding at a decreasing rate for rising values of Q/\bar{K} , since the marginal tradeoff is changing in such a way that increasingly more of the adjustment of the mix of the two augmentation terms is being brought about by the reduction of G_{E_K} , and less by a further increase of G_{E_L} . This is how the behavior of G_{E_L} produces an increase of G_Q at a decreasing rate, as in Figure 3.

It is worth adding that while in the second of our two models the growth rate and the income distribution in Golden Age depend exclusively on the characteristics of the frontier—on its abscissa intercept and on its slope at that intercept—the size of the inputs, in efficiency units, which the system will generate to arrive at Golden Age, depends also on the value of ρ . This follows from

$$(11) \quad \frac{Q_L L}{Q_K K} = \frac{wL}{r\bar{K}} = \left(\frac{E_K K}{E_L L} \right)^{-\rho}$$

For any initial inputs, the distance at which the system *would be* from shares equilibrium *were it not for the augmentation process*, depends on the value of ρ . Hence the degrees of augmentation during the Golden Age approach also depend on this parameter.

We have described a Golden Age approach from the left. The graphs and equations show also the nature of the approach from the right. In Figure 2, an "approach from the left" is represented by a movement downward in the first quadrant, while an "approach from the right" is a movement upward from below, that is from the quadrant expressing negative K augmentation coupled with high L augmentation. K disaugmentation is not the strange phenomenon it sounds, because through complementarity the productivity of K benefits at any event from

L augmentation. Figure 2 suggests correctly, that given a sufficiently high labor share, the optimum innovations of various successive periods may involve negative K augmentation, though it is true also that for any K/L it is possible to specify on the frontier a maximum degree of negative K augmentation beyond which the "innovation" would be a "disimprovement."

In our graphs G_Q and G_K were plotted in relation to Q/\bar{K} , rather than to time. As was pointed out in the text, the movement is slowing in time, regardless of whether we approach the Golden Age point from the left or the right. The approach is asymptotic in either case. The constant rate of increase of G_K in Figures 1 and 3 is a slowing rate of increase *in time*, because the movement along the Q/\bar{K} axis is slowing as the discrepancy between G_Q and G_K is diminishing. Lagged dynamic models, for tracing time sequences in detail, will not be formulated in this paper.

III. *What is Hidden Behind the Simplifying Assumptions?*

The type of macroeconomic theory which we are using here has a number of semiarticulate implications about matters that remain in the background.

1. As concerns advanced Western economies, *land* is regarded as a factor for which capital, in the sense of reproducible tangible wealth, can be gradually substituted with sufficient ease to make a two-factor model applicable. Such a conception implies that the relevant trend in Q/\bar{K} is more "upward" than is the trend we observe when following the usual practice of regarding reproducible tangible wealth (say, other than consumer durables) as a measure of \bar{K} . This is because on any given level of technological-organizational knowledge the natural resources of a modern Western economy should presumably be viewed as fixed in quantity.

2. Both our models disregard *economies of scale*, since both our functions are linear-homogeneous. It does make sense to assume that the long-run trend of events is not dominated by those economies of scale which are observable on any given level of technological knowledge. Nevertheless, if the average size of firms is growing, then the unexploited economies of one period become partially exploited when, in the next period, firms move to lower cost curves. Thus, what we capture in the technological-progress terms of such models includes economies of scale.

3. In the C-D Hicks-neutral model, which does not distinguish between the augmentation of L and that of K , we capture in the progress term also increments of *human capital* per person. Furthermore, in the C-D Hicks-neutral model progress not merely *appears to be* disembodied but there is absolutely nothing in that model that could take account

of the fact that *technological advance requires new capital goods*. Fortunately, this is not quite true of the CES innovation-frontier model, since here we at least take into account that significant L -augmentation—the prevalent form of technological advance in a modern economy—requires a significant rate of increase of K/L .

4. The practice of interpreting w as a measure of Q_L , and r as a measure of Q_K , implies *purely competitive* conditions in the hiring (or acquisition) of inputs and in the sale of goods. Purely competitive supply of labor is not implied. If the deviations from pure competition do not change much over time, they will not mislead the economist making intertemporal comparisons. Yet even in this case the employment of distributive-shares weights to L and to K in production function analysis, which would call for elasticity weighting, must of course be taken with a grain of salt for any one period.

In my opinion monopsonistic imperfections deserve in this context more attention than they have received in the current discussion [8] [9] [10].⁹

5. As for *shifts in the product mix*, our models can give only crude indications concerning the presumptive direction of their effects. We may perhaps derive some such indications from an analysis of the consequences of letting the Q term of our models stand for a type of product calling for more K -intensive methods of production. By this we mean methods—production functions—which at the time of their adoption would raise r and would lower w for the pre-shift quantities of input, or, differently expressed, initially make an unchanging r compatible with a higher K/L and a lower Q/K . A once-and-for-all adjustment of the value of the coefficient, or of the coefficients, by which the input terms are multiplied in the production functions may also be involved in a change so conceived, and thus we may avoid making the change equivalent to technological progress. In the C-D system the conclusion emerges that such a move toward greater K intensity, that is, here

⁹ The theory of induced innovation has not only the merits discussed in II, since it may explain also why the kind of monopsonistic imperfection which develops in particularly tight factor markets tends to call forth offsetting forces. If for example acute shortages develop from the rapidly rising demand for a factor, this may lead to the narrowing of the markets in which the individual employer can do his hiring at roughly "given" input-prices and without much deterioration of quality. He may become aware of being faced with a rising supply curve for the input in question. The rising marginal cost of the factor will then intersect the marginal product curve of the same factor at a higher point of the latter, than would be the case in non-monopsonistic circumstances; and $\sigma < 1$ implies that under these conditions the cost of the input in question rises relative to the cost of the not-so-scarce factor, per unit of output. This will favor a wave of innovations that is particularly factor-saving in the scarcer factor. Even if the monopsonistic imperfection survives this wave, the system will gradually move back to the pre-monopsony point of the innovation frontier, but the factor-augmentation that takes place in the meantime has the effect of reducing the acute scarcity which created the imperfection, and thus of reducing, or perhaps even eliminating, the imperfection itself.

toward a reduced α and hence toward an increased K share in output, will in due time result in a *higher* actual Q/\bar{K} —i.e., will result in a *higher* $(Q/\bar{K})^*$ —though with a detour over *lower* temporary values of Q/\bar{K} . This long-run conclusion concerning the increase of $(Q/\bar{K})^*$ as a result of shifts toward greater K intensity does not impose itself on us in the CES innovation-frontier system. The reason why in the C-D framework we do arrive at this conclusion is that given a lower value for α the value of $G_Q^* = G_K^*$ increases, provided we are faced with merely a temporary “accommodating” change of s during the transition, but with a permanent change of α .¹⁰ For a given λ , equations (4) and (5) show this clearly, and the result ceases to be astonishing if we take into account that a higher K share means a higher K elasticity of output, thus a greater G_Q -stimulating effect of any given amount of investment. This long-run conclusion has no analogy in the CES innovation-frontier model, because here $G_Q^* = G_{E_L}^*$ which for a given G_L is uniquely determined by the abscissa intercept of the innovation frontier.

In the CES framework we may conceive of the result of a K -intensive shift as expressing itself in a reduction of the numerical value of the (negative) ρ exponent. We may conceive of the result of the contrary shift as expressing itself in a higher numerical value of ρ . While in the state of Golden Age the distribution of income will be the same as before, a shift toward greater K intensity (or greater L intensity) will *reduce (or increase) the L -share for the initial pre-shift macroeconomic inputs*, and the gradual return to the initial distribution will result from more (less) K augmentation relative to L augmentation on the way to the new Golden Age. This statement ties in with equation (11) in II, and with our discussion of the role of ρ in that same context. There it was explained that the ratio of efficiency inputs needed to make the relative shares consistent with the slope of the frontier at the Golden Age point depends on the numerical value of ρ .

If the intersector shifts were sufficiently sustained and intense, they could render the whole approach—its C-D version as well as its CES version—useless, because the tendency to move toward the Golden Age

¹⁰ To illustrate with a K -intensive C-D shift, it would be possible to describe the change on the assumption that s remains unchanged *even during the transition*, in which case the “greater K intensity” would express itself exclusively in a higher K share and in a rise of $(Q/\bar{K})^*$, but in no temporary decline of Q/\bar{K} and in no effect on the K/L ratio (because r/w would rise sufficiently to be consistent with this result). But if into our simplified framework we wish to carry over some of the essential facts of life, it is preferable to assume a temporary, accommodating change in s . Given the identical, constant equilibrium value of s for all variants of our model, the *transition* from one variant to another (in C-D characterized by a change in the value of α) will then nevertheless be associated with a *temporary* change of s , namely, with more “reinvestment” while Q is changing toward higher K intensity (and with less in the contrary case). So Q/\bar{K} will be assumed to decline temporarily in the former case (and to increase temporarily in the latter), and r will be assumed to remain unchanged.

point could become vitiated (instead of merely becoming modified) by transitions from initial values of α or of ρ to successive other values. At any rate, in the models we are using an appraisal of the direction of the effect of changes in the product mix can be merely suggestive. Ours are not multisector models.

6. Even aside from changes in the product mix, it would be unrealistic to assume that our graphs would remain fixed, as an economy was moving toward the Golden Age intersection. The economy would at any event be chasing an intersection point that would alter its place in the passage of time, and the usefulness of models of this kind would at any event require that the tendency toward the point of intersection should not be wholly offset or outweighed by movements of the intersection point itself.

In this connection changes in s and in G_L deserve emphasis, and so do shifts of the innovation possibility frontier. Indeed, these will play a crucial role in our argument. Legitimately, because these problems are not of inherently multisectoral character.

(a) A reduction (increase) of s reduces (increases) the slope of the G_K curve, and it leads to a higher (lower) $(Q/\bar{K})^*$ leaving $G_K^* = G_Q^*$ at its initial value. For C-D and Hicks-neutrality the result that G_K^* and G_Q^* do not change follows directly from equation (4). For the CES innovation-frontier model the same result follows from equations (8) and (9), if we take into account that in any state of Golden Age $G_\gamma = 0$, and that for a constant G_L the value of $G_{E_L L}$ is wholly determined by the abscissa intercept of the innovation frontier. Furthermore, it is true of Figure 3 as well as of Figure 1 that if the value of the ordinate at the intersection (G_Q^*) is to remain the same then a flatter G_K curve must intersect with a flatter G_Q curve at a higher Q/\bar{K} , and a steeper G_K curve must intersect with a steeper G_Q curve at a lower Q/\bar{K} . We conclude that along the horizontal axis of Figure 1, and also of Figure 3, a reduction (increase) of s places a system that was initially in a state of Golden Age to the left (right) of a shifted Golden Age point; hence in Figure 2 such a change places the system northwest (southeast) of the purely L -augmenting Harrod-neutral tangency along the abscissa. A new approach to the Golden Age point starts from there.

(b) A rise (reduction) of G_L shifts the G_Q curve and raises (lowers) $G_Q^* = G_K^*$ as well as $(Q/\bar{K})^*$ in both models; hence it places an economy which initially is in a Golden Age to the left (right) of a new Golden Age. This too can be read directly from equations (4) and (5) for Hicks neutrality. In the CES innovation-frontier model the same follows from equation (9) and from the fact that $G_{E_L}^*$ is fixed by the abscissa intercept of the frontier at the point of pure L augmentation, and hence $G_{E_L L}^*$ must be greater (smaller) for a greater (smaller) G_L . In Figure 2 a rise of G_L moves the economy northwest, a decline southeast along the

frontier; and an approach to the purely L -augmenting tangency starts from there anew.

(c) An outward shift of the frontier places an economy which initially is in a state of Golden Age to the left of a new Golden Age. This then is followed by an approach to the new Golden Age point. A contrary shift of the frontier has the contrary consequence, but here too with a subsequent approach to the new point of Harrod-neutrality. In the new purely L -augmenting equilibrium the rate of continuous additional L -augmentation $G_{E_L}^*$ will be greater or smaller than was the case in the initial equilibrium, depending on whether the frontier has shifted outward or inward. Whether the distribution of income will have changed depends on whether the slope of the shifted frontier at its intersection with the abscissa differs from that of the old.

IV. *Diagnostic Suggestions*

At the "start"—in some reasonable sense of that hazy concept—were we "launched" from the left, with a high G_Q and a low G_K or from the right with the opposite combination? Differently expressed: were we launched with a low Q/\bar{K} , and were we subsequently moving toward higher values of Q/\bar{K} or the other way around?

No opinion will be ventured on the question as formulated above, partly because for early periods the question is rendered obscure by the obvious inadequacy of dispensing with the difficulty created by land in the particular fashion described in III, 1. We are, however, inclined to interpret the American trends of the late nineteenth and of the twentieth century as reflecting movements in the neighborhood of the Golden Age conditions, with a shifting Golden Age point usually located somewhat to the right of the actual position of the economy.

Data presented and discussed in [11] [12] [15] [17] and [18] point to the following tendencies in the behavior of the Q/\bar{K} ratio, when abnormally low depression ratios and abnormally high wartime ratios are disregarded. From the 1870s on, the ratio of annual NNP to \bar{K} —the former in the "Commerce" sense, the latter in the sense of reproducible tangible wealth net of depreciation and excluding consumer durables—has shown a sometimes constant, sometimes rising trend, with the probable exception of the closing decades of the past century and the turn of the present, at which time there seems to have been some degree of decline. If the findings are expressed with this generality, they apply both to price-corrected data (which are conceptually suspect because of the lack of intertemporal comparability of capital goods) and also to current-dollars data (which remain subject to limitations of a different kind); yet, as concerns the current-dollar ratio, the emphasis should be placed on the mildness of its movements except in depression and war.

At present the current-dollars ratio is in the neighborhood of 0.35.¹¹ The probable decline of Q/\bar{K} at the end of the nineteenth century—lasting perhaps into the very early part of the twentieth—does not qualify the suggested conclusion importantly. This is because any reasonable attempt to make allowances for land (III, 1) would change the findings in the direction of “more rise” or “less decline” for all periods under consideration, and because in the late part of the nineteenth century important shifts toward K -intensive sectors may well have moved the system temporarily to the left on the Q/\bar{K} axis even if the Golden Age point was located to the right (III, 4). Nor is it of course suggested that during three-quarters of a century the Golden Age point was *always* located to the right of the system’s actual position.

The rate of growth of “real” net capital input—expressed in [15] by an index that is subject to the conceptual difficulties already mentioned and that here includes an estimate of land in addition to reproducible wealth—had been declining gradually until about twenty years ago.¹² Subsequently it rose again to the pre-1929 level of the present century. The rate of growth of total man-hour input in the economy had been declining sharply until after World War II, and only quite recently has it picked up considerably. The annual instantaneous growth rate of L -input was 2.43 per cent for 1884–1900; 1.61 per cent for 1900–1929; 0.45 per cent for 1929–1948; and 0.70 per cent for 1948–1957. The comparable price-corrected NNP growth rates for these four periods are 3.62 per cent; 3.50 per cent; 2.69 per cent, and 3.39 per cent.

The saving ratio—interpreted for the present purpose as “capital formation as a percentage of NNP ”—declined from the late part of the nineteenth century to the present, and this seems to be a valid interpretation regardless of whether we do or do not engage in inevitably questionable price corrections, and also regardless of whether we do or do not include capital formation in the public sector. Whether we should conclude that the decline has continued over the period from 1929 to the present or was halted does, however, depend on how we handle the data in these regards. In current prices, and including all additions to

¹¹ If Q and \bar{K} are expressed in 1929 prices, then the present ratio is higher than roughly 0.35 (it is about 0.40), and in this case the rise from the level of the turn of the century to the present—a rise from somewhat less than 0.30 to about 0.40—becomes substantial. Yet price correction for capital goods whose prices appear to have risen sharply but whose identity has in fact changed is not a very revealing operation (the difficulty here is even greater than in the case of consumer goods).

¹² In the 27 years from 1874 to 1901 the K input rose by about 180 per cent; in the following 27 years by about 130 per cent. This is for the economy as a whole. The slowing is somewhat more accentuated for data limited to the private domestic economy. The data for the sixteen years following 1929 are strongly influenced by depression and war; they show a very small average rate of increase. As a result of a decline of G_L , the rate of increase in K/L was, however, rather stable until 1929; it was exceedingly small or negative during various subperiods of the span 1929–1945; and in the immediate postwar period it became even larger than it had been in the early periods.

reproducible tangible wealth other than military and consumer durables, the data in [16] point to a decline of the ratio from about 0.13 to about 0.09 or 0.10. This is from the turn of the century to the period after World War II.

Over the past sixty years the distribution of income has probably changed very slowly and gradually in favor of labor. This seems to be true even if we correct for the immediate consequences of shifts in the product mix [3], but in that event only to a very small extent. The extent of the change for the period as a whole depends quite a bit on the procedure used for estimation [3] [15]. The change seems to be somewhere *between* five and ten percentage points in terms of wL/Q , when correction is made for certain spurious sources of increase (e.g., for the rising weight of the public sector) but not for private intersector shifts. The wL/Q ratio for the private sectors is now somewhat in excess of 0.75. In the late part of the past century the private intersector shifts favored the relatively K -intensive industries, while more recently the contrary trend has shown to a small extent. Given these tendencies in the behavior of Q/\bar{K} and of $wL/r\bar{K}$, it seems reasonable to assume that r has not changed much. Other indications—all of these somewhat vague—also point to this being a reasonable assumption. As for the rate of technological progress, this has been increasing, as will be argued below.

It seems right to suggest that the approach to Golden Age intersection points has usually been from the region of somewhat lower-than-equilibrium Q/\bar{K} values. Much of the time a reduction of G_L has tended to shift the Golden Age point to the left; a reduction of s , as well as the acceleration of technological progress, have tended to shift it to the right (see III, 6).

V. *Preliminaries on Technological Advance: the Neighborhood of the Golden Bridge*

The clue to a reasonable interpretation of the data is provided by the rate of technological advance.

Were it not for the fact that from about 1890 on G_Q has shown a *very much* smaller tendency to decline than G_L , the observer *might* be tempted to explain the near-stability of Q/\bar{K} , or its tendency mildly to rise, by arguing that the Q/\bar{K} lowering effect of the sharp reduction of G_L was offset or possibly more than offset by the Q/\bar{K} raising effect of a reduction of s . A closer look at the matter leads to the conclusion that this interpretation of the behavior of Q/\bar{K} would at any event imply a much sharper reduction of s than it is reasonable to assume; still, with all the uncertainties of such calculations, one might say: it *could* have happened this way.

Yet, we do know better than that. If in our speculations for the period

ending in 1957—the outlook *as of now* we shall consider only in VI—we compensate the undeniably significant decrease in G_L by a decline of s , then we have found a strained explanation for the observed behavior of Q/\bar{K} but have found no explanation whatever for the failure of G_Q to decline to any appreciable extent. Both our models lead to the conclusion that *other things equal* G_Q^* should have declined by the same number of percentage points as G_L , and *in this regard* a decline of s does not serve as a compensating factor. In either of the two models—and also in less highly formalized frameworks—the investigator will turn to technological advance as the probable cause of the discrepancy we have pointed out.

We shall soon refer to direct evidence of an acceleration of technological progress. A piece of introductory reasoning is needed to explain that in a state of Golden Age—*only* in that state—two well-known macro-economic measures of technological advance should lead to identical results. It should not matter whether we use the algebraic product of the proportionate rate of increase of man-hour output with the L elasticity of output (i.e., in our models with wL/Q), *or* use the proportionate rate of increase in total factor productivity.¹³ The latter attempts to give us that part of the proportionate growth of output which is not explained by the growth of physical inputs on the basis of the elasticity of output with respect to these. In principle, the total factor-productivity method should give us the “correct” measure, though its computation inevitably involves a great many arbitrary assumptions and decisions [15]. But in a state of Golden Age the two measures should yield identical results. In either case we should obtain that output-growth which in the CES innovation-frontier model is attributed to the equilibrium rate of pure L augmentation, and which in the C-D Hicks-neutral model is attributed to λ in circumstances where λ enables a system with $G_L < G_K$ to function *as if* $G_L = G_K^* = G_Q^*$ were satisfied.¹⁴ These two things are

¹³ In [15] total factor-productivity is said to increase if output increases per unit of “total factor-input.” The latter is the weighted sum of physical inputs, where the base-period marginal products (factor prices) are used as weights. Along a static, linear-homogeneous production function total factor-productivity would remain unchanged. (Strictly speaking, the shorter the intervals in which the base-period weights are adjusted along the growth path, the more valid does the preceding sentence of this footnote become.)

¹⁴ In this regard the general logical implications of the C-D Hicks-neutral model are not identical with those of the CES innovation-frontier model, but the difference has no practical significance from the present point of view. In our CES model the only valid way of getting at the Q equivalent of Golden Age progress is to take the route through its L equivalent, because here Golden Age progress is purely L -augmenting. In the C-D model the route through the K equivalent or through some combination of the K equivalent with the L equivalent would *logically* be just as valid as is the route through the L equivalent. The reason for this is the same as which makes L augmentation indistinguishable from K augmentation in the C-D framework. However, when it comes to comparing *output per man hour* with total factor-productivity as measures of Golden Age progress then, even in the C-D model, the only *helpful* way of getting at the Q equivalent is to take the route through the L equivalent.

identical. In a state of Golden Age the proportionate rate of increase of output per man hour, before we multiply the increase by wL/Q , gives us that *deficiency* of G_L , in relation to G_K and to G_Q , which is made up by technological progress, so that prior to any weighting the L -input equivalent of progress is obtained (see the excellent discussion in [5]). If we then multiply this L equivalent by the L elasticity of output, we arrive at the Q equivalent of progress, and this is the same Q equivalent which we are trying to obtain by the total factor-productivity method.

However, by the standards of total factor productivity the proportionate increase in output per man hour multiplied by the L elasticity of output *understates* technological advance during an approach from the northwest in Figure 2 (i.e., during an approach from the left in Figure 3 or in Figure 1). The same measure *overstates* the advance during an approach from the other side. This is because the measure we are now considering is appropriate to circumstances in which $G_K = G_Q$, and in which therefore the role of technological advance can be described as filling in the gap between G_L and $G_K = G_Q$. If during the approach $G_K < G_Q$, as is the case coming from the left (i.e., from the northwest), then the man-hour output method implies a higher G_K than is the true value of *this* growth rate, and the method therefore gives K more than its due, hence underrates technological advance. The contrary is true of an approach from the other side.

In the CES innovation-frontier framework, with factor-augmenting progress, we arrive at the conclusion that approaches to the Golden Age point along a given innovation frontier will usually be associated with a change in the rate of technological progress, in the sense in which the total factor-productivity method attempts to measure progress.¹⁵ Denote here by \hat{X} the share of labor (wL/Q) at some initial point along the frontier, either northwest ("left") or southeast ("right") of Golden Age; and the share of labor at the Golden Age point by X^* ; the rate of new K augmentation per period at the initial point by \hat{G}_{EK} ; the rate of new L augmentation per period at the initial point by \hat{G}_{EL} ; the same at the Golden Age point by G_{EL}^* ; then for the transition from the initial point to the Golden Age point, the change in the instantaneous rate of technological advance—($A^* - \hat{A}$) *along the frontier*—will be

$$(12) \quad A^* - \hat{A} = X^* G_{EL}^* - [\hat{X} \hat{G}_{EL} + (1 - \hat{X}) \hat{G}_{EK}]$$

Whether $A^* - \hat{A}$ is positive or negative (or conceivably zero) depends therefore partly on the relationship between G_{EL}^* and $\hat{G}_{EL} + \hat{G}_{EK}$ (i.e., on the slope of an arc expressing the tradeoff between augmentation

¹⁵ In the CES innovation-frontier model, with factor-augmenting progress, the increase in total factor-productivity results from the summation of the Q -raising effects of the two individual factor-augmentations.

rates during the transition as a whole), and partly on the change in the relevant X weights as a result of the curvature of the frontier.

We conclude:

1. When proportionate rates of increase of a total factor-productivity index are used to measure technological advance, a change in the rate of advance should be expected during approaches to Golden Age conditions. This conclusion presupposes the CES innovation-frontier model, with factor-augmenting progress. In the C-D Hicks-neutral system the rate of technological advance remains constant, as long as the production function remains unchanged.

2. If the measure of technological advance is constructed by way of multiplying the proportionate rate of increase of output per man hour by the L elasticity of output (say by wL/Q), we should observe a lower rate of technological advance than is obtained by the total factor-productivity method while the system is moving toward Golden Age from the left, and vice versa for a movement from the right, but the difference should gradually diminish as Golden Age is approached. The conclusion is valid for both our models, and in our CES innovation-frontier model it is possible to add that what we called an approach from the left (right) can alternatively be described as a Figure 2 approach from the northwest (southeast). In either model the conclusion derives its justification from the fact that the man-hour output method understates technological progress when Q/K is rising and overstates progress when Q/K is declining, but this understatement or overstatement is gradually decreasing as we get nearer the Golden Age point.

3. As was explained on p. 1090, in Golden Age the two measures should yield identical results. This conclusion too is valid for both our production-function models. Furthermore, since man-hour output measures are acceptable also to those economists who try to avoid production functions involving "real" capital inputs, we have here, at least at one point, a Golden Bridge between two groups of economists with very different methodological preferences. In a state of Golden Age the two groups should be able to agree on the proposition that the effect of technological progress is that of making up the gap between G_L and G_Q .¹⁶ A judgment concerning the existence of Golden Age conditions need not necessarily be interpreted as an explicit judgment on the stability of Q/K —hence as an explicit judgment on K inputs—because it may be possible to arrive at the same diagnosis indirectly via the constancy of rates of return and of wL/Q . As for weighting of the increase of the man-hour output index by the L elasticity of output, it seems to be generally accepted that multiplication by wL/Q gives at least a crude approximation to the correct weighting, but we should note also that

¹⁶ See footnote 14.

obtaining merely the "golden" L equivalent of progress (rather than its "golden" Q equivalent) does not even call for such weighting.

4. The man-hour output measure (advocated in [5]) avoids some of the worst difficulties that are inevitably connected with total factor-productivity estimation, and it therefore has obvious advantages whenever a general appraisal of the data suggests the existence of near-Golden Age conditions. This is true in spite of the fact that the idea underlying the total factor-productivity method incorporates the theoretically correct principle, practical application of which, however, requires very far-reaching simplifying assumptions.

5. If a disturbance moves the system in the direction opposite that in which the Golden Age point is located, and if for a while the direction of the movement is determined predominantly by the disturbance itself, rather than by the forces leading to a subsequent Golden Age approach, then, temporarily, the measures of technological advance should be expected to behave in a fashion contrary to that in which they would behave if the system had continued to move in the direction of the Golden Age point (see III, 5). Example: An economy approaching Golden Age from the left may be moved back, further left, by a sufficiently pronounced shift of the product mix toward K -intensive industries, and the subsequent Golden Age tendency may not come through for a while; during the interim period when Q/K is declining, man-hour output measures will tend to overstate the rate of technological advance even if in the circumstances here envisaged the Golden Age point is located to the right of the system's actual position. The conclusion is valid for both models. The man-hour output measure necessarily gives technological progress too much credit whenever K/Q is increasing (and vice versa), irrespective of the reasons why K/Q changes.

VI. *The Rate of Technological Advance: Conclusions from Empirical Observations*

We now turn to the data.

1. With reliance on [15] we calculate the following instantaneous growth rates p.a. for the index of total factor-productivity (NNP-productivity of inputs) in the private domestic economy. From the year 1884 to the year 1900: 0.55 per cent; from 1900 to 1929: 1.42 per cent; from 1929 to 1948: 2.01 per cent; from 1948 to 1957: 2.21 per cent.

Using the same source we calculate, for the private domestic economy, the following instantaneous growth rates p.a. in the (net) output per man-hour index, *not yet multiplied by the share of labor*. From 1884 to 1900: 1.22 per cent; from 1900 to 1929: 2.06 per cent; from 1929 to 1948: 2.39 per cent; from 1948 to 1957: 3.25 per cent. Rounded to the

first decimal, the simple annual compound rates of increase would in all cases be the same as the instantaneous rates.

2. For the entire period 1884–1957 we find that the (net) output per man-hour index for the private domestic economy rose at a 2.11 per cent instantaneous rate p.a., and that the total factor-productivity index rose at a 1.50 per cent instantaneous rate. Thus we find that, for the *period as a whole*, weighting the proportionate increase in man-hour output by about 0.71 yields the same result as using the proportionate increase in the total factor-productivity index as one's measure. The discussion in V3, comes to mind: this is very nearly the relationship one would expect to find for an economy in a state of Golden Age. However, this same statement concerning the empirical confirmation of the Golden Age relationship between the two compound rates is not valid for the individual subperiods with different rates of progress. Nor did of course G_Q , G_K , or s show Golden Age constancy, as was explained in V.

3. It follows from VI, 1 that, if G_F stands for the proportionate rate of increase of the total factor-productivity index, and G_M for the proportionate rate of increase of the man-hour output index from one year to the next, then regressing G_F or G_M on time (t) will give not only positive constant terms ($a > 0$), but also positive regression coefficients ($b > 0$). We first used three-year moving averages, and fitted by least squares for 1891–1956, a period for which yearly estimates are found in [15]. The value of the regression coefficient b —i.e., of the coefficient of t when the latter is measured in years—is somewhat in excess of 0.02 in both linear regressions.¹⁷ In the G_F regression this coefficient is significantly different from zero at the 5 per cent level, but just barely so; in the G_M regression it misses that particular mark by a shade.

Subsequently, we used ten-year moving averages (first decade: 1890–1899, last: 1948–1957), and for G_F this resulted in

$$(13) \quad \begin{aligned} y &= G_F = 1.087 + 0.025t \\ n &= 59; \quad S_y = 0.8153; \quad \sigma_b = 0.0069 \end{aligned}$$

For G_M we obtained:

$$(14) \quad \begin{aligned} y &= G_M = 1.662 + 0.025t \\ n &= 59; \quad S_y = 0.9082; \quad \sigma_b = 0.0062 \end{aligned}$$

Here both b coefficients—pointing to a one percentage point increase of the growth rates of the indexes in 40 years—are significantly different from zero at the 1 per cent level. The deviations show a pattern that is distinctly cyclical, i.e., they reflect so-called long swings. Considering

¹⁷ Here again the indexes we have used relate to the private domestic economy. The proportionate rate of increase of man-hour output is *not* weighted by wL/Q .

the methodological problems hidden behind techniques of this sort, we should remind ourselves of the fact that VI, 1 seemed rather convincing without much further elaboration.

4. In VI, 1 and 3, the trend of G_F was compared with the trend of G_M but it *should* have been compared with the trend of $(wL/Q)G_M$. Finer shadings in labor-share estimates cannot be trusted sufficiently to make this rewarding. However, it is likely that, over our long period as a whole, $(wL/Q)G_M$ rose by slightly less, in terms of percentage points, than did G_M . This is very likely in spite of the fact that, as a result of the rise in the labor-share, $(wL/Q)G_M$ must have risen in a somewhat higher *proportion* than G_M . Weighting G_M by L elasticity would presumably have reduced the resulting estimate of the trend-slope of $(wL/Q)G_M$ somewhat below the values suggested for G_F by equation (13), since the percentage point difference between, say, $G_M=3$ per cent and $G_M=1.5$ per cent is a little greater than the difference that results after weighting 3 per cent by say, 0.75 or even 0.80 and 1.5 per cent by say, 0.70. The discrepancy between weighted and unweighted results does not remain constant as we move on in time; and if he had found such a difference it would at any event have been too small to serve as a basis for the interpretation of facts.

In view of VI, 1 and 3, we suggest that the rate of technological advance has been subject to a consistent uptrend, though with large variations about the trend. This leaves the question open whether in the CES innovation-frontier model the increase should be interpreted as a movement along a given frontier, down from the northwest toward a Golden Age point (V, 1), or as an outward shift of the frontier itself, with a small steepening of the outward-shifting frontiers in the neighborhood of pure L augmentation. We suggest placing more emphasis on the second than on the first of these two interpretations, i.e., on the outward shift. A look at V, 3, and at VI, 2 shows that, as a result of the mutual cancellation of the effects of changing parameters, our long period as a whole had *pretty nearly* the technological-progress characteristics of a Golden Age. To be sure, the subperiod data in VI, 1 show, as do other indicators, that this long-period result should be attributed to the mutual offsetting of the effects of deviations observable in successive intervals. These subperiods had somewhat differing traits, partly no doubt because of the product-shift phenomenon explained in III, 5, and V, 4. But if, as concerns measures of technological advance, the long period points to near-Golden Age conditions via the mutual offsetting of successive deviations, it becomes unconvincing to attribute the consistent increase of the rate of technological advance, in the sense of a rising G_F and of a rising G_M , *mainly* to a sustained movement of the economy toward the Golden Age point *along* any given frontier.

A significant decline of G_L , as described in IV and V, seems to have been the most important Q/\bar{K} -diminishing force, but it seems to have been balanced by two Q/\bar{K} -raising forces, namely, by a diminution of s and by a rise in the rate of technological advance (particularly through an outward shift of the frontier). While the last two of these forces do indeed seem to have *jointly* balanced or even overbalanced the first in their effect on Q/\bar{K} , the outcome is somewhat different when we consider the effect of these forces on G_Q . In this regard too the reduction of G_L remains an important diminishing force—i.e., it is a force diminishing G_Q as well as Q/\bar{K} —but the increase of the rate of technological progress is the only important G_Q -raising force. The decline in s does not work in that direction (III, 6). Hence on balance we do obtain a small decline in G_Q (as observed in IV and V). Most of the time the economy has been moving in the direction of a Golden Age point which along the abscissa of Figures 1 and 3 was probably shifting somewhat to the right (see pp. 1087–88). Changes in the product mix tended to push the economy temporarily away from the Golden Age point mainly at a time when these changes favored the K intensive industries and thus exerted a temporary push toward lower Q/\bar{K} ratios.

If the near future should bring a high G_L , and no further decline of s , it will be reasonable to expect a more pronounced tendency toward higher Q/\bar{K} values and, in contrast to the past, also a tendency toward rising values of G_Q and of G_K in the post-1957 period.

In I we explained why we prefer the CES innovation-frontier model to the C–D Hicks-neutral framework, though the relative advantages of the two approaches have so far remained controversial (see [20] and the reference on its p. 577 to other writings of the same author). The model we prefer has the considerable advantage of deriving fairly stable distributive shares from reasonable maximization assumptions. Shares-stability is a matter of great importance, because in market economies with a high and rising rate of technological advance it is likely to lead to a steep uptrend in real wages along with favorable trends in the rate of return on investment. Any such statement obviously has implications concerning the adequacy of economic policies, the forces of competition, etc., but on these we shall not elaborate here. The mild increase in the L share, which seems to have occurred even if correction is made for the effects of intersector shifts, is easily explained in the CES innovation-frontier model, particularly if we take account of a gradual outward shift of the frontier. The increasingly intense and systematic research-and-development effort has doubtless played a role in sustaining these outward shifts; but in L -augmenting economies the obstacles that need to be overcome are likely to be somewhat greater in the region surrounding pure L augmentation than in other regions of the frontier. A small degree of steepening of the frontier in that region, if coupled

with a gradual rise of $(Q/\bar{K})^*$ and of Q/K , should not lead the observer to expect a downtrend in r .

PRODUCTIVITY GROWTH IN LATIN AMERICA

By HENRY J. BRUTON*

Most observers are now convinced that long-run increases in national product cannot be fully explained in terms of increasing inputs of capital and labor as these factors are conventionally measured. Although there are severe difficulties of measurement, the accumulated evidence, covering numerous countries and a variety of time spans, indicates clearly that more capital and more labor of unchanging quality can rarely explain more than one-half the estimated growth of Gross National (or Domestic) Product. The obvious consequence of this evidence is a search for other sources of growth, for the "residual" component of growth theory [5] [21]. The purpose of the present paper is to examine the growth of Gross Domestic Product in five Latin American countries (Argentina, Brazil, Chile, Colombia, and Mexico) in the period 1940-1964 in terms of hypotheses about possible explanations of the "residual" source of growth in these countries. The development and appraisal of the various hypotheses considered is based on a comparison of the rate of growth of productivity (the residual) among the several Latin American countries and a comparison between these countries and a group of more economically advanced countries.

Part I outlines the approach employed and describes the data. Part II presents the principal results, Part III offers an interpretation of these results, and Part IV is a short summing-up.

I

A. *The Approach*

The arguments are built around an aggregate production function, and the residual is isolated in the manner originated by Robert Solow [13]. That this approach is both useful and treacherous is now well established, and little is gained from continued debate as to its conceptual and theoretical basis. The contention here is that its use enables us to learn a great deal about Latin American growth, and, in the present context, this is defense enough. Richard Nelson [12] has recently provided an admirable review of all aspects of the model, and here we need

* The author is professor of economics at Williams College. The present paper is part of a larger study on productivity in Latin America prepared while he was visiting professor of economics at the Institute of Economics, University of Chile, Santiago, Chile. He also acknowledges assistance provided under a research grant to Williams College by the Agency for International Development. The Agency is of course in no way responsible for any of the results reported here.

only define symbols and note points of special relevance to later discussion.

The Cobb-Douglas production function may be written as

$$(1) \quad P_t = A_t K_t^a L_t^b$$

where P is "potential" (i.e., full employment) GDP in year t ; K and L are quantities of capital and labor available in the same period, A an index of productivity, and a and b are elasticities of output with respect to capital and labor respectively. Assume further that the sum of a and b is unity, and that their respective values are not affected by changes in A . Take logarithms and differentiate with respect to time and get

$$(2) \quad r_P = r_A + ar_K + br_L$$

and

$$(3) \quad r_A = r_P - (ar_K + br_L)$$

where r_P , r_A , etc., refer to annual proportionate rates of growth of GDP, productivity, etc. The task is to explain r_A , the rate of growth of productivity of capital and labor.¹ Given the production function the explanation is necessarily in terms of improved quality of the two inputs and improvements in their utilization. Nelson, following Solow, Denison [14] [4], and others, seeks to break down r_A into components of improved quality of labor and technical change embodied in newly created capital. He then derives an expanded version of (2) in which these sources of growth are explicitly included, and leaves a residual explicable chiefly in terms of improved allocation.² For the present investigation only one modification of this approach is necessary.

The use of potential output washes out the effect on r_A of changes in the extent of underutilization of existing capacity. This procedure is justified on the grounds that underutilization is largely due to problems of aggregate demand, and as such has nothing to do with the productivity of the inputs. Estimates of the contributions to productivity growth of embodied technology, improved education, and better allocation must

¹ The derivation given by (3) shows why the term "residual" is suggested for r_A . It refers to that part of r_P not accounted for by increased capital and labor, and is obtained by simple subtraction. Since a positive r_A results in capital and labor becoming more productive, it is convenient to refer to it as the rate of growth of (total) productivity.

² Let λ_K refer to the rate of growth of capital productivity embodied in machines, λ_L to the rate of growth of the quality of labor (both constant over time), and $\bar{\alpha}$ as the average age of capital. Then the Nelson expansion of (2) is

$$r_P = r'_A + a\lambda_K + b\lambda_L + a\lambda_K\Delta\bar{\alpha} + br_L + ar_K$$

where r'_A is increased productivity not embodied in capital or due to improved quality of the labor force. Nelson [12] derives this equation rigorously, but once derived it is intuitively obvious.

then be made directly. For the Latin American countries, however, the evidence (cited below) is convincing that the underutilization is not due to inadequate demand. It is therefore more fruitful to assume that the ability to exploit capacity is an important factor in potential output, and that changing utilization is a key variable explaining productivity growth in the Latin American countries (hereafter LAC). Indeed the principal empirical result of the investigation is that virtually all of the variance of r_A for LAC can be explained by variation in the degree of utilization. Given this result we can then deduce something about the rate of growth of "pure" (i.e., that not explained by changing utilization) productivity: namely, that it has been virtually zero over the time period covered. The task of Parts II and III is to derive and defend this conclusion, and to offer an explanation for the failure of r_A for LAC to grow independently of changes in the degree of utilization.

B. *The Data*

The data for both the advanced group (AG) of countries and for LAC are open to many questions. I have not constructed any new series, but have pieced together data from a variety of sources and have modified and adjusted a number of existing series to arrive at estimates of the variables called for in equation (2). Despite the questionableness of many of the individual observations, the series in general appear consistent with other available evidence, and, in general, their conceptual bases are acceptable. We work exclusively with rates of growth, rather than absolute numbers or ratios of absolute numbers, and in general rates of change are more meaningful than the absolutes from which they are drawn. In view of all this we have concluded that the data are worthy of analysis, and should not be relegated merely to filling yearbooks.

The findings which we will seek to analyze are presented in Tables 1 and 2. The logic of the time periods chosen for the Latin American group is indicated as we proceed. For the advanced countries the dates selected were those for which diversity in the value of r_A was most marked.

The values for a and b used in estimating r_A are the relative shares of output accruing to the two inputs. In the case of the advanced countries capital share is given as .30 in all cases except for the United States where .25 is used. For the five Latin American countries capital's share was taken to be the following:

| | |
|-----------|-----|
| Argentina | .40 |
| Brazil | .45 |
| Chile | .50 |
| Colombia | .45 |
| Mexico | .50 |

While these percentages for LAC are based on incomplete data, they are consistent with a substantial body of evidence, and can be taken as a close approximation to what complete data would indicate. In the manufacturing sector alone capital's share will exceed 60 per cent in almost all the Latin American countries.

II

The simplest point to make about the data of Tables I and II has to do with the mean values of r_A and r_A/r_P of the two groups of countries. For the Latin American countries, r_A averages 1.4 and that of r_A/r_P is .26. For the advanced group of countries the averages are 2.8 and .58 respectively. If the extreme cases of Mexico for 1940-45 and Canada were excluded, the differences between the two groups would be even more marked.

This result is contrary to the frequently encountered notion that less developed countries with a somewhat primitive technological base may reap large windfalls by exploiting recently developed knowledge. If this were a valid hypothesis, one would expect that during years when modernization of the economies was actively promoted and the rate of capital formation comparatively high, LAC should have experienced an r_A considerably higher than that achieved by those countries already technologically advanced. That this did not occur requires some explanation.

A. *The Role of Capital*

If productivity growth played a smaller role in the growth of output in LAC than in AG, then obviously inputs must have played a larger role. That growth of capital should be more important in LAC is suggested by the estimates of relative shares given above. But then why should capital's share be greater in LAC? The answer seems to be partly a matter of technology and partly of market structure. Available data suggest that the variance of capital output ratios (aggregate and sectoral) is considerably less than the variation in labor output ratios. Further, the observed differences in the capital output ratios—unlike those of the labor output ratios—are not all in one direction, i.e., one cannot say that the capital output ratios in LAC are systematically higher or lower than in AG, while of course the labor output ratios are much lower across the board in AG than in LAC.³ Given this evidence the assumption that the capital output ratio in LAC is about equal to that in AG is an acceptable approximation.⁴

³ This point has been noted by several people. See especially Balassa [2] and Leontief [10].

⁴ If the argument were limited to the fixed-capital full capacity output ratio in the manufacturing sector, the evidence is even more convincing.

TABLE 1—GROWTH RATES OF INPUTS, OUTPUT, AND PRODUCTIVITY IN
LATIN AMERICAN COUNTRIES

| Country and Period | r_P | r_K | r_L | r_A | r_A/r_P |
|--------------------|-------|-------|-------|-------|-----------|
| Argentina | | | | | |
| 1940-45 | 2.9 | 0 | 2.1 | 1.6 | .55 |
| 1946-51 | 3.4 | 3.9 | 2.4 | .4 | .12 |
| 1955-59 | 1.7 | 3.4 | 1.5 | -.6 | -.35 |
| 1960-64 | 1.2 | 4.6 | 0 | -.6 | -.50 |
| Brazil | | | | | |
| 1940-45 | 3.2 | 2.2 | 1.7 | 1.3 | .41 |
| 1947-53 | 5.6 | 5.9 | 2.4 | 1.6 | .29 |
| 1955-59 | 5.6 | 5.2 | 2.8 | 1.7 | .30 |
| 1960-63 | 5.0 | 5.1 | 2.8 | 1.2 | .24 |
| Chile | | | | | |
| 1940-45 | 2.7 | .9 | 1.8 | 1.4 | .52 |
| 1946-53 | 3.9 | 3.0 | 2.1 | 1.4 | .36 |
| 1955-59 | 3.0 | 3.4 | 2.5 | .1 | .03 |
| 1960-64 | 4.0 | 4.8 | 1.4 | .9 | .23 |
| Colombia | | | | | |
| 1940-45 | 2.8 | 1.5 | 1.8 | 1.1 | .39 |
| 1946-53 | 5.2 | 4.0 | 2.1 | 2.3 | .44 |
| 1955-59 | 4.0 | 4.9 | 2.6 | .4 | .10 |
| 1960-64 | 4.5 | 4.3 | 2.0 | 1.5 | .33 |
| Mexico | | | | | |
| 1940-45 | 9.0 | 1.7 | 2.8 | 6.7 | .74 |
| 1946-53 | 5.0 | 4.9 | 2.6 | 1.2 | .24 |
| 1955-59 | 5.7 | 4.2 | 3.1 | 2.0 | .35 |
| 1960-64 | 6.2 | 4.2 | 2.5 | 2.8 | .45 |

Source: Col. 1 (r_P)—computed from the published data of the national accounts of the various countries. Rates are for Gross Domestic Product in 1950 prices. Data after about 1950 are more satisfactory than those for the 'forties, and in some cases pre-1950 are quite rough. Also data for GDP 1963 and 1964 are preliminary and subject to revision. A description of the national accounts data for Latin American countries is given in [17].

Col. 2 (r_K)—in all cases the capital stock figures on which the r_K 's are based were obtained from bench mark capital stock estimates and accumulations from gross investment and depreciation estimates provided by the national accounts. A general survey of capital stock estimates in Latin America with additional references to specific country studies is Alexander Ganz [7].

Col. 3 (r_L)—computed from estimates of employment made by ECLA and presented in [16, p. 3]. Data for certain years were obtained by logarithmic interpolation.

If the capital output ratio is broadly similar for both groups of countries while capital's share is significantly greater in LAC, then the marginal product of capital must be greater in LAC than in AG. Why should this be? If the marginal product of capital in LAC exceeds that in AG because capital is combined with more labor in the former, then the capital output ratio in AG must exceed that in LAC. This latter

TABLE 2—GROWTH RATES OF INPUTS, OUTPUT AND PRODUCTIVITY
IN ADVANCED COUNTRIES

| Country and Period | r_P | r_K | r_L | r_A | r_A/r_P |

Source: Data for the United States from Nelson [12], for the European countries [15], and for Israel and Japan from Aukrust [1]. The Aukrust paper contains a summary report of productivity growth in all the countries included in this table except the United States.

inequality, as already noted, does not exist, and hence a conventional variable proportion argument will not explain the deduced differences in the marginal product of capital. Neither can one appeal to technological factors as the source of the difference, since technical progress is surely more rapid in AG than in LAC.

The similarity of capital output ratios can be explained in terms of the preponderance of imported physical capital in the more rapidly growing sectors of the developing economies. This equipment is usually designed for a high-wage economy, and rarely are modifications made in this imported equipment. Wage rates in LAC are much lower than in AG, and despite the fact that LAC has a much lower capital labor ratio her wage bill is a smaller proportion of total output than in AG. This could not be the case, however, if the marginal product of capital were very low in LAC. Two factors seem to account for the higher marginal product of capital in LAC. In the first place there are in LAC numerous and obvious "gaps" in the capital structure to be filled. To a considerable degree investment represents efforts to fill in these gaps, i.e., to add to the extensiveness of the capital structure. In the richer countries with an already extensive capital structure, investment was much more in the form of replacing and duplicating existing capital. In this latter case, new capital as such is expected to add less to the capacity of the economy since it is replacing or duplicating capital capacity already there. Secondly, the import substitution policy—the policy of curtailing or eliminating entirely the importation of certain products to encourage their domestic production—also creates gaps that in turn provide possibilities for profitable investments. The monopolistic position of most plants then permits the maintenance of prices at levels sufficient to assure relatively high returns on the capital. In the context of the present discussion, it is this latter explanation of the high marginal product of capital that is particularly relevant.

B. The Role of Productivity Growth

The preceding argument suggests why capital's role in LAC is more important than it is in AG. It does not, however, tell us why productivity growth is generally lower in the former country than in the latter. It is this question that we now consider.

It may be asserted that at least part of r_A is explained in terms of the flow of new technical knowledge from research and development activity. Such activity is carried on to a much larger extent in the advanced countries than in LAC. This new technical knowledge is rarely easily and costlessly transferred to countries with different factor endowments and different organizational arrangements. Thus whatever opportunities for the exploitation of new technology existed, there did not exist the capacity to adapt and modify this technology to use it effectively in Latin America. It is also probably correct to assume that the rate of growth and of improvement in the educational establishments was greater in the former group than in the latter. In terms then of the customarily identified sources of r_A , technical advance and education, the Latin American countries lagged. This argument is intuitively appeal-

ing, but its validity depends very much on the assumption as to the sources of productivity growth. We need then to investigate the extent to which the data in Tables 1 and 2 support this generalized notion of the sources of productivity growth.

The production function states that the growth of output is explained by the growth of inputs and an increase in their productivity. If then we calculate for a group of similar countries a simple regression of r_P on the rate of growth of inputs, r_n , ($r_n = ar_K + br_L = r_P - r_A$), the resulting equation should indicate, by its intercept, the average value of r_A and the regression coefficient of r_n should of course be about unity. The estimates of r_P and r_n for the 18 observations of the advanced group of countries yields the following equation:

$$(4a) \quad AG \ r_P = 2.47 + 1.17 \ r_n \quad \bar{r}^2 = .64$$

(.21)

Equation 4a conforms to expectations reasonably well. The regression coefficient is not significantly different from unity, and the equation accounts for almost two-thirds of the variance in r_P .

For LAC, for the 1940-64 period, the corresponding equation is

$$(4b) \quad LAC \ r_P = 1.26 + 1.06 \ r_n \quad \bar{r}^2 = .23$$

(.40)

Equation 4b shows LAC's smaller r_A (the lower value of the intercept compared to that in 4a) and a regression coefficient not significantly different from one. The equation however explains such a small proportion of the variance of r_P that it is not appropriate to interpret it as describing the relationship between r_P and r_n for LAC in the same manner that equation 4a does for AG.

Data in Table 1 suggest that the relative magnitude of the sources of growth in LAC was in fact substantially different during the war years from that of later years. If the observations for the war years are eliminated, equation 4b becomes

$$(4c) \quad LAC \ (1946-64) \ r_P = -1.73 + 1.89 \ r_n \quad \bar{r}^2 = .66$$

(.35)

and if the observations for the immediate postwar period are also eliminated, the regression becomes

$$(4d) \quad LAC \ (1955-64) \ r_P = -2.87 + 2.21 \ r_n \quad \bar{r}^2 = .76$$

(.39)

The changes in the regression equations all move in a similar direction, the values of r_A (the vertical intercepts) fall sharply and those for

the regression coefficient and \bar{r}^2 rise. The rising values of the regression coefficients and the \bar{r}^2 's indicate an increasing dependence of r_P on r_n . However, both the negative intercept and the regression coefficient in excess of unity imply that this increased dependence is due to the effects of changes in the degree of utilization. Thus a negative rate of growth of productivity can be most satisfactorily explained in terms of output falling more rapidly than it is possible to reduce the quantity of inputs. Similarly the regression coefficients of equations 4c and 4d, both significantly greater than one, imply that the growth of output exceeds the growth of inputs, not because of a "pure" productivity effect, but because a positive r_n reduces the extent of utilization.

These regressions suggest the following conclusion: for AG equation 4a provides an economically and statistically meaningful summary of the data of Table 2 and of the relationship between the rates of growth of output, inputs, and productivity. The same regression for LAC is revealing in a different way. Equation 4b takes a form consistent with Equation 4a but the low value of \bar{r}^2 suggests that the relationship changes over the time period considered. Equation 4c and 4d verify this result. These latter equations also indicate that r_n becomes increasingly important in the explanation of r_P as the period progresses. Given the observed change in r_A , we may conclude that this rising importance is due both to the role of inputs on the supply side and their role in preventing or reducing underutilization.

Another way of looking at the data is in terms of a direct explanation of r_A . The notion that increases in productivity result from improvements embodied in capital equipment and from better educated, better trained workers suggests that r_A and r_n should move together, i.e., that r_n is a carrier of r_A . Thus for countries with similar technology and similarities in rate of technical progress and comparable improvements in education a positive and significant relationship between r_A and r_n is expected. Equation 5a is this regression for the eighteen observations for AG.⁵

$$(5a) \quad AG \ r_A = 2.47 + .17 \ r_n \quad \bar{r}^2 = .02$$

(.21)

This equation shows, contrary to expectations, that inputs are not carriers of the sources of productivity growth. From 4a and 5a we may conclude that for AG the rate of growth of productivity was in fact simply added to whatever growth is produced by increased inputs. In particular the evidence is consistent with the hypothesis that r_A is autonomous with respect to the growth of inputs.

For the Latin American countries the regression of r_A or r_n with all

⁵ It should be recognized that equations (5a)–(5d) are derivable from equations (4a)–(4d).

twenty observations yields

$$(5b) \quad \text{LAC } r_A = 1.26 + .06 r_n \quad \bar{r}^2 = 0$$

(.40)

The form and interpretation of this regression are similar to 5a. Again, however, eliminate the war years and then the first postwar period to get equations 5c and 5d.

$$(5c) \quad \text{LAC (1946-64) } r_A = -1.73 + .89 r_n \quad \bar{r}^2 = .29$$

(.35)

$$(5d) \quad \text{LAC (1955-64) } r_A = -2.87 + 1.21 r_n \quad \bar{r}^2 = .50$$

(.39)

The regression coefficients and adjusted coefficients of determination rise through time, but this change cannot mean that in the later periods r_n began to carry r_A for if this were the case, the vertical intercept would not turn negative. The negative intercept implies that the increasing strength of the relationship is due not to r_n 's role as a possible carrier of increasing productivity, but as a source of demand, i.e., r_A becomes increasingly dependent on the growth of demand. More specifically, the rate of growth of productivity seems increasingly dependent on changes in the degree of utilization, and the evidence shows little or no independent growth of "pure" productivity.

The preceding discussion suggests a final way to consider the data, namely a regression of r_A on r_P . For AG this regression is

$$(6a) \quad \text{AG } r_A = .64 + .44 r_P \quad \bar{r}^2 = .51$$

(.10)

This equation indicates that if r_P were zero r_A is still about .64, and hence implies that if r_P were zero (or slightly above) r_n must be negative (e.g., capital not replaced, increased unemployment, etc.). This result is also consistent with the notion that productivity growth occurred in AG more or less independently of the growth of inputs. That the equation explains one-half the variation in r_A is due simply to the fact that, for AG, r_A is a very large proportion of r_P .

The picture for LAC emerging from the regression of r_A on r_P is again different from that for AG and again changes over the time period considered.

$$(6b) \quad \text{LAC} = -1.71 + .74 r_P \quad \bar{r}^2 = .75$$

(.10)

$$(6c) \quad \text{LAC (1946-64) } r_A = -1.62 + .63 r_P \quad \bar{r}^2 = .85$$

(.07)

$$(6d) \quad \text{LAC (1955-64)} \quad r_A = -1.67 + .64 r_P \quad \bar{r}^2 = .91$$

(.06)

The value of the intercepts again shows that productivity growth is negative unless r_P is substantially positive, a result directly opposite to that shown by equation 6a for AG. Similarly, the rising \bar{r}^2 indicates a heightened dependence of r_A on r_P , i.e., changes in the degree of utilization account for an increasing proportion of the variation in r_A . In the decade 1955-64 over 90 per cent of the variation of r_A is accounted for by variation in r_P . And this occurs even though r_A/r_P in this latter period is much smaller than it was in the earlier period.⁶

Summary

The results of the regression analysis may now be summarized. We have examined three relationships for AG and LAC: r_P on r_n , r_A on r_n , and r_A on r_P . For AG both r_A and r_n are important in explaining r_P , and their effect on r_P is more or less additive. Thus the evidence is consistent with the notion that r_A represents a flow of improvements that can be employed independently of the growth of inputs.

For LAC the 1941-45 period reveals a picture very similar to that summarized for AG. After 1945, this picture changes. The rate of growth of output and the rate of growth of productivity become increasingly dependent on r_n . The negative vertical intercepts in both sets of regressions suggest that this dependence is due to the effect of r_n on the rate of growth of capacity utilization. This last possibility is further supported by the rise in \bar{r}^2 between r_A and r_P over the twenty-five year period. From these results we concluded that the variation in the values of r_A is due primarily (after 1945 and especially after 1955) to the ability of LAC to exploit fully its capital and labor resources. If this is correct, then the important conclusion that "pure" productivity growth has, in the past decade or so, been about zero emerges.

The findings for LAC would be consistent with the assumption that underutilization is due to a conventional oversaving problem. The evidence that this is not the case is convincing. In the first place, there are the inflations. A simple excess demand theory of inflation is probably not adequate to explain inflation in Latin America, but equally probably such inflations could not continue if demand were not pressing against capacity in key sectors of the economies. Also the rate of capital formation (see Table 1) has generally been quite high, and this fact is difficult to reconcile with a general oversaving problem. There is evidence of a positive nature [18] [19] which indicates that the underutilization is due to bottlenecks on the input side. Finally, an oversaving argument

⁶ The regression of r_A on r_P for LAC for the ten observations 1940-53 is $r_A = -1.53 + .78r_P$ $\bar{r}^2 = .73$.

would not explain why "pure" productivity growth was negligible in recent years. It seems appropriate to rule out oversaving as the explanation of the behavior of r_A in LAC.

III

This final section seeks to explain the behavior of r_A in terms of the development strategies and policies followed in LAC and in terms of the productivity of capital discussed in Part I above.

The central hypothesis defended here is that the development policies which created the profitable opportunities for investment (especially in the years after 1955) also created conditions that had two other effects: made it extremely difficult, for technological reasons, to achieve a high r_A and secondly, created an economic environment in which the entrepreneur had little incentive to search for productivity-increasing improvements. During the war years, on the other hand, both the technological and the incentive factors worked in favor of a relatively high r_A . The war period provided protection without distortion, while the import substitution approach to development has provided protection but has also imposed severe distortions, and it is these distortions that create the two effects just enumerated. The general evidence supporting the hypothesis is easily stated, but a detailed investigation would require a country-by-country survey. Such a survey is not possible here, but the following points are generally pertinent.

A. *The War Period*

An examination of the 1940-45 period is especially helpful. In this period the rate of growth of capital was much lower than in later periods due to the curtailment of imported capital goods. During the war there existed a strong and obvious demand in both the internal markets and for exports. Consequently, there was great incentive to increase output among all firms in the five Latin American countries, but virtually no ability to obtain new plant and equipment, spare parts, and replacements. Similarly, the flow of many raw material imports was irregular and unpredictable. With foreign supplies of capital equipment difficult to obtain, firms (to capitalize on the favorable market) were forced to find ways to use their existing capital stock with increasing effectiveness. Improvisation and adaptation of existing equipment were common, and one can find many examples of ingeniously and indigenously devised machines producing various items for household and business use [14a] [20]. The war then not only provided "protection" from foreign competition, but also helped to create an environment within which entrepreneurs had incentives to use available resources with increasing effectiveness. The innovative activity observed

in this period involved not only changes in technique to fit the domestic supply of inputs complementary to capital (labor of various skills and quality, raw material imports, and managerial ability), but also included adaptation of techniques to fit market size and of product to fit market demand.

Although the growth of the labor supply was not thwarted the way capital imports were, the wartime isolation had some effect on labor's use. One of the consequences of the efforts to use physical capital more effectively was the adaptation of the tools and equipment to fit the quality of the available labor. Thus the form of the capital became increasingly appropriate for the workers and thereby *their* productivity tended to rise. We conclude then that strong and obvious demand in a situation where availability of new, imported capital was *recognized* to be almost nil is part of the conditions necessary for entrepreneurs to achieve a relatively high rate of increase in productivity. The important thing to note is that the relatively high r_A in this period was accomplished without capital goods imports. We cannot say that it was generally high export earnings permitting a high level of imports that were responsible for a strong showing of r_A .⁷

B. *The Post-1955 Period*

The wartime experience is most clearly contrasted with the post-1955 period. In this latter period a large sector of the domestic economy of LAC again was isolated from foreign competition, but this time by high tariffs and other forms of import impediments rather than by a world war. As the war had created profitable opportunities for increased output of a wide range of manufactured goods, so also did the import substitution strategies of development followed in LAC create opportunities in the post-1955 years. The response to these opportunities that produced the high r_A in 1940-45 seemed to be absent in the later period. The question now is why?

In comparing the later periods with the war period, three characteristics seem especially relevant.

1. The most obvious difference has to do with the supply conditions of imported capital goods. During the war, as already noted, they were virtually unavailable. After 1955 the almost universal and continuous overvaluation of the local currencies made capital imports cheap, relative to domestic inputs. Entrepreneurs not only knew that foreign-made capital was available, but had a major incentive to use

⁷ Strong external demand did not mean in all cases higher exports or more favorable terms of trade than prevailed later. Exports as well as imports were handicapped by transportation. The rate of growth of exports was much higher than later and all producers knew a demand existed for all that they could produce.

it intensively in their production. But the regression analysis of Part II gave us no reason to think that capital formation carried the sources of productivity growth. On the labor side, a variety of social welfare policies (minimum wage rates, paid vacations, factory infirmaries) instituted (or enforced) in the 'fifties added to the cost of employing labor.⁸ It is also probably correct to say that wage earners were better able to protect themselves from inflation in the 'fifties and 'sixties than they were in the 'forties. There is no doubt then that prevailing market prices for capital and labor reflected the real factor supply situation much more accurately in the war period than they did in the later periods. In a very general sense, it seems correct to say that the capital equipment imported from and designed for capital rich, labor scarce countries was more nearly appropriate (for the individual producer) in its unmodified state than was the case in the war years. In this sense, the entrepreneurs had less incentive to modify and adapt (and thereby raise the productivity of) their imported capital than they had in the earlier period. Indeed, their incentives worked in the opposite direction: they were encouraged to meet any demands for increased output by acquiring more capital from abroad. It is important to emphasize that the misleading factor prices arose largely from specific policy measures, not from some endemic characteristic of the economy. Similarly, note should be taken of the fact that "entrepreneurial response" did not change, i.e., entrepreneurs reacted to market signals in both periods with considerable rationality.

2. Another difference between the two periods has to do with the composition of output. Although industrialization was underway in LAC before the war, it was not until the 'fifties that an explicit import substitution policy of industrialization became effective. In the present context the most relevant characteristic of this policy is the haphazard and *ad hoc* manner in which trade barriers have been applied. There is no evidence of a careful review leading to the protection of this or that activity on the basis of expected productivity growth or infant industry considerations. Rather import limitations have been in response to immediate balance-of-payments difficulties or to pressures from specific interests wishing to expand into new activities.⁹ The result of such a policy has been not only a reduction in current income in accordance with the conventional free trade model. More importantly, an industrial

⁸ Wage rates in most Latin American countries have risen considerably less than total labor costs since 1950. The owner of a very modern textile mill in Mexico told me that his skilled labor cost the equivalent of one dollar per hour. Of this 53 cents was "fringe benefits." The fringe benefit contribution in the early 'forties—according to the same source—was negligible. See also [18].

⁹ The most thorough documentation of this point is Santiago Macario [11]. See also the papers prepared for the Latin American Symposium on Industrial Development [18] and the analysis of Raul Prebisch [22, especially the first 25 pages].

structure has tended to emerge that is so alien to factor endowments that full utilization of existing capacity came to depend more, not less, on a constant flow of imports.¹⁰

The following sequence is typical and illustrates the way the development pattern affects productivity growth. In response to balance-of-payments difficulties, a certain category of imports (almost always a consumer durable, e.g., fully assembled automobiles for general use) are prohibited. Demand for the product is strong, and a number of plants come into being to exploit this newly created investment opportunity. Initially, almost all produced inputs used are imported. The underpricing of foreign exchange means that it must be rationed by an exchange authority and that demand always exceed supply. With a strong demand for the product, with output dependent on access to foreign exchange, and with the latter allocated among the firms independently of their competitive strength there is no market test for survival, and no need to increase productivity to survive or even to make acceptable profits.

The next step in the sequence occurs when the governments require the new firms to buy a given proportion of their produced inputs from domestic manufacturers. Usually this proportion rises over time; also, the policy usually has its origin in efforts to reduce imports.¹¹ This new requirement has two consequences. It creates a new gap (in the sense of Part I above) in the capital structure, i.e., a new obvious opportunity for profitable investment. Secondly, it forces the originally protected activity to use some inputs which are more costly, of lower quality, and less reliably supplied than was the case when imported inputs were used. The costs of the first activity are thus pushed up.¹² Foreign exchange allocations to the first activity are reduced, in line with the requirement to buy domestically fabricated inputs, and excess demand for foreign exchange by this activity continues. The consequence is also

¹⁰ Several investigations have shown that the income elasticity of demand for imports has risen in recent years in LAC due to a reduction in the average propensity to import while the marginal remained about constant. See especially David Felix's study of Argentina [6].

¹¹ Whether it does in fact have this effect obviously depends on the quantity of imported materials used by the local manufacturers of the produced inputs. See [3] for a model defining the conditions necessary for such a sequence to reduce the import content of the output of the initially protected product.

¹² Unreliable supply conditions have their most obvious consequence on inventory policy. The Chilean automobile assembly activity, for example, follows practically a seasonal pattern of production as the plants must have inputs on hand in sufficient quantity to permit an assembly run. Leland Johnson [8] has a good description of the problems of the Chilean automobile industry. Irregular supply and its consequence for inventory policy is not limited to purchases from domestic manufacturers. Almost all producers import (if permitted) well in excess of current needs on the grounds that they do not know what import policies will be next month. ECLA [13] places heavy emphasis on the lack of continuity and predictability of import policy. Finally, the usually misleadingly low interest rates reduce any incentive the producer might have to find ways to avoid carrying large inventories.

a continuation of the protection of the high-cost producers by allocating to them a share of the foreign exchange essential for production. Strong internal demand pushes product prices up, the overvalued exchange rate (and other investment incentive concessions) keeps capital costs low, and even the relatively inefficient producer makes a comfortable profit. The relatively efficient producer cannot increase his share of the market because he cannot acquire the necessary inputs, especially those that are imported. Meanwhile the most recently protected sectors (supplying the domestically produced inputs to the *initially* protected activity) attract investment.

The final stage arrives when it appears unacceptably costly to try to find ways to reduce the import content of output in the initially protected activity.¹³ Then the process is begun again by levying a prohibition against the importation of another consumer durable. Investment then seems to take place over a wide range of activities as advantage is taken of the gaps in the economy created by import policies, and there is little evidence of investment in response to profit opportunities created by increased efficiency and rising productivity.¹⁴

New investments require capital goods imports, and when foreign exchange sufficient for an acceptably high rate of capital formation and full utilization of existing capacity is not available, one or the other had to give way. As profit rates on invested capital even with considerable underutilization, were acceptable, as new gaps offered opportunities for further investment, and as foreign loans and aid were more easily obtainable for increasing capacity than for using capacity, r_K remained reasonably high in these post-1955 years. Consequently, an economic structure emerged which, when subjected to strong pressure on the demand side, produced rising prices rather than rising productivity. This final result is of course exactly opposite to that described in the war period.

3. A final element in the picture has to do with the extent and nature of external competition prevailing during the war with that prevailing in the later periods. During the war direct competition between LAC and AG was virtually nil. With demand strong in AG, Latin American countries were in effect competing among themselves for the AG market as well as for their domestic markets. With the end of the war and reconstruction and the beginning of the emphasis on industrialization in LAC, competition with AG was direct. That producers in LAC tend not to respond to direct competition with AG, while they do seem to respond to competitive threats with producers in other less developed

¹³ Or when domestic demand at the going price is satisfied.

¹⁴ ECLA recognizes this point in [18, p. 53] where "development in depth" is contrasted with "development in breadth." Similarly David Felix [6] speaks of a "premature widening" of the market in Argentina.

countries is reasonably clear. The most appealing explanation of this is simply the initial difference in costs. A Chilean manufacturer of refrigerators may seek ways to undersell a Colombian manufacturer because their costs are at least comparable. The Chilean manufacturer would, however, fold up immediately if he were confronted with producers who could offer refrigerators at less than one-third his costs. Protection was thus believed necessary, and competition in large segments of the individual economies became almost nonexistent.

IV

A short summary statement of the main conclusions may be useful. Evidence has been presented that is consistent with the hypothesis that in neither LAC nor AG are inputs (capital and labor) the carrier of productivity growth. Also evidence has been presented which leads to the conclusion that the observed changes in the rate of growth of productivity in LAC could, in the periods after 1945, be accounted for largely by the ability of LAC to utilize all its available resources. From this conclusion and on the basis of comparison with data for AG, the further important conclusion was reached that "pure" productivity growth has been virtually zero in LAC in the past decade or so. The explanation of this last result rested on three points: (1) a growing inappropriateness of the input mix of production due in large part to the continued undervaluation of foreign exchange to interest and wage rate policies, etc.; (2) a growing inappropriateness of the composition of output in the sense that productive activity was not based on cost or potential cost considerations, but rather has evolved in response to the incentives generated by protectionist policies made up largely to meet balance-of-payments crises; (3) a decline in competition.

A more general conclusion is also suggested by the argument of this paper. Recently a number of studies have shown that the increased output to be expected if all deviations from a conventionally defined optimal allocation of resources were eliminated is exceedingly small. Therefore concern with the traditional allocation questions is of little interest in understanding development.¹⁵ If, however, productivity growth is an important element in development, and if it is handicapped by severe misallocations, then the solving of the allocation problem in a satisfactory way is a crucial element in development policy.

TECHNOLOGICAL CHANGE AND THE DEMAND FOR COMPUTERS

By GREGORY C. CHOW*

To what extent has the use of electronic computers grown in the United States since 1955? What can explain the rate of growth?

We propose to measure different computers by their monthly rentals which would have been charged if the models had been introduced in the year 1960. This method of measurement requires first establishing a relationship between rental and the computer's basic characteristics for 1960 models, and then applying the relationship to estimate what each computer would have cost if it had been introduced in 1960. By this method, the stock of general-purpose, digital computers has grown from an estimated 1960 rental of about \$370 thousand per month at the end of 1954 to about \$194 million at the end of 1965. An average annual rate of growth of 78 per cent would have accomplished this.

To explain this tremendous growth, one has to isolate the natural growth which would have prevailed had there been no technological change, and the growth induced by technological change. In other words, two elements account for the increase in the use of computers. First, it takes time for a new product to reach an equilibrium level even without quality change. Second, in the meantime, the quality of the product is improving, so that the equilibrium level is being continuously raised. An explanation ought to combine these two elements and assess their roles in the growth process.

For the natural growth, two differential equations have been popular. They are the differential equations generating the Gompertz curve and the logistic curve [3, pp. 302-18]. For reasons of empirical validity as well as analytical convenience, we have chosen the former, but a test of the latter will also be presented.

A simple way of incorporating the effect of technological change into the natural growth process is to assume that the equilibrium level, which the growth curve approaches, is a function of price, given quality. A price index can be constructed once the quantity of each computer is established, by its hypothetical 1960 rental as previously indicated.

* The author is a research staff member at the IBM Watson Research Center and adjunct professor of economics at Columbia University. This study would be less convincing without the advice, comments, and assistance from G. S. Becker, L. Chimerine, C. W. Gillmore, J. H. Griesmer, A. J. Hoffman, and A. J. Karchere. Neither they nor any organization with which the author is associated should be held responsible for the views expressed, which are entirely his own.

An average of the ratios of rentals to quantities, for models introduced in a period, would serve as a price index for the period.

Our price index, deflated by the GNP deflator, shows an average rate of reduction of 20 per cent per year between 1954 and 1965. If the price elasticity of demand for equilibrium stock of computers is 1.3, say, price reduction alone would account for a 34 per cent annual growth, out of a total of 78 per cent observed.

The remainder of this paper develops more fully the ideas sketched above, provides measurements of the use of computers and of their prices, and attempts to explain the growth of computers in the United States between 1955 and 1965. The theory will be formulated in Section I. Section II describes the construction of quantity and price indexes. Section III performs statistical analyses of the time series data and draws some conclusions.

I. *Theory*

To describe the process of natural growth of a new product, it is often assumed that the rate of growth depends on two factors. First, the quantity of existing stock y , asserts a positive influence, partly rationalized by the idea that the more the product has been accepted, the more prospective buyers have come in contact with and learned about the product. Second, the difference or ratio between the equilibrium level y^* , ultimately to be reached, and the existing level y , also asserts a positive influence. Although the existing stock y , has a positive effect on the rate of growth as it shows the extent of the awareness of the product, the closer it comes to the equilibrium level y^* , the smaller will be the number of prospective buyers remaining.

One formulation of the growth process incorporating these two factors is

$$(1) \quad \frac{dy}{dt} = \alpha y (\log y^* - \log y)$$

or

$$\frac{d \log y}{dt} = \alpha (\log y^* - \log y)$$

The solution of the differential equation (1) yields the Gompertz curve. Another formulation is

$$(2) \quad \frac{dy}{dt} = \gamma y (y^* - y)$$

or

$$\frac{d \log y}{dt} = \gamma(y^* - y)$$

the solution of which is the logistic curve. Both formulations assume that the two factors affecting the rate of growth enter multiplicatively. Hence they become hypotheses explaining the percentage rate of growth. According to (1), the percentage rate of growth is a linear decreasing function of $\log y$.¹ According to (2), the percentage growth is a linear decreasing function of y . Thus, in a later stage of the growth process, or for a large value of y , any given increment in y will dampen the rate of growth more for the logistic hypothesis than for the Gompertz hypothesis. In other words, in the later stages, the Gompertz rate of growth is more nearly constant than the logistic rate of growth.

A further observation on the difference between these two growth curves is in terms of the stage at which the maximum rate of growth is reached. Setting the derivative of (1) with respect to y equal to zero, one finds $y = e^{-1}y^* = .37 y^*$. Setting the derivative of (2) equal to zero, one finds $y = .5 y^*$. Hence, the maximum rate of growth is reached when the stock is about 37 per cent of its equilibrium level by the Gompertz curve, and when the stock is 50 per cent of equilibrium by the logistic curve. Since the rate of growth given by equation (2) is the same for y equal to $.5 y^* + k$ or to $.5 y^* - k$, the logistic curve is symmetrical. On the other hand, the Gompertz curve attains its maximum rate of growth at an earlier stage, and maintains a more nearly constant rate of growth later on, than the logistic curve.

There are two a priori reasons for choosing the Gompertz differential equation (1). According to a study of the growth of television sets in the United Kingdom by A. D. Bain [1], the growth curve is not symmetric as the logistic would imply, but the growth rate is higher at an early stage and declines gradually in later stages. The Gompertz curve possesses this characteristic; yet Bain has rejected it because it is too rigid, implying the maximum rate of growth to be at 37 per cent of equilibrium. We have no reason to reject the Gompertz in favor of the equally rigid logistic curve. In fact, rigidity is the cost we have to pay in choosing an equation with only one parameter.

The second reason for preferring the Gompertz differential equation is analytical convenience. We will approximate the derivative of $\log y$ by its difference $\log y_t - \log y_{t-1}$, and the existing stock y by y_{t-1} . (1) will then become

$$(3) \quad \log y_t - \log y_{t-1} = \alpha(\log y^* - \log y_{t-1}).$$

¹ Log always refers to natural logarithm in this paper.

If the equilibrium stock y^* is assumed to be a function of certain variables with constant elasticities, the right-hand side of (3) will be a linear function of the logarithms of these variables and of $\log y_{t-1}$. Unless we assume y^* to be a linear function of these variables, a similar transformation of (2) would be nonlinear and more difficult to analyze statistically.

Equation (3), with $\log y^*$ replaced by a linear function of the logarithms of certain variables affecting the equilibrium level, is familiar in econometrics. One wonders why this model has scarcely been applied, if at all, to the study of a new product. In another occasion [2], I pointed out the need to integrate the growth process with the comparative static theory of demand in the study of a new product. Why not let this model provide such an integration?

By the comparative static theory of the demand for input, two of the most important determinants are relative price p_t and the output x_t of the firms employing the input. In the case of a durable good, the quantity of the input used can be measured by the stock. Assuming constant elasticities, one can determine the equilibrium stock y^* by

$$(4) \quad \log y_t^* = \beta_0 - \beta_1 \log p_t + \beta_2 \log x_t$$

On substituting (4) for $\log y^*$ in (3), one obtains

$$(5) \quad \log y_t - \log y_{t-1} = \alpha\beta_0 - \alpha\beta_1 \log p_t + \alpha\beta_2 \log x_t - \alpha \log y_{t-1}$$

For any new product that one can think of, its price always declined, and the output of the industries employing the product in case it is an input, or the income of the consumers in case of a consumer good, always increased. It is only by allowing for the price and output effects explicitly that one can isolate the process of natural growth.

II. *Measurement of Quantity and Price of Computers*

In this study, we assume that all general-purpose digital computers can be grouped into one commodity. The quantity of a computer is measured by an estimate of what its monthly rental would have been if it had been introduced in 1960. To form such an estimate, we first establish a relationship between rental and the computer's basic characteristics for models introduced in 1960.

Three characteristics are chosen to establish the required relationship: multiplication time, memory size, and access time. Multiplication time is the average time required to get and complete the multiplication instruction, in microseconds. It should have a negative effect on rental. Addition time was considered instead, and has been found to be a slightly inferior variable. Memory size, in thousands of binary digits or equivalents, is the product of the number of words in the main memory

(in thousands) and the number of binary digits per word, with a decimal digit counting as four, and an octal digit counting as three, binary digits. It should assert a positive influence on rental. Access time is the average time required to retrieve information from the memory. Its effect on rental should be negative.

It is recognized that the hardware of a computer has many other characteristics, and that the characteristics of software support may be important. As far as the omitted characteristics of the hardware are concerned, it is assumed that they are highly correlated with the three included ones so that our estimate of the hypothetical 1960 rental would not be too inaccurate. Insofar as the software has been improving through time, its omission may be more serious. The only defense for this omission is to include software improvement as part of the adjustments allowed in reaching long-run equilibrium in our model.

The relationship between rental and the above-mentioned characteristics for models introduced in the same year is assumed to be linear in the logarithms of all variables. Our quantity index will be independent of the base year (the year chosen to establish this relationship) if the coefficients in the linear function are the same for different years. The intercept is expected to decline through time because the price of computers with the same characteristics has been declining. To examine how similar the coefficients are for different years, we have computed a regression for each year from 1955 to 1965. For each year beginning 1960, the number of new computer models introduced during the year is at least 10. For each year up to 1959, the number of new models is less than 10, and we have included models introduced in the preceding year. The main source of data on rental and computer characteristics is the three surveys by M. H. Weik [5]. A supplementary source is the June issue of *Computers and Automation*, in which a section entitled "Buyers Guide" contains the relevant information. From October 1962 on, *Computers and Automation* has included a "monthly computer census" in which data on average monthly rental can be found. We have relied on Weik's surveys as much as possible because they provide rental figures corresponding to different memory sizes available for the same computer model whereas *Computers and Automation* has only an "average rental" and a range for memory sizes.

The estimated coefficients (with standard errors in parentheses) of the regressions of rental on the three characteristics, all variables in logarithms, are presented in Table 1. Judging from the 11 cross section regressions for the individual years, memory size has a larger coefficient (in absolute value) than either access time or multiplication time. Three of the coefficients of multiplication time, and one coefficient of access time, have wrong signs, though they are small fractions of their

TABLE 1—RELATIONSHIP BETWEEN RENTAL AND COMPUTER CHARACTERISTICS
(All variables in logarithms)

| Year | Multiplication Time | Memory Size | Access Time | Intercept | R^2 s^2 | Number _i Observations |
|---------|----------------------------|----------------------------|----------------------------|----------------------------|---------------------------|-------------------------------------|
| 1955 | .0108 (.1021) | .4297 (.1530) | -.2895 (.0618) | 2.027 | .947 .0461 | 9 |
| 1956 | -.0505 (.1911) | .4495 (.1624) | -.1991 (.1076) | 1.675 | .890 .2081 | 11 |

| 1965 | -.0411 (.0779) | .5778 (.0821) | -.1465 (.0999) | -1.354 | .877 .2518 | 16 |
| 1960-65 | -.0654 (.0284) | .5793 (.0354) | -.1406 (.0293) | -.1045 | .908 .1476 | 82 |
| | -.1398 d_{61} (.1665) | -.4891 d_{62} (.1738) | -.5938 d_{63} (.1661) | -.9248 d_{64} (.1663) | -1.163 d_{65} (.166) | |

standard errors. While the standard errors are large for many coefficients, as a result of the high correlations among the three explanatory variables and of the small sample sizes, the orders of magnitude of the three coefficients do not appear to have changed drastically through time. Note also that the intercept tends to be smaller for later years, but its decline is far from being uniform.

We have decided to pool the data from 1960 on, assuming unchanging coefficients but introducing a dummy variable d_i for each year beginning 1961 to allow for change in the intercept. The estimated regression is

presented in the bottom of Table 1. All three coefficients are highly significant, in spite of the strong correlations among the explanatory variables. The proportional effects of multiplication time, memory size, and access time on rental are about -7 per cent, 58 per cent, and -14 per cent respectively. The coefficient of the dummy variable is decreasing uniformly, reflecting the price decline.

If one were to test the null hypothesis that the three coefficients have remained the same from 1960 to 1965, he would compute the sum of squares A of the residuals in the pooled regression, with 73 degrees of freedom, and the sum of squares B of the residuals in the six individual regressions, with 58 degrees of freedom. Under the null hypothesis, together with the assumption that the residuals in the individual regressions are normally distributed with the same variance, the ratio of $(A-B)/15$ to $B/58$ would be distributed as the F distribution with 15 and 58 degrees of freedom. From our calculations, A is 10.77 and B is 9.04. The F statistic is only .74, strongly supporting the null hypothesis. Therefore, we will use the coefficients obtained by the pooled regression, with $-.1045$ as the intercept for 1960, in the estimation of the hypothetical 1960 rental for each computer model. The quantity index so constructed is independent of the base year chosen, at least from 1960 to 1965; it would hardly be affected even if a year in the 1950s were chosen as the base year, in view of the temporal stability of the coefficients in Table 1.

The computer models included in our quantity index are those listed in the "monthly computer census" of *Computers and Automation*; they are U.S.-made general-purpose digital computers only, and exclude certain very small models that are not internally programmed, notably IBM 604, 607-610, and CPC. The author has used IBM data, where available, on the number of IBM (domestic) installations as of December each year. For installation figures of other models, he has relied on *Computers and Automation* and the *Automatic Data Processing Newsletter*, published by the Diebold Group, Inc.² The quantity index,

² The earliest time period for which even sketchy information on numbers of computer installations can be found is December, 1954. See [6, March 1955, p. 30] [6, Feb. 1955, pp. 23-29] [6, April 1955, p. 41]. Data for approximately November 1955 can be found in the first survey of Weik [5]. Data as of September 1956 are available from the Diebold *Newsletter*, reprinted in [6, Dec. 1956, p. 27]. For February 1958, see the Diebold *Newsletter*, March 3, 1958 or in reprint in [6, May 1958, pp. 8-9]. From 1958 on, December figures can be found in Diebold's *Newsletter*, reprinted in [6], up to 1961. From October 1962 on, *Computers and Automation* has published its own "monthly computer census" giving installation figures for the preceding month, presumably including installations of American-made computers outside the United States while the Diebold figures do not.

We have estimated December figures for 1955, 1956, and 1957 by logarithmic interpolations, performed separately on individual makes, and based on the above-mentioned data. The Diebold figures were used from 1962 on, but the *Computers and Automation* figures are almost identical. We have presented the quantity index using the former source, noting that the latter source has given almost the same results.

in thousands of dollars of estimated 1960 monthly rental, is presented in Table 2.

To measure the price, per fixed quantity, for each computer model, one simply takes the ratio of its rental to its quantity, the latter being measured by its hypothetical 1960 rental as described. To obtain a price index number for a given year, one may average the prices over all models currently introduced. Some weighted average was considered, but it was not easy to decide on the weights. An obvious possibility would be to use the quantity (measured in our sense) of the installations as of December of each year, but this weight would depend too much on the date when the model was first introduced. In principle, one could

TABLE 2—QUANTITY, PRICE AND RELATED DATA ON THE DEMAND FOR COMPUTERS

| Year | Quantity (thousands of 1960 rentals) | $\frac{\text{Quantity}_t}{\text{Quantity}_{t-1}}$ | Absolute Price Index | GNP Deflator | GNP (billions of 1958 dollars) |
|------|---|---|----------------------------|-----------------|---|
| 1954 | 370.26 | | 3.2554 | .896 | |
| 1955 | 991.67 | 2.678 | 2.9610 | .909 | 438.0 |
| 1956 | 2389.9 | 2.410 | 2.5336 | .940 | 446.1 |

| 1958 | 8362.0 | 1.644 | 2.0342 | 1.000 | 447.3 |
| 1959 | 12549. | 1.501 | 1.5884 | 1.016 | 475.9 |
| 1960 | 19072. | 1.520 | 1.0716 | 1.033 | 487.8 |
| 1961 | 38264. | 2.006 | .9042 | 1.046 | 497.3 |
| 1962 | 64349. | 1.682 | .6873 | 1.057 | 530.0 |
| 1963 | 95815. | 1.489 | .5712 | 1.071 | 550.0 |
| 1964 | 136845. | 1.428 | .4186 | 1.089 | 577.6 |
| 1965 | 194136. | 1.419 | .3416 | 1.109 | 614.4 |

use the quantity as of a fixed period after the first installation, but such quantity data are difficult to obtain. Furthermore, a weighted mean, when the weights are highly uneven, is subject to much larger sampling error than an unweighted mean, something which we can ill afford in view of the sizable errors in estimating price and the small numbers of observations revealed in the individual regressions of Table 1.

Another alternative to the simple arithmetic mean is the geometric mean. In fact, the logarithm of the geometric mean from 1961 on has already been calculated in Table 1; it is the coefficient of the dummy variable for the corresponding year. We have constructed the geometric mean price index for the entire sample period, and have found the results to be virtually identical with those obtained by employing the simple arithmetic mean presented in Table 2. Note, incidentally, that while the geometric mean equals one for the base year 1960, the arithmetic mean is slightly above one.

Now that we have explained and presented the quantity and price indexes, the magnitudes of their errors should be noted. After examining installation figures from different sources, the author would not be too surprised to find an error, in our aggregate quantity index, to be as large as 10 per cent for some year after 1956, or as large as 15 per cent for an earlier year. Of course, if our sources consistently over- or underestimate the installation figures by the same percentage, it does not matter for our analyses of the proportional rate of growth, but we cannot be sure of this.

As far as the price index is concerned, assuming that the error of observation on actual rental is unbiased, one can get an upper bound on its standard error by noting the standard errors of the logarithms of the geometric mean index, i.e., of the coefficients of the dummy variables in the pooled regression of Table 1. A standard error of .17 means that the percentage error of the geometric mean is approximately 18 per cent. This estimate of the standard error is too high for our purpose, because it has included the variations of the price-quantity ratios for the same year due to different firms' pricing policies. Conceptually our index is the (population) mean of the prices (per fixed quantity) of the models introduced in a given year. The variations in these prices, alone, should not produce an error in our index.

III. *Statistical Analyses*

With the quantity and price indexes at our disposal, we would like to raise three empirical questions. First, without explicitly accounting for the change in equilibrium stock, is the growth pattern closer to the Gompertz hypothesis or to the logistic hypothesis? Second, do the data support the notion of a moving equilibrium, due mainly to the drastic price reduction, and, if so, how large is the price elasticity of equilibrium demand? Third, can we measure the output effect on equilibrium stock?

The answer to the first question is obvious from the data. A plot of the logarithm of the ratio y_t/y_{t-1} (a ratio exhibited in Table 2) against $\log y_{t-1}$ is much closer to a linear function, as the Gompertz hypothesis implies, than against y_{t-1} , as the logistic hypothesis would imply. If one were to insist on a linear relation between $\log (y_t/y_{t-1})$ and y_{t-1} , he would have to stop in 1959. Unless one is willing to use two models, one for initial growth and another based on the theory of comparative statics, there seems to be no way of maintaining the logistic hypothesis. But it is precisely the purpose of this study to integrate both elements into one model.

To answer the second question, pursuing the Gompertz hypothesis further, we examine the partial effects of price on $\log (y_t/y_{t-1})$, given $\log y_{t-1}$. This amounts to performing a regression of $\log (y_t/y_{t-1})$ on

both $\log p_t$ and $\log y_{t-1}$. The price variable p_t used is the relative price, obtained by deflating our absolute price index by the GNP deflator.³ The result of the regression, using 11 annual observations from 1955 to 1965, is

$$(6) \quad \log (y_t/y_{t-1}) = - .3637 \log p_t - .2526 \log y_{t-1} + 2.950$$

(.1726) (.0739)

$$R^2 = .834$$

$$s^2 = .0104$$

The coefficient of $\log p$ is negative, as expected. The ratio of the estimated coefficient to its standard error is -2.107 . The null hypothesis of no price effect, against the one-sided alternative hypothesis of a negative price effect, would be rejected at the 5 per cent level where the critical value of the t ratio is -1.860 , but would not be rejected at the 2.5 per cent level, where the critical t value is -2.306 . Since there are only 8 degrees of freedom, the power of the t test is low. Under this circumstance, the rejection of the null hypothesis tends to give strong support for the negative price effect. The Durbin-Watson statistic is 1.77, consistent with no serial correlation in the regression residuals.⁴

A point estimate of the price elasticity of demand for equilibrium stock can be obtained as the ratio of the two coefficients in equation (6). It is 1.44. Partly because of our small sample size and the high correlation between the two explanatory variables, the standard error of the price coefficient is large, being almost half of the coefficient itself. However, the ratio between the two coefficients is subject to smaller error than the former coefficient by itself, because the two coefficients are positively correlated. A 60 per cent confidence interval for the ratio is $1.379 \pm .274$, and an 80 per cent confidence interval is $1.326 \pm .382$.⁵ The parameter α of the Gompertz difference equation is about .253, with a standard error of .074.

In Figure 1, $\log (y_t/y_{t-1})$ is plotted against time t , together with its

³ The GNP deflator is found in [7, Aug. 1965, p. 53, and July 1966, p. 38].

⁴ Since $\log y_{t-1}$ is a regressor, the power of the Durbin-Watson test is low; one could get a D-W statistic close to 2 even if there were positive serial correlation.

⁵ To obtain an interval estimate of the ratio between two regression coefficients b_1 and b_2 , form the linear combination $b_1 - zb_2$, where z is yet to be determined. This linear combination has a variance equal to $\text{var } b_1 + z^2 \text{ var } b_2 - 2z \text{ cov}(b_1, b_2)$, which, as estimated by our data, is $.02979 + .005463z^2 - .02484z$. If z is the true ratio, this linear combination would have mean zero. The probability is 60 per cent that the sample value of this linear combination is within .889 times its standard deviation, where .889 is obtained from the t table. Thus

$$(.3637 - .2526z)^2 < (.889)^2 (.02979 + .005463z^2 - .02484z)$$

with probability .60. Treating the above as a quadratic equation of z , we find $z = 1.379 \pm .274$. Replacing .889 by 1.397, we obtain an 80 per cent confidence interval for z , namely, $1.326 \pm .382$. This method is described in Fisher [4, pp. 143-44].

FIGURE 1

estimated value by equation (6). The general pattern of the rate of growth appears to have been explained fairly satisfactorily. However, the model underestimates, by a fairly sizable margin, the local peak in the rate of growth that occurred in 1961. That was the year when the "first-generation" computers using vacuum tubes were changed to the "second-generation" solid-state computers, a transition which had begun in 1960. Possibly, the excess of orders over actual deliveries of the new IBM 360 systems in 1965 could account for the difference between the observed and the estimated rate of growth in that year.

Just to be sure that the logistic difference equation cannot be salvaged by allowing the price effect on the equilibrium level, we have regressed $\log(y_t/y_{t-1})$ on $p_t^{-\beta}$ and y_{t-1} , assuming a constant elasticity of equilibrium demand. The regression, being not linear in p_t , can be estimated by trying different values for β to maximize the multiple correlation, or to minimize the standard error of the regression. Table 3 shows the regression results for different values of β . For small values of β , the

TABLE 3—REGRESSIONS BASED ON LOGISTIC GROWTH FOR DIFFERENT VALUES OF PRICE ELASTICITIES

| Elasticity β | Coefficient of $p_t^{-\beta}$ | Coefficient of $y_{t-1}(10^5)$ | R^2 | Durbin-Watson Statistic |
|-----------------------|----------------------------------|-----------------------------------|-------|----------------------------|
| .50 | -.7103 (.3999) | .3244 (.3736) | .563 | 1.000 |
| 1.00 | -.4259 (.3339) | .6571 (.7212) | .505 | .990 |
| 1.50 | -.0588 (.4144) | -.0669 (1.698) | .392 | .743 |
| 2.00 | .1498 (.1361) | 1.408 (1.008) | .471 | .726 |
| 2.50 | .0544 (.0459) | -1.012 (.608) | .482 | .739 |
| 3.00 | .0220 (.0193) | -.8078 (.4562) | .476 | .737 |
| 4.00 | .0047 (.0044) | -.6318 (.3348) | .464 | .730 |
| -1.00 | .1825 (.0638) | -.00087 (.1433) | .699 | 1.193 |

coefficients of both $p_t^{-\beta}$ and y_{t-1} have wrong signs, but the multiple correlation is higher than for larger values of β . If we ignore the calculations for β below 1, the best R^2 is obtained when β is approximately 2.50, in which case both coefficients have the correct signs, but the goodness of fit is much worse than equation (6) based on the Gompertz hypothesis. If one assumes the equilibrium stock to be a linear function of price, he will improve the R^2 , but find a price effect in the wrong direction and the stock effect absent, as shown in the last row of Table 3. The most acceptable fit based on the logistic model, or the least unacceptable fit, is for a constant price elasticity of 2.50. Its residuals are much larger than those of the Gompertz model (6), and it fails to trace the pattern of the rate of growth, as the dotted line in Figure 1 shows.

The remaining task is to measure the output effect on the equilibrium demand for computers. Practically all industries employ the services of some computers, although in varying degrees.⁶ Ideally, one should weigh the outputs of different industries by the corresponding output elasticities of demand. However, a simple aggregate of output, such as the Gross National Product, would suffice if the relative contributions of

⁶ For an estimate of the distribution of the value of computer installations by industry, see the market report appearing in [6, Nov. 1966, p. 16].

different industries remain approximately the same. One could even tolerate the relative gains of some industries, at the expense of others, if the former, as a group, have the same output elasticity as the latter. If the gaining industries had higher output elasticities than the losing industries, the growth of GNP would be smaller than the growth of the weighted output.

Adding GNP, in billions of 1958 dollars,⁷ as an additional variable in equation (6), we obtain

$$(7) \quad \log (y_t/y_{t-1}) = -.5924 \log p_t - 1.160 \log \text{GNP} - .2828 \log y_{t-1} + 10.45$$

(.4056) (1.845) (.0906)

with an R^2 of .843. The coefficient of $\log \text{GNP}$ has the wrong sign, but is very insignificant. The inclusion of this additional variable, which is highly correlated with price, also affects our estimate of the price coefficient. From the data, we have failed to measure the separate effect of output. Furthermore, there is the possibility that the omission of an output variable in equation (6) might seriously bias our estimation of the price effect.

To examine this possibility, we assume that the output coefficient equals two times the negative of the price coefficient, and employ the combined variable $\log p - 2 \log \text{GNP}$ to replace $\log p$ in the regression. The result is

$$(8) \quad \log (y_t/y_{t-1}) = -.2448 (\log p_t - 2 \log \text{GNP}_t) - .2306 \log y_{t-1} - .0306$$

(.1260) (.0689)

$$R^2 = .824$$

$$s^2 = .0110$$

This regression explains the dependent variable almost as well as equation (6). The ratio of the coefficients is 1.062, a little smaller than in equation (6). Since output has been increasing, while price has been declining, part of the growth attributed to the price effect in equation (6) may be due to the output effect. In other words, equation (6) may overestimate the price effect. However, the rate of price reduction has been much greater than the rate of output increase. Even if the output effect were twice as big as the price effect, as we have assumed in the calculation, it could only take away a small fraction of the effect attributed to price in equation (6). Thus, while we have not been able to measure the output elasticity, this failure would not seriously affect our estimation of the price elasticity even if the output effect were present.

Technological change in the computer industry is a very complicated phenomenon. We have not dealt with its causes. Neither have we dealt

⁷ GNP in billions of 1958 dollars is found in [7, Aug. 1965, p. 27, and July 1966, p. 11].

with many interesting aspects of its consequences, such as the adjustments of the management and production processes. Only one aspect of its consequences, namely, the effect on demand, has been studied in this paper. This limited objective is achieved by employing a univariate measurement of technological change from the viewpoint of demand, namely, the measurement of price reduction. Even with this limited objective, it has been necessary to measure the quantity of computers in constant dollars, to construct a price index, and to formulate a theory of demand applicable to a new product while preserving the elements of comparative statics.

As matters of historical facts, we have found the stock of computers growing by more than 100 per cent per year between 1954 and 1957, and by more than 40 per cent per year between 1962 and 1965, averaging to about 78 per cent from 1954 to 1965. During the same period the relative price of computers has declined by 20 per cent per year, on the average. On the theoretical side, we have found that the Gompertz difference equation, modified by a moving equilibrium due to the comparative statics of price change, can explain the rate of growth for this new commodity, and is much better than the logistic difference equation. The price elasticity of equilibrium demand is somewhat over unity, the growth parameter of the Gompertz difference equation is about one quarter, but no output elasticity has been successfully estimated.

INTEREST RATES AND THE DEMAND FOR CONSUMER DURABLE GOODS

By MICHAEL J. HAMBURGER*

The purpose of this paper is to examine the effects of monetary variables on the demand for consumer durable goods. Since the publication of Keynes' *General Theory*, it has generally been assumed that consumption is insensitive to interest rates. Consequently, the only monetary variable that has been included in the consumption function with any regularity has been liquid assets. The view taken here is that monetary variables have a significant effect on consumer purchases of durable goods and that the most appropriate measures of these variables are interest rates. Other measures which will be considered are the monetary base, the aggregate money supply, the rate of change in the money supply, and the consumer stock of liquid assets. If the results support the hypothesis, they would (1) cast considerable doubt on the widely accepted notion that consumers do not respond to changes in interest rates,¹ and (2) provide an alternative to both the Keynesian and the Chicago views concerning the channels through which monetary policy operates. Contrary to the Keynesian income-expenditure approach, they would imply that monetary policy has a direct effect on consumer behavior. They would also suggest, however, that for the consumer sector of the economy the interest rate effects of monetary policy are more important than the "monetary" effects.

Section I presents a model to explain the quarterly movements in two major components of consumer durable goods: automobiles and parts, and all others. (The most important items included in the latter are furniture and household equipment.) In Section II the model is subjected to empirical test. The data used are quarterly observations of the variables for the period 1953-64. Section III tests for differences in the

* The author is economist, Federal Reserve Bank of New York. While he alone takes responsibility for this paper, he acknowledges debt to David M. Jones for valuable discussion and to Maurice Mann for his encouragement and helpful comments. The suggestions made by Richard G. Davis and Allan H. Meltzer and the excellent assistance of Cynthia M. Latta have contributed to the paper. Useful comments on an earlier draft were received from members of the Monetary Workshop, Columbia University, and from members of the Federal Reserve System Committee on Financial Analysis.

¹ Despite its general acceptance there is very little empirical evidence to confirm the proposition that consumption is independent of interest rates. The only studies that have come to my attention in which interest rates are considered as explanatory variables in the consumption function are Liu [27] and deLeeuw [8]. Liu's results (which are not shown in his article) tend to support the received theory; deLeeuw's suggest that interest rates are significant and that they operate with a long lag. Two recent studies in which interest rates are conspicuously absent from the consumption function are Goldfeld [17] and Evans and Kisselgoff [10].

results when alternative formulations of the equations are employed. The implications of the results for monetary and macroeconomic theory are discussed in the concluding section.

I. *Consumer Demand for Durable Goods*

Our model of the demand for consumer durable goods may be expressed as follows. First, let the desired aggregate stock of any given physical asset (\bar{A}) be a linear function of Y , aggregate income valued in constant prices, r , a vector of yields on financial assets and liabilities, and P , the price of the asset relative to the prices of all other goods and services purchased by consumers. That is,

$$(1) \quad \bar{A} = a + bY + cr + dP$$

where the parameters b , c , and d denote the long-run effects of the independent variables on the desired stock. Except for the inclusion of r , this formulation of the demand function for consumer durable goods is similar to those that have been used elsewhere.²

Second, purchases of the asset during period t (X_t) are defined as the sum of consumption (or depreciation, D_t) and net investment (ΔA_t):

$$(2) \quad X_t \equiv D_t + \Delta A_t$$

where it is assumed that

$$(3) \quad \Delta A_t = \theta(\bar{A}_t - A_{t-1}); \quad 0 \leq \theta \leq 1,$$

and

$$(4) \quad D_t = e_1 X_t + e_2 A_{t-1}.$$

A_t denotes the existing stock of the asset at the end of the t^{th} period. Equation (3) is a standard stock adjustment relationship where θ is the reaction coefficient. It measures the percentage of the adjustment that consumers make towards equating their actual and desired asset balances during any time period. It is assumed that (a) the response patterns associated with each of the explanatory variables may be described by a simple decay function, and (b) the parameters associated with these functions are identical.

² See, for example, Atkinson [3], Burstein [4], Chow [6], Fromm and Klein [16], Roos and von Szeliski [31], and Stone and Rowe [35]. Three variables that are not introduced explicitly into the model are the expected rate of change in the price level, population and nonhuman wealth. The exclusion of wealth is one of the more important limitations of this study. Its omission is almost certain to introduce some bias into the estimates of the income coefficients. The variable is not included because of the difficulties involved in measurement. For a discussion of these and other problems, see Hamburger [18] and Johnson [19]. It may also be mentioned that a more appropriate measure than the relative price variable used here would be a vector of the implicit yields on consumer durables. The typical element in the vector would be the price of the services of a unit of a durable good as a ratio to the price of a unit of the good. At the present time these variables cannot be measured—and even conceptually the absence of a market for the services of many consumer durables presents serious difficulties.

The model described above may be modified slightly by allowing the adjustment process to begin at different time periods for the various independent variables. This is done by introducing lagged values of the variables on the right-hand side of equation (1), i.e.,

$$\bar{A}_t = a + bY_{t-n_1} + cY_{t-n_2} + dP_{t-n_3}$$

or alternatively

$$(1') \quad \bar{A}_t = a + bY_{t^*} + cY_{t^*} + dP_{t^*}$$

where the n 's indicate the lags associated with the independent variables and t^* is used as a shorthand device for $(t-n_1)$, $(t-n_2)$ and $(t-n_3)$. The values of t^* will generally not be the same. For nonzero values of n_1 , n_2 , and n_3 , equations (1') and (3) imply that the adjustment of expenditures to changes in the explanatory variables is negligible for some initial time period, then rises abruptly to its maximum, and declines geometrically thereafter. Of course, actual expenditures, even if lagged, would probably not start off at their peak response but are more likely to build up gradually to the peak and then taper off. Hence, the adjustment pattern used here may be overly restrictive. However, in view of our interest in assessing the effects of monetary variables on the demand for consumer durable goods this pattern seems to provide a reasonable first approximation.³

Equation (4) suggests that depreciation is a constant percentage, e_2 , of the existing stock plus some percentage, e_1 , of current purchases. At least two views may be identified concerning the relative values of e_1 and e_2 . Stone and Rowe [35] assume that (a) the rate of depreciation for any particular asset is constant throughout its life, and (b) current purchases are distributed evenly during the period of observation. From these assumptions they derive the equation

$$(5) \quad e_1^{SR} = 1 + \frac{e_2}{\ln(1 - e_2)}.$$

Equation (5) implies that, for aggregate analysis, the rate of depreciation on current purchases is approximately one-half the rate on the existing stock.⁴ Other students of consumer durable goods have ob-

³ For more general treatments of the distributed lag model, see Almon [1], Hamburger [18], Jorgenson [21], and Solow [34].

⁴ The following table provides some illustrative values of e_1^{SR} and the annual rate of depreciation on the existing stock (e_2^A) for various values of e_2 .

| e_2 | e_2^A | e_1^{SR} |
|-------|---------|------------|
| .04 | .1507 | .0203 |
| .08 | .2836 | .0407 |
| .12 | .4003 | .0613 |
| .16 | .5021 | .0824 |

The values of e_2^A are derived from the formula $e_2^A = 1 - (1 - e_2)$.⁴

jected to the first of Stone's and Rowe's assumptions. They argue that some durable goods, particularly automobiles, depreciate much faster during the quarter in which they are purchased than they do during subsequent periods. If this is correct, e_1^{SR} would serve as a lower bound for e_1 . One of the desirable features of the approach taken here is that many of the important parameters of the model may be estimated without making any assumptions about the absolute or relative values of e_1 and e_2 . To show this, we proceed with the development of our estimating equation. The objective is to eliminate those variables that are not readily observable— A_t , \bar{A}_t , and D_t .

Substitution of equations (3) and (4) into (2) yields

$$(6) \quad X_t = \theta(\bar{A}_t - A_{t-1}) + e_1 X_t + e_2 A_{t-1}$$

which after some algebraic manipulation becomes

$$(7) \quad X_t = [\theta \bar{A}_t - (\theta - e_2) A_{t-1}] / (1 - e_1).$$

Replacement of \bar{A}_t by its determinants and the use of a transformation suggested by Nerlove [29] yields

$$(8') \quad \begin{aligned} X_t = & \frac{a\theta}{1 - e_1} + \frac{b\theta}{1 - e_1} [Y_{t*} - (1 - e_2) Y_{t*-1}] \\ & + \frac{c\theta}{1 - e_1} [r_{t*} - (1 - e_2) r_{t*-1}] \\ & + \frac{d\theta}{1 - e_1} [P_{t*} - (1 - e_2) P_{t*-1}] + (1 - \theta) X_{t-1} \end{aligned}$$

or, more simply,

$$(8) \quad \begin{aligned} X_t = & a' + b' [Y_{t*} - (1 - e_2) Y_{t*-1}] + c' [r_{t*} - (1 - e_2) r_{t*-1}] \\ & + d' [P_{t*} - (1 - e_2) P_{t*-1}] + (1 - \theta) X_{t-1} + v_t \end{aligned}$$

where the residual term v_t has been added and the relationship between the two sets of constants may be expressed as

$$(9) \quad z' = \frac{z\theta}{1 - e_1}; \quad z = a, b, c, d.$$

The parameters with prime superscripts denote the short-run effects of the exogenous variables on current purchases. According to equation (8), the latter are related to weighted differences of the exogenous variables and to lagged purchases.⁵

⁵ It is well known that the inclusion of the lagged dependent variable on the right-hand side of a regression equation may lead to biases in the parameter estimates if the residuals are serially correlated. Moreover, biases may arise as a result of the treatment of Y , P , and r as exogenous variables. It seems unlikely, however, that corrections for these biases would alter any of the major conclusions reached in this paper.

As indicated above, the model summarized by equation (8) embodies a slightly modified version of the standard "stock adjustment" assumptions. Two other differences between the specification used here and the usual formulation of the stock adjustment equations for durable goods are worth noting. First, equation (8) explicitly recognizes the rate of depreciation on current purchases, which is generally ignored in other treatments (see Evans and Kisselgoff [10], Burstein [4], and Chow [6]). Second, the use of weighted differences of the explanatory variables as opposed to the levels of the variables tends to reduce the amount of multicollinearity which might otherwise be present.

If e_2 and the lags associated with the independent variables were known, or could be assumed, least squares estimates of a' , b' , c' , d' , and θ [the coefficients in equation (8)] could be obtained. However, these parameters are not known. Consequently, an iterative estimation procedure is employed. It can be shown (Nerlove [29]) that if the residuals in equation (8) are normally and independently distributed, the technique yields maximum likelihood estimates for each of the coefficients that can be separately identified.⁶ The procedure is as follows: (a) Compute the weighted differences of the exogeneous variables for each of a number of values of e_2 and the lags associated with the independent variables. (b) For each of these values compute the least squares regression of X_t on the weighted differences of the independent variables and X_{t-1} . (c) Find the maximum of R^2 with respect to e_2 and the lags associated with the independent variables. The values of these parameters at the maximum and the values of the other coefficients, given the values of the former, are the maximum likelihood estimates.

To complete the development of the model, it is necessary to provide operational definitions of the variables. These are given in the appendix. Here we consider some of the characteristics of the interest rate variables employed in the study. The interest rate vector r is defined to include the following components: r_{SV} , the yield on savings accounts (a weighted average of the rates paid on savings and loan shares, mutual savings bank deposits, and time and savings deposits at member banks of the Federal Reserve System); and r_{FS} , the yield on financial securities, measured alternatively as r_{Aaa} , Moody's A_{aa} rate on long-term corporate bonds, and r_{FCP} , the yield on directly placed three-to-six-month finance company paper. The estimates of r_{FS} have two functions. They serve as measures of the yields available on marketable financial assets and, perhaps more important, the rates paid for borrowed funds by the suppliers of consumer credit—that is, as proxy variables for the rates that households pay for consumer credit.

⁶ Since e_1 and the long-run stock coefficients (a , b , c and d) always appear in combination [see equation (8')], it is impossible to obtain separate estimates for them, unless some assumption is made about e_1 .

Note: The data for all variables except interest rates are adjusted for seasonal variation.

The numbers in square brackets denote the lags associated with the independent variables.

The Durbin-Watson statistics for the automobile and other durables equations are 1.25 and 2.09, respectively.

^a The quarterly estimate from which this statistic is derived was estimated within an interval of $\pm .01$.

II. A Test of the Model

The empirical analysis of the demand for consumer durable goods is presented in two parts. This section examines the properties of the model developed above. In Section III we investigate a number of alternatives.

Table 1 reports the results obtained when expenditures on automobiles and parts and on other durable goods (in 1958 dollars) are regressed against lagged expenditures and weighted differences of real disposable personal income, the yield on savings accounts, the yield on *Aaa* rated long-term corporate bonds, and relative price.⁷ The price data are the implicit deflators provided by the Department of Commerce. The symbol e_2^A denotes the estimated annual rate of depreciation on the existing asset stock. The numbers in square brackets are the lags associated with the independent variables, indicating the number of quarters which elapse between changes in the independent variables and the peak adjustments in expenditures. \bar{R}^2 is the squared multiple correlation coefficient adjusted for degrees of freedom; S is the adjusted standard error of the regression; and R_P is the partial correlation between the dependent variable and the "economic" (or exogenous) variables in our model, given the prior effects of the dependent variable lagged one period.⁸

⁷ An alternative measure of income is provided by Friedman's permanent income variable (Friedman [14]). This measure is generally introduced into a regression equation to allow for a lag in the adjustment of the dependent variable in response to fluctuations in income. In the present study this lag is taken into account through the introduction of the lagged value of the dependent variable.

⁸ Partial correlation is defined as the square root of the proportion of residual variation ex-

The statistical fit of the model is obviously close. First, almost all of the regression coefficients have the proper sign and are at least twice their standard errors. The only exception is the coefficient for the yield on savings accounts in the automobile equation, which has the proper sign but is not statistically significant (at the .05 level). Second, the estimates of the partial correlation coefficients (R_P) suggest that after the prior effects of the lagged dependent variable have been taken into account, the remaining variables explain approximately 53 per cent of the variance in the expenditures on automobiles and approximately 66 per cent of the variance in other durables. Third, the independent variables in the two equations are almost identical. Previous observers have not obtained this result. Generally, the only variables that the two equations have in common are income and possibly the lagged dependent variable (or lagged stock).⁹ Thus, the inclusion of interest rates in the analysis seems to yield a more general explanation of consumer investment behavior than that provided by previous treatments.

Finally, the acceptability of the model may be evaluated by examining the annual rates of depreciation on existing asset stocks. For automobiles, the estimated rate of 28 per cent is within the range implied by the behavior of prices in the used car market (see Chow [6] and Friedman [13]). For other durables the estimated rate seems high. However, the difference between this rate and the one for automobiles is not statistically significant. The probability that the "true" rate of depreciation for other durables is the same as the rate on automobiles is greater than 30 per cent.¹⁰

We turn next to the effects of the independent variables. Of particular

plained. Thus,

$$R_P = \left[\frac{S_D^2 - S^2}{S_D^2} \right]^{1/2}$$

where S_D^2 is the sum of squared residuals for the regression of the dependent variable on its lagged value and S^2 is the sum of squared residuals for the regressions shown in Table 1.

One of the principal limitations of the iterative estimation procedure is that the parameter estimates are complicated functions of the observations on the variables; hence, the usual tests for the statistical significance of individual parameters are not strictly appropriate. Nerlove [28] has shown that it is possible to test practically any point hypothesis by means of the likelihood ratio test. This test is used to answer a number of questions concerning the values of e_2 and when there is some question about the statistical significance of the regression coefficients. For the most part, though, we rely on conditional t -statistics for the regression coefficients, given the estimated values of e_2 and the lags associated with the independent variables. These statistics are derived by adjusting the standard errors computed from the equations for the loss in degrees of freedom resulting from the estimation of e_2 . No adjustment is made for the introduction of the lags, since the estimation of these parameters was not pursued intensively.

⁹ See Atkinson [3], Liebenberg, Hirsch and Popkin [26], Fromm and Klein [16], Suits and Sparks [37], and Evans and Kisselgoff [10].

¹⁰ These statements are based on the application of the likelihood ratio test discussed in *n.8*. The probability that the true value of either of the depreciation rates is zero is less than .05.

concern are interest rates. However, before discussing them, it seems appropriate to point out two of the similarities between our income and price results and those reported in other studies. First, the estimates of the new purchase elasticities for automobiles with respect to income and relative price (see Table 2) correspond very closely to those obtained by Roos and von Szeliski [31], Atkinson [3], Chow [6], and Suits [36] (Table 3). The results suggest that income has a greater effect on automobile expenditures than relative price and that the difference between the effects has grown with time.¹¹ Second, changes in income appear to

have a greater effect on new car purchases than on the purchases of other durable goods, but with a slightly longer lag. This suggests that consumers begin the adjustment in their expenditures on other durables during the quarter in which there is a change in income, but do not begin the adjustment in their automobile expenditures until one quarter later. Thus, the results support the view that consumers spend more time planning their larger expenditures than their smaller ones.¹²

¹¹ The similarities between our results for the automobile equation and those shown in Table 3, which are based on annual observations, also provide some support for the use of seasonally adjusted data. The use of this data has recently come under question (see Jorgenson [20] and Nerlove [30]). An alternative procedure, which has been employed by Goldfeld [17] and others, is to use unadjusted data and seasonal dummy variables.

¹² Evidence derived from interview studies is presented in Ferber [11], [12] and Katona and

For interest rates, there are several points that warrant comment. To begin with, the new purchase elasticity for automobiles with respect to the yield on *Aaa* rated corporate bonds is three-fourths of the elasticity with respect to price and approximately one-fifth of the elasticity with respect to income. For other durables, the effects of interest rates are more important. The sum of the elasticities with respect to the yield on bonds and savings accounts is more than 30 per cent of the elasticity with respect to either income or relative price. This plus the statistical significance of the variables clearly indicates the importance of interest rates as determinants of the demand for consumer durable goods.

The lags associated with the yield on bonds are also of interest. A strict interpretation of the results suggests that it takes between four and six quarters for changes in bond yields to have their maximum effect on consumer expenditures on durable goods. After that, the intensity of the response declines exponentially.¹³ The length of these lags relative to those associated with the other independent variables suggests that r_{Aaa} is acting primarily as a proxy for the rates charged on consumer credit, rather than as a measure of the yields available on marketable financial assets. If this is the case, it follows that (a) marketable financial assets are relatively poor substitutes for consumer durable goods, and (b) the estimated lags may be more appropriately viewed as estimates of the reaction times of the suppliers of consumer credit than those of consumers. That is, they serve as indicators of the speed with which the rates charged on consumer credit adjust to changes in open-market rates.

Direct evidence on the relationship between open-market rates and new-auto finance rates is reported by Shay [32], [33]. He finds that

Mueller [23]. Leaving aside the question of the initial lag, we note that the coefficients of the lagged dependent variables ($1-\theta$) suggest that the adjustment of the actual stock of automobiles to its desired level is accomplished more quickly than the adjustment for other durables. In addition, if the income coefficients in the two equations are divided by the adjustment coefficients, the long-run effects of income on the desired stocks of automobiles and other durables are practically the same. The estimates of these effects are $.69(1-e_1)$ and $.76(1-e_1)$, respectively (see equation 9).

¹³ While this adjustment pattern is not what we would have expected, it is similar to those obtained in two recent studies of business investment expenditures by Jorgenson [21] and Fromm and Klein [16]. In Jorgenson's study expenditures on plant and equipment are disaggregated on the basis of four major industrial classifications: durable manufactures, nondurable manufactures, regulated industries, and all other industries included in the OBE-SEC Investment Survey. The results indicate that for three of the groups the first noticeable effects on expenditures do not occur until three to six quarters after there is a change in the independent variables. In each case, the peak response occurs one quarter later and thereafter the intensity of the response declines at something which very quickly approaches a constant rate. Fromm and Klein use the same classifications and obtain similar results. They find that for two of the classifications both the initial and the peak response to changes in interest rates occur after a lag of five quarters.

(1) the rates are positively correlated, and (2) during the period 1954–59 the yield on *Aaa* rated corporate bonds moved more promptly at business cycle turns than new-auto finance rates. Although the data are not sufficiently numerous to permit a detailed analysis, visual examination suggests that the two series are out of phase by about two or three quarters. In this respect the behavior of automobile finance rates corresponds very closely to that of bank rates on short-term business loans. During the period 1953–61 the peaks in the latter series occurred approximately six months after the peaks in the *Aaa* corporate rate, and troughs occurred about four months later.¹⁴

The substitution relations for savings accounts are somewhat different from those for bonds. In particular, savings accounts appear to be more effective substitutes for durable goods other than automobiles. The techniques used here to study the substitution relationships between liquid assets and consumer durable goods differ from those which have been used in the past. As a general rule, it is the stock of liquid assets rather than their yield which is used as an independent variable in the durables equations. Despite this difference, our conclusions are similar to those implied by the results of Liebenberg, Hirsch, and Popkin [26], and Suits and Sparks [37]. They differ, however, from those of Evans and Kisselgoff [10], and Fromm and Klein [16].

To determine the extent to which measurement of the variables is critical for the results, equation (8) was re-estimated using BLS data in place of the implicit price deflators, and using the yield on finance company paper (r_{FCP}) as a measure of r_{FS} . The parameter estimates for the first two regressions in Table 4 suggest that the two sets of price data yield the same conclusions. There are no significant differences between these estimates and those in Table 1.¹⁵ The second set of equations presents the results obtained when r_{FCP} is substituted for r_{Aaa} . Their only major difference from the results in Table 1 is that the absolute values of the coefficients for the short-term interest rate are lower than those for the long-term rate. This discrepancy can be attributed almost entirely to the difference in the variances of the rates. Since both yields are assumed to provide measures of the rates charged on consumer credit we would expect the coefficients to be inversely related to the standard deviations. This is precisely what we find. When the coeffi-

¹⁴ Cagan [5]. It is also worth noting that if (as was suggested in Section I) the response patterns used here are viewed as approximations to those where the adjustment builds up gradually to a peak and then tapers off, our estimates of the lag between changes in open-market rates and the peak adjustments in expenditures are similar to those reported by deLeeuw [8]. The latter estimates are six quarters for "other" durable goods and seven quarters for automobiles. For the results of an interview study of consumer sensitivity to finance rates see Juster and Shay [22].

¹⁵ The simple correlations between the alternative measures of relative prices are .678 for automobiles and .994 for other durables.

cients are multiplied by the standard deviations of the independent variables the remaining differences are not statistically significant.¹⁶ Thus, it appears to make very little difference whether short- or long-term market rates are used as measures of the rates that consumers pay on their liabilities.

In summary, the results suggest that expenditures on consumer durable goods can be explained as a relatively simple function of income, relative price, and interest rates. In many respects, these findings are in agreement with the evidence that has been accumulated in the area. What sets this study apart from those which have preceded it is that we are able to isolate a significant relationship between expenditures on consumer durable goods and interest rates.

From our point of view these results make a considerable amount of economic sense. They imply that in the aggregate consumer purchases of durables are influenced by *both* the prices of the goods and the costs of financing them. This conclusion does not necessarily mean that an increase in interest rates will lead consumers to postpone or cancel purchases that they had already planned. All that is indicated is that consumers spend less than they otherwise would. This may be accomplished by purchasing a lower-priced model or by forgoing some marginal extras. The vast array of models and extra equipment available on automobiles is well known. But other durables, too, come in a wide variety of models, colors, sizes, shapes and materials.

III. *Alternative Formulations*

In view of the interest rate results reported above, i.e., the significant coefficients and the long lags associated with open-market rates, it seems appropriate to subject the model developed in Section I to a number of additional tests. First, there is the possibility that interest rates merely reflect the effects of other monetary variables, e.g., the stock of money. Second, it is useful to test the hypothesis that the relationship between open-market rates and purchases of "other" durables can be attributed to the combined effects of (1) the negative association between interest

¹⁶ The following table presents the beta coefficients (and the standard errors) for r_{Aaa} and r_{FCP} in the automobile and other durables equations.

| <i>Dependent Variable</i> | r_{Aaa} | r_{FCP} |
|---------------------------|-------------------|-------------------|
| C_A | -.1511 (.0426) | -.0903 (.0491) |
| C_{DEA} | -.0405 (.0133) | -.0356 (.0107) |

The beta coefficient for a variable is defined as the regression coefficient multiplied by the ratio of the standard deviation of the variable to the standard deviation of the dependent variable. It is easily seen that the differences between the beta coefficients for r_{Aaa} and r_{FCP} are not statistically significant.

rates and residential construction and (2) the positive correlation between housing expenditures, on the one hand, and expenditures on furniture and household appliances on the other. Third, we examine the effects of a number of additional variables. Finally, the explanatory power of the model developed in Section I is compared with that of several other models that have appeared in the literature during the past few years.

The monetary variables included in this study, in addition to interest rates, may be divided into two groups: those which reflect actions taken by the monetary authorities and those which measure consumer liquidity. The former include

M_B : the monetary base (defined as bank reserves plus currency in the hands of the public)

M_{T1} : the aggregate stock of demand deposits plus currency

M_{T2} : M_{T1} plus time deposits at commercial banks

\dot{M}_{T1} : The rate of change in M_{T1}

\dot{M}_{T2} : The rate of change in M_{T2} ¹⁷

These variables are included in the analysis to provide some indication of the manner in which monetary operations influence consumer behavior. More specifically, we wish to test the views expressed by Friedman and Meiselman. They argue that while the effects of monetary policy may be described as operating through interest rates, it is not very useful or illuminating to do so ([15], p. 217).

Consumer liquidity is measured as

M_{C1} : the consumer stock of demand deposits plus currency

M_{C2} : M_{C1} plus consumer holdings of time and savings accounts at commercial banks, mutual savings banks, and savings and loan associations

These variables have been used in previous studies of the demand for consumer durable goods for two reasons: (1) as measures of the ability of consumers to make large purchases or down payments [24] and (2) as proxies for total consumer wealth [25].

Let m serve as a general measure for the variables noted above. The effects of the variables on the purchases of consumer durable goods may be estimated by rewriting equation (3) as

$$(3.1) \quad \Delta A_t = \theta(\bar{A}_t - A_{t-1}) + \delta m_t$$

According to equation (3.1) investment in consumer durables is influenced both by the discrepancy between desired and actual stocks and

¹⁷ The use of the rate of change in the money supply as a measure of monetary tightness or ease has been suggested by a number of writers. See, for example, Cagan [5].

| C_{DEA} | .100 (.017) [0.0] | -.315 (.100) [0.0] | -1.10 (0.35) [6.0] | -3.39 (0.79) [0.0] | | .053 (.018) [0.0] | .693 (.050) | .68 ^a | .9953 .2721 |
| C_{DEA} | .111 (.017) [0.0] | -.423 (.102) [0.0] | -.980 (.347) [6.0] | -3.17 (0.91) [0.0] | .173 (.084) [3.0] | | .859 (.037) | .50 ^a | .9949 .2805 |

Note: The data for all variables except interest rates are adjusted for seasonal variation. The numbers in square brackets denote the lags associated with the independent variables.

^a The quarterly estimate from which this statistic is derived was estimated within an interval of $\pm .01$.

by some measure of either aggregate or consumer liquidity.¹⁸ Substitution of equation (3.1) for (3) yields

$$\begin{aligned}
 (8.1) \quad X_t = & a' + b'[Y_{t^*} - (1 - e_2)Y_{t^*-1}] + c'[r_{t^*} - (1 - e_2)r_{t^*-1}] \\
 & + d'[P_{t^*} - (1 - e_2)P_{t^*-1}] + \frac{\delta}{1 - e_1}[m_{t^*} - (1 - e_2)m_{t^*-1}] \\
 & + (1 - \theta)X_{t-1} + v_t
 \end{aligned}$$

Each of the monetary variables discussed above was introduced into equation (8.1). Although the variables do not reflect the same considerations, the results obtained were fairly similar. Table 5 presents the results for the variables that yielded the highest multiple correlation coefficients: M_{C3} (the broad measure of consumer liquidity) and \dot{M}_{T1} (the rate of change in the money supply). The similarities between the interest rate coefficients in these equations and those in Table 1 provide little, if any, support for the view that interest rates serve as proxies for other monetary variables. Thus interest rates appear to have an inde-

¹⁸ The use of m_t as a determinant of the investment in durables instead of the desired stock has no effect on the form of the regression equations estimated below. What is affected is, of course, the interpretation of the parameters.

pendent effect on the purchases of consumer durables. This implies that consumer behavior is influenced not only by the supply, but also the demand for loanable funds, in particular the demand for credit by other sectors of the economy. It follows that the effects of monetary policy on the consumer sector will depend to a very important extent on what is going on elsewhere in the economy.

Some difficulty is encountered in choosing between M_{C3} and \dot{M}_{T1} as an additional monetary measure. Neither is significant in the automobile equation. In the nonauto equation both variables are significant and M_{C3} yields a slightly higher estimate of \bar{R}^2 ; however, the estimate of the annual rate of depreciation associated with M_{C3} (.68) seems excessive. This suggests that \dot{M}_{T1} is the more appropriate of the two measures, but additional evidence will be presented below.

The second hypothesis to be tested is that variations in residential construction expenditures (E_{RC}) play a major role in explaining the association between market rates of interest and the purchase of "other" durable goods. The addition of E_{RC} to the right-hand side of equations (3) and (3.1) yields the following estimation equations:

$$(8.2) \quad X_t = a' + b'[Y_{t^*} - (1 - e_2)Y_{t^*-1}] + c'[r_{t^*} - (1 - e_2)r_{t^*-1}] \\ + d'[P_{t^*} - (1 - e_2)P_{t^*-1}] \\ + \frac{\Omega}{1 - e_1} [E_{RC,t^*} - (1 - e_2)E_{RC,t^*-1}] + (1 - \theta)X_{t-1} + v_t$$

$$(8.3) \quad X_t = a' + b'[Y_{t^*} - (1 - e_2)Y_{t^*-1}] + c'[r_{t^*} - (1 - e_2)r_{t^*-1}] \\ + d'[P_{t^*} - (1 - e_2)P_{t^*-1}] + \frac{\delta}{1 - e_1} [m_{t^*} - (1 - e_2)m_{t^*-1}] \\ + \frac{\Omega}{1 - e_1} [E_{RC,t^*} - (1 - e_2)E_{RC,t^*-1}] + (1 - \theta)X_{t-1} + v_t$$

The parameter estimates and other results for these equations are shown in Table 6. Once again the interest rate coefficients are statistically significant. In addition, the coefficients for residential construction have the anticipated signs (positive) and are significantly different from zero. This finding provides some support for the view that consumers treat houses and household furnishings as complements. However, similar results are obtained when E_{RC} is included in the automobile equation. Hence, all that we may be observing is a tendency for housing expenditures to act as a leading indicator, i.e., to lead expenditures on other physical assets by one or two quarters.¹⁹

¹⁹ The appropriate way to evaluate the substitution relationships between housing and other physical assets is to use the relative price of houses as an explanatory variable in equation (3).

TABLE 6—PARAMETER ESTIMATES FOR EQUATIONS INCLUDING EXPENDITURES ON RESIDENTIAL CONSTRUCTION: QUARTERLY DATA, 1953-64
(standard errors in parentheses)

| Dependent Variables | Y | P | r_{Aco} | r_{SV} | E_{RG} | M_{CS} | \dot{M}_{T1} | Lagged Dependent Variables | C_2^A | \bar{R}_S^A |
|---------------------|-------------------------|--------------------------|--------------------------|--------------------------|-------------------------|-------------------------|-------------------------|----------------------------|------------------|----------------|
| C_{DZA} | .094 (.017) [0.0] | -.404 (.095) [0.0] | -0.82 (0.33) [6.0] | -3.16 (0.85) [0.0] | .181 (.055) [1.0] | | | .888 (.037) | .50 ^a | .9957 .2612 |
| C_{DZA} | .082 (.017) [0.0] | -.293 (.092) [0.0] | -0.83 (0.33) [6.0] | -3.09 (0.73) [0.0] | .145 (.051) [1.0] | .042 (.017) [1.0] | | .744 (.051) | .70 ^a | .9960 .2512 |
| C_{DZA} | .092 (.017) [0.0] | -.399 (.096) [0.0] | -0.80 (0.33) [6.0] | -3.13 (0.85) [0.0] | .158 (.060) [1.0] | | .081 (.086) [3.0] | .892 (.037) | .50 ^a | .9957 .2616 |
| C_A | .186 (.033) [1.0] | -.204 (.103) [0.0] | -3.80 (1.21) [4.5] | | .489 (.191) [2.0] | | | .521 (.076) | .55 ^a | .9234 .8886 |

Note: The data for all variables except interest rates are adjusted for seasonal variation. The numbers in square brackets denote the lags associated with the independent variables.

^a The quarterly estimate from which this statistic is derived was estimated within an interval of $\pm .01$.

The evidence presented in Table 6 also bears on the importance of using M_{C3} and \dot{M}_{T1} as explanatory variables in the durables equations. Once E_{RC} is added to the model, the t -ratio for \dot{M}_{T1} falls below 1.0. Thus the case for including either of these variables in the analysis appears to be rather weak.

Two other variables that were considered as determinants of the demand for durable goods are (1) the yield on equities (measured as Moody's dividend yield on industrial common stocks)²⁰ and (2) the rate of unemployment. The latter variable may be viewed as a general cyclical indicator (see Evans and Kisselgoff [10]) or as a rough means of separating unemployment benefits from other income, the assumption being that unemployment benefits are unlikely to be spent on durable goods (Suits and Sparks [37]). The results for these variables are inconclusive. Though each might be expected to have some effect, their inclusion does not yield a significant improvement in the explanatory power of the durables equations. This is particularly true when the expenditures on residential construction are incorporated in the model. The t -values for the variables never exceed 1.5. Although the apparent effects are in the expected direction, more data will be required before one can be reasonably sure of the persistence and the magnitude of their influence.

The interest rate results obtained in these tests are similar to those reported above. Thus, the case for including interest rates is strengthened considerably. Regardless of what variables are added to the analysis the interest rate effect remains significant. Moreover, the only additional variable that contributes significantly to the explanatory power of the model is the expenditures on residential construction.

One difficulty which often affects estimates from economic time series is largely absent in the present study. For the period under consideration there is little significant correlation among the weighted differences of the variables included in equation (8), the equation estimated in the previous section. For example, the highest correlation involving the yield on *Aaa* rated corporate bonds ($-.54$) is between the bond yield and the relative price of "other" durables.

Finally, let us compare the performance of equation (8) with that of three other models that have appeared in the literature during the past few years (Suits and Sparks [37]; Liebenberg, Hirsch and Popkin [26]; and Evans and Kisselgoff [10]). The time periods used to fit the regression equations in these studies and the estimates of the adjusted coefficients of determination are given in Table 7, Part A. Part B shows the results obtained when equation (8) is reestimated for the periods (1953:3–1961:4) and (1953–62).

²⁰ This specification of the yield on equities is discussed in Hamburger [18].

TABLE 7—ALTERNATIVE DEMAND FUNCTIONS FOR CONSUMER DURABLE GOODS

Part A: Estimates of the Adjusted Coefficients of Determination
and the Time Periods Used in Several Studies

| Study | Time Periods | Adjusted Coefficients of Determination | |
|----------------------------------|---------------|---|----------------|
| | | Autos | Other Durables |
| Suits and Sparks | 1953:3–1961:4 | .686 | .942 |
| Liebenberg, Hirsch and Popkin | 1953–1964 | .91 | .98 |
| Evans and Kisselgoff | 1953–1962 | .710 | .986 |

Part B: Parameter Estimates for Equation (8) for the
Periods 1953:3–1961:4 and 1953–62—Quarterly Data
(standard errors in parentheses)

| De- pendent Vari- ables | Time Period | F | P | r_{Aaa} | r_{SV} | Lagged De- pendent Variables | e_2^A | \bar{R}^2 S |
|----------------------------------|----------------|-------------------------|--------------------------|--------------------------|--------------------------|---------------------------------------|------------------|--------------------|
| C_A | 1953:3–61:4 | .266 (.066) [1.0] | –.222 (.110) [0.0] | –4.13 (1.47) [4.5] | | .630 (.090) | .19 ^a | .7712 .9576 |
| C_A | 1953–62 | .249 (.047) [1.0] | –.245 (.108) [0.0] | –4.58 (1.24) [4.5] | | .631 (.081) | .34 ^a | .8258 .9290 |
| C_{DEA} | 1953:3–61:4 | .109 (.016) [0.0] | –.468 (.129) [0.0] | –1.03 (0.37) [6.0] | –2.52 (1.78) [0.5] | .810 (.072) | .50 ^a | .9837 .2584 |
| C_{DEA} | 1953–62 | .105 (.016) [0.0] | –.465 (.100) [0.0] | –1.12 (0.34) [6.0] | –3.21 (1.55) [0.0] | .876 (.066) | .45 ^a | .9883 .2694 |

Note: The data for all variables except interest rates are adjusted for seasonal variation. The numbers in square brackets denote the lags associated with the independent variables.

^a The quarterly estimate from which this statistic is derived was estimated within an interval of $\pm .01$.

Note first that although two of the time periods differ from the one used to specify equation (8), the variance explained by it is greater than that explained by the alternatives. The only instance in which the estimates of \bar{R}^2 are fairly close is the comparison between the automobile equation presented here and the one estimated by Liebenberg, Hirsch and Popkin. However, a considerable portion of the explanatory power of the latter can be attributed to the inclusion of a dummy variable, da (see the Appendix). If da is eliminated from the equation the estimate of \bar{R}^2 is approximately .86.

Second, there is some evidence to suggest that the parameters in equation (8) are fairly stable over time. The only possible exception is the coefficient for the yield on savings accounts in the "other" durables equation. The absolute value of that coefficient and its *t*-ratio increase with time. This result may be explained in several ways. For example, it might be argued that the growth in the competition among thrift institutions in recent years has increased consumer sensitivity to interest rates. Alternatively, there is the argument that the rates offered by savings institutions may not have a significant effect on consumer expenditures until they reach some critical level. Other explanations could be provided. However, it is more important to note that the present results furnish additional confirmation for the conclusion reached earlier, namely, that interest rates are an important determinant of consumer behavior.

IV. *Conclusion*

The findings reported in the previous sections have a number of broader implications. First, they are not entirely consistent with either of the two most widely held views concerning the channels through which monetary policy operates. According to the Keynesian income-expenditure approach, changes in monetary policy affect interest rates, interest rates affect the level of investment, and the level of investment in turn affects income and consumption through the multiplier process. The evidence presented here suggests that there is a much more direct link between monetary operations and consumer expenditures on durable goods. This more direct link is recognized in the alternative approach expounded by Friedman and Meiselman, but they argue that it is neither very useful nor illuminating to view the effects of monetary policy as operating through interest rates. While their view may be appropriate for aggregate analysis, it does not appear to be consistent with the evidence for the consumer sector. This finding should not surprise those who favor either the Chicago or the Keynesian approach. It implies that purchases of consumer durables are influenced by both the money supply and the demand for credit by the other sectors of the economy. Thus the results of this study, although not in complete agreement with either of the two principal views concerning the channels through which monetary policy operates, may serve to bring them closer together.

The discussion above suggests that purchases of consumer durables should be treated as investment, that is, as autonomous expenditures. This casts doubt on the interpretations of the correlations between induced and autonomous expenditures that have appeared in a number of recent articles [2] [9] [15]. Generally, the correlations are viewed as providing support for the stability of the investment multiplier. How-

ever, if most of the short-run variation in consumption can be attributed to fluctuations in the purchases of durables, these results may do little more than reflect similar cyclical movements in two different kinds of autonomous expenditures.²¹

Finally, it seems worthwhile to say a few words about the lag in the effect of monetary policy. Tucker's analysis [38], [39] implies that the lags observed in both the consumer durables equations and the business investment equation (see, for example, [16]) do not indicate a corresponding lag in the effect of monetary policy. This conclusion is founded, however, on the assumption that either the availability of credit or quoted interest rates and other terms of lending contracts adjust fairly rapidly to changes in the money supply—in other words, that the suppliers of credit pass on every change in their costs when it occurs. To the extent that this is not done, the effects of monetary policy on the real sector will be postponed. Our results suggest that the suppliers of consumer credit do not behave in the manner assumed in Tucker's model, i.e., that they do not alter their prices every time there is a change in open market rates. It seems likely that other creditors (for example, the suppliers of trade credit) behave in a similar way, but this is an empirical question upon which there is very little evidence at the present time.

APPENDIX

Definitions of Symbols

- e_{21}^A : annual percentage rate of depreciation on existing stock.
- P_A : relative price of automobiles measured alternatively as: (1) the implicit price deflator for personal consumption expenditures on automobiles and parts divided by the implicit deflator for all consumption expenditures, 1958=100; and (2) the new car component of the Bureau of Labor Statistics' Consumer Price Index deflated by the index value for all items, 1957-59=100.
- P_{DEA} : relative price of other durables measured alternatively as: (1) implicit price deflator for personal consumption expenditures on durable goods other than automobiles and parts divided by the implicit deflator for all consumption expenditures, 1958=100; and (2) the BLS index of the prices of house furnishings deflated by the value of all items, 1957-59=100.
- C_A : personal consumption expenditures on automobiles and parts, seasonally adjusted at annual rates in billions of 1958 or 1957-59 dollars.

- C_{DEA} : personal consumption expenditures on durable goods other than automobiles and parts, seasonally adjusted at annual rates in billions of 1958 or 1957-59 dollars.
- Y : disposable personal income, seasonally adjusted at annual rates deflated by either the all items component of the CPI or the implicit deflator for all consumption expenditures, seasonally adjusted at annual rates in billions of 1958 or 1957-59 dollars.
- r_{Aaa} : Moody's *Aaa* rate on long-term corporate bonds, per cent.
- r_{FCP} : interest rate on directly placed three-six month finance company paper, per cent.
- r_{SV} : a weighted average of the rates paid on savings and loan shares, mutual savings bank deposits and time and savings deposits at member banks of the Federal Reserve System, per cent.
- M_B : monetary base, bank reserves plus currency in the hands of the public at the beginning of the period, seasonally adjusted in billions of 1958 dollars.
- M_{T1} : aggregate stock of demand deposits plus currency at the beginning of the period, seasonally adjusted in billions of 1958 dollars.
- M_{T2} : M_{T1} plus time deposits at the beginning of the period, seasonally adjusted in billions of 1958 dollars.
- M_{C1} : consumer stock of demand deposits plus currency at the beginning of the period, seasonally adjusted in billions of 1958 dollars.
- M_{C3} : M_{C1} plus consumer holdings of time and savings accounts at commercial banks, mutual savings banks and savings and loan associations at the beginning of the period, seasonally adjusted in billions of 1958 dollars.
- \dot{M}_{T1} : rate of change of M_{T1} during the period.
- \dot{M}_{T2} : rate of change of M_{T2} during the period.
- E_{RC} : expenditures on residential construction, seasonally adjusted at annual rates in billions of 1958 dollars.
- da : dummy variable for Liebenberg, Hirsch and Popkin [26] auto equation (-1 during strike quarter; $+1$ following strike quarter; $+1$ in 1955 to reflect abrupt credit and taste changes; 0 otherwise).

THE GROWTH OF OUTPUT AND INPUTS IN SOVIET TRANSPORT AND COMMUNICATIONS

By NORMAN M. KAPLAN*

The separate performance of major sectors of the economy has engaged the attention of many students of Soviet economic growth. In the case of transport, the aggregative aspects of performance have been neglected because neither the official measures nor the various non-Soviet estimates of output growth have contributed an index.¹ One purpose of this paper is to summarize the results of an attempt to construct and use output indexes for transport and communications. Part I presents the indexes and their growth rate implications and compares the output increases with increases in capital and employment; U.S. data for similar sectors are assembled as a framework for appraising U.S.S.R. performance. Because detailed descriptions and comparisons are available in [4] and [5], only the major results are briefly offered here.

Among the findings in Part I is a marked retardation in output growth within the postwar period. Part II seeks to explore that retardation by distinguishing between changes in the rate of increase of factor inputs and changes in the rate of increase of combined factor productivity.

I. *The Growth of Output and Inputs*

Table 1 presents output indexes for transport and its major components and for transport and communications combined. Transport includes the freight and passenger operations of the railroad, maritime, internal waterway, pipeline, motor and air systems. Excluded are the taxi, trolley-bus, and subway systems, as well as freight and passenger services rendered by administrative or producing units for their own respective uses. Communications include the postal system, the telephone and telegraph system, and wireless broadcasting.

The individual physical output components of the transport index are ton-kilometers of freight traffic and man-kilometers of passenger traffic for each of the carriers. The weights used to combine the output series into indexes of transport output are ruble operating costs per

* The author is Xerox Professor of Economics at the University of Rochester. He is indebted to the National Science Foundation for support of the preparation of this paper and the research underlying it.

¹ For example, an index of national product, estimated in 1964 from sector output indexes, uses ton-kilometers of railroad freight as a surrogate for all transport output [12, p. 94]. The 1965 and 1966 successors to [12]—[13, p. 20] and [14, p. 128]—incorporate the transport and communications indexes to be described here.

TABLE 1—INDEXES OF TRANSPORT AND COMMUNICATIONS OUTPUT, 1928-1963
(1955=100)

| | Transport Output | | | | Transport and Communica- tions Output |
|------|-----------------------|-------------------------|---|-------------------------|---|
| | All Freight (1) | All Passenger (2) | Railroad Freight and Passenger (3) | All Transport (4) | |
| 1928 | 9.3 | 14.9 | 11.2 | 10.6 | 10.7 |
| 1929 | 11.1 | 19.2 | 14.0 | 12.9 | 13.0 |
| 1930 | 13.4 | 31.2 | 18.7 | 17.4 | 17.5 |
| 1931 | 15.4 | 36.7 | 21.7 | 20.1 | 20.4 |
| 1932 | 16.8 | 49.0 | 26.3 | 24.0 | 24.3 |
| 1933 | 17.2 | 43.0 | 25.1 | 23.1 | 23.8 |
| 1934 | 20.5 | 41.4 | 27.5 | 25.2 | 26.1 |
| 1935 | 25.5 | 39.9 | 31.2 | 28.7 | 29.7 |
| 1936 | 31.1 | 44.9 | 37.9 | 34.1 | 34.9 |
| 1937 | 33.5 | 52.8 | 42.4 | 37.8 | 38.5 |
| 1938 | 34.6 | 49.8 | 42.9 | 37.9 | 39.2 |
| 1939 | 36.1 | 55.1 | 45.9 | 40.4 | 41.7 |
| 1940 | 37.8 | 58.1 | 48.4 | 42.3 | 43.7 |
| 1945 | 29.4 | 38.8 | 35.4 | 31.4 | 32.1 |
| 1946 | 31.2 | 54.3 | 41.9 | 37.4 | 38.2 |
| 1947 | 33.4 | 58.2 | 42.8 | 38.9 | 40.0 |
| 1948 | 41.7 | 51.7 | 48.6 | 43.9 | 45.0 |
| 1949 | 48.9 | 51.7 | 54.7 | 49.5 | 50.7 |
| 1950 | 56.3 | 56.3 | 62.0 | 56.3 | 57.5 |
| 1951 | 62.9 | 63.7 | 69.8 | 63.1 | 64.4 |
| 1952 | 69.5 | 70.2 | 76.3 | 69.9 | 70.9 |
| 1953 | 76.0 | 79.0 | 82.5 | 76.7 | 77.8 |
| 1954 | 85.0 | 87.9 | 88.9 | 85.6 | 86.4 |
| 1955 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 |
| 1956 | 113.5 | 104.7 | 108.9 | 111.6 | 111.1 |
| 1957 | 129.3 | 119.6 | 121.4 | 127.1 | 125.8 |
| 1958 | 142.7 | 133.7 | 129.4 | 140.7 | 138.8 |
| 1959 | 159.0 | 150.2 | 140.6 | 157.1 | 154.5 |
| 1960 | 173.6 | 169.1 | 147.7 | 172.6 | 169.6 |
| 1961 | 185.7 | 190.2 | 153.6 | 186.7 | 183.3 |
| 1962 | 197.5 | 217.1 | 162.0 | 201.8 | 198.1 |
| 1963 | 212.9 | 241.9 | 170.7 | 219.4 | 215.2 |

Sources: [4, Tables A-4 and A-7] as revised and extended in [5, Table 4]. Column (5) is the Variant III index in [5, Table 4] and the communications component is the combined employment and ruble output series. For an extension of these indexes to 1964 and 1965, see fn. 2.

ton or passenger-kilometer for the relevant carrier in 1955. I omit here the several reservations that need to be attached to the results and the somewhat different results obtainable with different weights because they are stated in [4] and [5]. In submitting the indexes as a first attempt to measure the change in Soviet transport output I would be more diffident than I am were it not for the observation of similar solu-

tions to the problems of measuring U.S. transport output [6, Appendix G] [10, Appendix I].

Because Soviet capital data combine transport and communications, sector comparisons of output and input growth require an index of combined transport and communications output. Therefore, despite inherent difficulties for a sector like communications and the paucity of published data on Soviet communications, I have assembled an index of communications output by using an official ruble output series for several years and an employment series for interpolations and extensions to other years. The communications and transport indexes are combined with 1955 gross value weights to obtain the index in Table 1, Col. (5). Fortunately, the combined transport and communications index is relatively insensitive to alternative measures of communications output and alternative weights.²

For selected periods, Table 2 presents the average annual rates of output increase implied by the indexes in Table 1. The periods represented are the consequences of the following considerations. Students of the Soviet economy have noted a marked retardation in output growth after 1958 in comparison with earlier periods, a retardation observed not only for agriculture but also for industry and the economy as a whole, e.g. [12, pp. 91-98]; to determine whether a similar retardation holds for transport and communications, pre- and post-1958 periods are distinguished. To exclude years of substantial war damage and possibly cheap recovery, the postwar data begin with the early 1950s and the precise years chosen depend on the years for which capital data are available. After very rapid growth in 1928-32, the indexes in Table 1 show less rapid growth in 1932-37 and little growth in 1937-40 despite the territorial acquisitions for which no adjustment is made; to provide alternative prewar perspectives for viewing the postwar rates of growth, 1932-40 is separated from 1928-40.

In order to provide a benchmark for assaying the Soviet growth rates, Table 2 also presents growth rates for at least roughly comparable sectors in the United States from 1869 to 1950. The major conclusions from Table 2 are:

A. For Soviet transport and communications and its indicated components, the rates of output increase in 1958-63 are substantially below those in 1951-58 or 1953-58. The deceleration noted for other segments of the economy and for the economy as a whole holds also for transport and communications. It should be noted, too, that the conclusion does not depend on the precise time demarcations in Table 2: the marked

² See [4, Tables A-3 and A-7] and [5, Table 4]. It should also be noted that output data now available make it possible to extend the indexes to 1964 and 1965. The results are: for transport, 242.2 in 1964 and 266.0 in 1965; for transport and communications, 237.2 and 260.7. The output data are from [21, pp. 431, 433, 485, 500], [23, pp. 97, 98, 102], and 1962-64 relationships between motor freight output of "general use" and total motor freight output.

TABLE 2—AVERAGE ANNUAL RATES OF OUTPUT INCREASE, U.S.S.R. AND U.S. TRANSPORT AND COMMUNICATIONS

(per cent per year)

| | Transport and Communications | Transport | Railroad Transport |
|---------------|------------------------------|-----------|--------------------|
| U.S.S.R. | | | |
| 1928-40 | 12.4 | 12.2 | 13.0 |
| 1932-40 | 7.6 | 7.3 | 7.9 |
| 1951-58 | 11.6 | 12.1 | 9.2 |
| 1953-58 | 12.3 | 12.9 | 9.4 |
| 1958-63 | 9.2 | 9.3 | 5.7 |
| 1951-63 | 10.6 | 10.9 | 7.7 |
| United States | | | |
| 1869-79 | 7.0 | 7.0 | — |
| 1879-89 | 9.7 | 8.5 | 8.5 ^a |
| 1890-1909 | 6.4 | 6.1 | 5.7 |
| 1909-29 | 3.7 | 3.3 | 2.6 |
| 1929-50 | 3.3 | 3.3 | 1.2 |

^a 1880-90

Sources: For the U.S.S.R., the underlying indexes are in Table 1. For the United States, the 1869-79 and 1879-89 data are from [6] obtained by methods described in [4, Table 5, Note c] and the other data are from [10, pp. 458-59, 464-65, 472-73, 486-87]. The 1869-79 and 1879-89 data differ from the other data in that the former include street and electric railways. To obtain post-1889 transport and communications output, I have subtracted from the total for all regulated industries the output of electric light and power, manufactured and natural gas, and street and electric railways. Similarly, for post-1889 transport output the output of street and electric railways has been subtracted. The inclusion of street and electric railways for the years since 1889 yields essentially the same rates of increase except for 1929-50 with noticeably lower rates of increase.

deceleration survives with 1962, 1964, or 1965 as the terminal year of the later period, with 1954 as the initial year of the earlier period, and with 1959 as the dividing year between the two periods. On the other hand, there is no evidence of any appreciable decline in growth rates *within* the 1951-58 period.

B. Whether the post-1951 rates of increase exceed or are exceeded by the prewar rates of increase depends upon the prewar period considered. The 1951-58 and 1951-63 rates of increase are below the 1928-40 rates and, except for 1951-63 railroad transport, above the 1932-40 rates. Thus, the decline in growth rates between 1951-58 and 1958-63 cannot be dismissed as a simple continuation of past trends.³

³ One difficulty with these comparisons is that the growth rates are the conventionally defined average annual rates of increase, the rate which for a given period yields the terminal-year value from the initial year value. I am led by Boris Pesek's excellent essay on growth measures [9] to an appreciation of this difficulty, to a general preference for a measure that depends on all observations, and to specific candidates. Applying his methods VI and VII to the data at hand, I observe that the alternative measures make little or no difference except for 1928-40. For 1928-40, his method VII yields 10.5, 10.3, and 11.0 in place of the respective entries in Table 2. Thus, the conclusion in the text is strengthened by the use of this alternative measure. It should also be observed that none of the conclusions in the preceding or subsequent paragraph is affected by the use of the alternative measures from Pesek.

C. The growth rates for Soviet transport and communications and its major components generally exceed those for the United States and by very substantial amounts. The exception is the decade of the 1880s in the United States when the growth rates exceed those for *some* subperiods in the U.S.S.R.⁴ With that exception, even the 1958-63 growth rates for U.S.S.R. transport and communications substantially exceed those in the U.S.

To compare the Soviet output increases with capital and employment increases, Table 3 presents the basic series for selected years from 1928 to 1963 and the relative increases in each for several subperiods. The capital values are the official series for fixed capital at July 1, 1955 prices gross of depreciation. The results are clear. Over the 1928-63 period as a whole, output has increased by much more than the increase in either employment or capital and, therefore, by much more than the increase in combined factor inputs regardless of the input weights. For each of the indicated subperiods considered separately the same inequality holds: an output increase in excess of each of the input increases.

Since the persistence of that inequality might be construed to question the reliability of the output or capital series, it is relevant to cite similar comparisons for the United States. In [4, Table 7] I have derived and assembled roughly comparable data for U.S. transport and communications from [5] and [10]: output at 1929 prices, fixed capital net of depreciation at 1929 prices, and persons engaged and man-hours employed, for selected years from 1869 to 1953. The results are essentially the same as the U.S.S.R. results: over the period as a whole, output has increased by much more than the increase in either capital or employment and the same inequality holds for each of the separate subperiods.⁵ For the United States but not for the U.S.S.R., it is possible to make the same comparisons for separate components of transport, communications, and public utilities and in virtually all cases the comparisons show output increases in excess of the increases in either capital or labor.⁶

⁴ Application of Pesek's method VII (fn. 3) yields Soviet growth rates of 10.4, 10.7, and 8.7 for columns (1)-(3), respectively, of Table 2 in 1928-40 and 1948-63 combined. For 1932-40 and 1948-63, the rates are essentially the same.

⁵ The results, however, differ in one respect. In the U.S.S.R., capital-labor ratios increase throughout. In the U. S., capital-labor ratios increase for some subperiods and decrease for others and capital per man-hour is the same in 1948 as in 1869.

⁶ See [6, Appendixes G and H] [10, pp. 235-36, 256-67, 320-21, 374-75, 405, 406, 440, and Appendix I]. The components for which comparisons are possible are: transport, railroad transport, local street railways, local bus lines, communications and public utilities, electric power, manufactured and natural gas, the telephone system, and the telegraph system. The indicated result holds for all cases except natural gas, local bus lines since 1919, and the post-1929 telephone system.

TABLE 3: OUTPUT, CAPITAL AND EMPLOYMENT, U.S.S.R. TRANSPORT AND COMMUNICATION 1928-1963

| | Output (1955=100) (1) | January 1 Capital (billion 1955 rubles) (2) | Average Annual Employment | |
|---|-----------------------------|---|--------------------------------|--------------------------------|
| | | | Man-Years (millions) (3) | Man-Hours (1955=100) (4) |
| Basic Series | | | | |
| 1928 | 10.7 | 45 | 1.365 | 21.4 |
| 1940 | 43.7 | 156 | 3.903 | 68.2 |
| 1951 | 64.4 | 215 | 4.899 | 87.4 |
| 1953 | 77.8 | 237 | 5.352 | 95.0 |
| 1954 | 86.4 | 256 | 5.536 | 98.1 |
| 1958 | 138.8 | 330 | 6.332 | 105.8 |
| 1959 | 154.5 | 357 | 6.663 | 108.7 |
| 1962 | 198.1 | 450 | 7.509 | 111.0 |

| 1951-58 | 216 | 154 | 129 | 121 |
| 1958-63 | 155 | 150 | 122 | 108 |

Sources:

Output: Table 1.

Capital: For average 1928, 1941, 1951, and 1963, from the 1964 value and indexes in [20, pp. 55-56]; for 1928 and 1940, from the average semi-annual rate of increase between average 1928 and 1941. For 1953, from the 1960 value in [17, p. 67] and indexes in [19, pp. 52-53]. For 1954, from the 1963 value in the table and indexes in [22, p. 31]. For 1962, from [18, p. 69]. The 1958 figure is estimated from investment data on the assumption of the same ratio between 1953-57 and 1953-58 capital increments and investment.

Man-Years: From [18, p. 567], [20, p. 475], and [16, pp. 658-59] except for 1951 and 1954 which are estimates in [11, p. 60].

Man-Hours: From man-years and an index of hours worked per year. The latter is the product of days worked per year and hours worked per day. The data on days worked per year are from [8, Table Q-3] for 1928, 1940, 1950, 1958 and 1959; from [13, p. 80] for 1952, 1955, 1962 and 1963; and interpolated for 1951, 1953 and 1954. The data on hours are from [8, Table Q-3] for 1928 and from [13, p. 80] for all other years except 1951, 1953, and 1954 which are interpolated.

The appearance of the same results in both U.S. and U.S.S.R. transport and communications suggests the existence of some characteristic indigenous to the sector. The nature of the data makes it impossible to specify the substance of the characteristic, but the least demanding explanation may well be the relevant one. Suppose each individual system in transport and communications is characterized by substantial indivisibilities with, once the system has been established, declining capital and operating costs per unit of output. For time series aggregating such systems' data, output increases will exceed capital and labor

input increases so long as the indivisible capital expenditures for new systems are more than offset by the declining costs of existing systems.⁷ If this explanation is relevant, the conventional characterization of the transport and communications system as "social overhead" capital has economic substance to it.

The excess of output over input increases also raises other issues. Given the excess in the increase of national product over the increase of combined factor inputs for the economy as a whole, observed for both the United States and U.S.S.R., the problem is to explain the residual output increase. The question raised here is how much of the observed residual for the economy is accounted for by the pronounced residual in transport and communications. The substantial and persistent decreases in capital-output ratios for both U.S. and U.S.S.R. transport and communications are in strong contrast to the behavior of capital-output ratios for each economy as a whole. In the U.S.S.R., the capital-output ratio for the economy appears to have increased since 1928 or 1951 [8, Tables T-1 and P-1]. In the United States, it has been stable or rising over long periods of time, excluding the link between 1929 and the early postwar period.⁸ If these observations are correct, there must be in both the United States and U.S.S.R. either (a) some sectors for which the capital-output ratio has been increasing markedly or (b) substantial shifts in the relative importance of sectors. The implication would seem to be that studies involving capital-output ratios or the residual between output and input increases should not stop with the economy as a whole but should, whenever possible, incorporate the separate behavior of specific sectors and shifts in their relative importance.

II. *The Growth of Output per Unit of Inputs*

For many purposes the incremental capital-output ratio is a more relevant magnitude than the average capital-output ratio. In particular,

⁷ If this is the explanation, one should expect to find early periods of the development of transport and communications systems when the establishment of new systems predominates and when capital-output ratios increase with time. In the U. S. case this finding does tend to appear for major components of transport and communications except railroads. See [6, pp. 546, 548, 580, 581, 585-86, 592, 594] and [10, pp. 482, 486]. For railroads, however, the data on capital-output ratios begin in 1880 when substantial amounts of track were already in operation [10, pp. 268-69, 472-73].

⁸ Here I rely on: (1) Kendrick's Commerce Concept of GNP compared with fixed capital both net and gross of depreciation from Kuznets and Goldsmith; and (2) for the 1946-59 period separately, the Department of Commerce GNP data compared with similar capital data from Goldsmith. The GNP data are from [6, Tables A-III and A-IV] [24, Table I-2] [15, Table 5]. The Kuznets capital data in [7, pp. 64-65] include inventories; I have reproduced the fixed capital component by methods and with the results indicated in [3, Table III.10 and notes, pp. 145-47]. The Goldsmith capital data are from [1, Table W-3] [2, Tables A-35 to A-37 and A-46 to A-48].

given the evidence of a deceleration in the Soviet economy shared by transport and communications, it seems especially interesting to know the changes if any in incremental capital-output ratios. Calculating from Table 3 the ratio of the capital increment to the output increment for 1928-40, 1940-51, 1951-53, 1953-58, and 1958-63, I observe a substantial decline in the ratio from 1928-40 through 1953-58 and a substantial increase from 1953-58 to 1958-63.⁹ If these data can be interpreted even roughly as requirements indicators, they point to a marked recent increase in the investment burden per additional ruble of transport and communications output. What is not clear is why. The incremental capital-output ratio at best is an omnibus variable which summarizes the effects of such influences as the rates of increase of capital and labor, changes in their marginal productivities, economies or diseconomies of scale, technical change, etc.

Perhaps one can move a step further in the study of relationships between output and input increases by distinguishing between the influence of the rate of increase of inputs and the influence of all other factors. More specifically, let us begin with the previous observation of a decline in the average annual rate of output increase between 1951-58 and 1958-63 and seek to account for this decline in terms of (a) changes in the rate of increase of combined factor inputs and (b) changes in the rate of increase of factor productivity. To do so, consider the construction of an index of factor productivity in geometric form. Let: X_t , K_t , L_t = output, capital, and labor for year t ; a and $1-a$ = relative weights for capital and labor, respectively. The indexes for 1958 and 1963 with 1951 = 1.00 are:

$$\frac{\frac{X_{58}}{X_{51}}}{\left(\frac{K_{58}}{K_{51}}\right)^a \left(\frac{L_{58}}{L_{51}}\right)^{1-a}} \quad \text{and} \quad \frac{\frac{X_{63}}{X_{51}}}{\left(\frac{K_{63}}{K_{51}}\right)^a \left(\frac{L_{63}}{L_{51}}\right)^{1-a}}$$

where the subscripts denote the year.

The problem as posed involves comparisons of average annual rates of increase between the two time periods. Simplify the notation by letting X_1 , K_1 , L_1 represent the indexes of the variables over period 1 (here, 1951-58) and X_2 , K_2 , L_2 the indexes over period 2 (here, 1958-63).

⁹ In [4, Table 8] I present: (1) a similar calculation for somewhat different periods; and (2) for both transport and communications and railroad transport, a calculation of the changes in the ratio of investment to the output increment with investment lagged one year. The results are the same: an initial decline in the ratios followed by a recent substantial increase. From [4, Table 7] one can also observe declining or, sometimes, stable incremental capital-output ratios for the United States from 1869-79 through 1929-50.

Call the indexes of factor productivity, constructed as above, A_1 , and A_2 .¹⁰

Take logarithms of the indexes and, to handle comparisons between periods of unequal duration, divide by N_1 or N_2 —the number of years in the respective periods. In each case the result—denoted by \bar{A}_1 , $\bar{X}_1, \bar{K}_1, \bar{L}_1$, etc.—is a number whose antilogarithm is one plus the average annual rate of increase of the variable. Thus we have:

$$(1) \quad \bar{A}_1 = \bar{X}_1 - a\bar{K}_1 - (1-a)\bar{L}_1$$

$$(2) \quad \bar{A}_2 = \bar{X}_2 - a\bar{K}_2 - (1-a)\bar{L}_2$$

Known are: $\bar{X}_1, \bar{X}_2, \bar{K}_1, \bar{K}_2, \bar{L}_1, \bar{L}_2$. If a were known, one could account for the decline in the average annual rate of output increase between periods 1 and 2 in terms of changes in the rates of increase of factor inputs and factor productivity. That is to say, with known a one could account for $\bar{X}_1 > \bar{X}_2$ in terms of:

$$a\bar{K}_1 + (1-a)\bar{L}_1 \geq a\bar{K}_2 + (1-a)\bar{L}_2;$$

and

$$\bar{A}_1 \geq \bar{A}_2$$

The difficulty is to obtain the relative weights for capital and labor (a and $1-a$) in U.S.S.R. transport and communications. Perhaps the most obvious procedure is to use national-income-originating data by distributive shares. Apart from conceptual limitations in this use, such data are not readily available for the U.S.S.R. In addition, in the U.S.S.R. the "owners" of capital do not receive or impute a rate of return to capital as a distributive share. This institutional feature has led other students to introduce nonSoviet data on rates of return or distributive shares, either directly or with guessed adjustments.

To avoid such procedures, I have turned the problem around. Rather than seeking solutions for given a , I ask: for what values of a will specified conditions hold? The first entry in Panel I of Table 4 records the values of a for which:

$$(3) \quad \bar{A}_1 > \bar{A}_2.$$

$$A_1 = \frac{\frac{X_{58}}{X_{51}}}{\left(\frac{K_{58}}{K_{51}}\right)^a \left(\frac{L_{58}}{L_{51}}\right)^{1-a}} = \frac{X_1}{K_1^a L_1^{1-a}}$$

$$A_2 = \frac{\frac{X_{63}}{X_{51}}}{\left(\frac{K_{63}}{K_{51}}\right)^a \left(\frac{L_{63}}{L_{51}}\right)^{1-a}} \div \frac{\frac{X_{58}}{X_{51}}}{\left(\frac{K_{58}}{K_{51}}\right)^a \left(\frac{L_{58}}{L_{51}}\right)^{1-a}} = \frac{\frac{X_{63}}{X_{58}}}{\left(\frac{K_{63}}{K_{58}}\right)^a \left(\frac{L_{63}}{L_{58}}\right)^{1-a}} = \frac{X_2}{K_2^a L_2^{1-a}}$$

TABLE 4—CRITICAL VALUES OF THE CAPITAL SHARE (a) IN U.S.S.R. TRANSPORT AND COMMUNICATIONS

| I. Values of a for which factor productivity increases <i>more rapidly</i> in Period 1 than Period 2: | | | | | |
|---|-----------|-----------|-----------|-----------|-------------------|
| Period 1: | 1951-58 | Period 1: | 1951-53 | Period 1: | 1928-40 |
| Period 2: | 1958-63 | Period 2: | 1953-58 | Period 2: | 1951-58 |
| | > -0.34 | | $> +1.10$ | | $> +2.35$ |
| | | | | | Period 1: 1928-40 |
| | | | | | Period 2: 1951-63 |
| | | | | | $> +1.46$ |
| II. Values of a for which factor inputs increase <i>more rapidly</i> in Period 1 than in Period 2: | | | | | |
| Period 1: | 1951-58 | Period 1: | 1951-53 | Period 1: | 1928-40 |
| Period 2: | 1958-63 | Period 2: | 1953-58 | Period 2: | 1951-58 |
| | $< +0.37$ | | $< +0.54$ | | $< +2.64$ |
| | | | | | Period 1: 1928-40 |
| | | | | | Period 2: 1951-63 |
| | | | | | $< +1.88$ |
| III. Values of a for which factor productivity increases <i>within</i> indicated period: | | | | | |
| 1951-58 | 1958-63 | 1951-53 | 1953-58 | 1928-40 | 1951-63 |
| $< +2.43$ | $< +1.10$ | $< +7.57$ | $< +2.11$ | $< +2.68$ | $< +1.66$ |

Sources and Methods: The critical values of a are those which satisfy the inequalities (3), (4) and (5), pp. 1162 and 1164. The underlying data are in Table 3, Cols. (1), (2), and (4).

That is to say, the values of a are those for which the average annual rate of increase of factor productivity in 1951-58 *exceeds* that in 1958-63. The first entry in Panel II records the values of a for which the rate of increase of combined factor inputs in 1951-58 *exceeds* that in 1958-63: i.e., the values of a for which

$$(4) \quad a\bar{K}_1 + (1 - a)\bar{L}_1 > a\bar{K}_2 + (1 - a)\bar{L}_2.$$

The first two entries in Panel III records the values of a for which factor productivity increases in *each* of the periods 1951-58 and 1958-63: i.e., the values of a for which

$$(5) \quad \bar{A}_t > 0.$$

Other entries in Panels I, II, and III answer the same questions for different periods.

Consider, first, the results for 1951-58 and 1958-63. My desk calculator, unable to distinguish a set of possible or plausible weights from a numerical solution to an equation or inequality, simply grinds out the answer in Panel I that for $a > -0.34$, $\bar{A}_1 > \bar{A}_2$. This is an ignorant but, I submit, important result. It says that for *all possible* capital shares ($0 \leq a \leq 1$), or independently of the weights, the rate of increase of factor productivity in 1951-58 exceeds that in 1958-63. In Panel II, the answer similarly provided is ambiguous: whether the rate of increase of factor inputs in 1951-58 exceeds or is exceeded by that in 1958-63 depends upon whether a is less than or greater than $+0.37$. The answer in Panel III is again unambiguous¹¹ for all possible weights, factor productivity increases in both 1951-58 and 1958-63.

Thus, something has been added in explanation of the decline in average annual rates of output increase between 1951-58 and 1958-63. It is not clear whether the rates of increase of factor inputs have similarly declined: to know this one needs to know the appropriate weights for capital and labor. No matter what this answer is, however, and no matter what the appropriate weights are, the rates of increase of factor productivity have declined between 1951-58 and 1958-63 and so account for at least part of the decline in the rates of output increase.

Moreover, in several respects the results are stronger than indicated by the direction of inequality between 1951-58 and 1958-63 rates of increase of factor productivity.

A. From equations (1) and (2), one can calculate for any given pair of periods the quantitative difference between the rates of increase of factor productivity as a function of a . Numerically, the amount by which the 1951-58 rate of increase exceeds the 1958-63 rate turns out

¹¹ But here it is easy to see: it follows from output increases that are relatively greater than the separate increases in capital and labor.

to be an increasing function of a . Illustrative calculations for 1951-58 and 1958-63 are as follows:

AVERAGE ANNUAL RATES OF INCREASE OF FACTOR PRODUCTIVITY
(per cent per year)

| | $a=0$ | $a=.2$ | $a=.4$ | $a=.6$ | $a=.8$ | $a=1.0$ |
|---------|-------|--------|--------|--------|--------|---------|
| 1951-58 | 8.6 | 7.9 | 7.1 | 6.4 | 5.7 | 5.0 |
| 1958-63 | 7.5 | 6.1 | 4.7 | 3.3 | 2.0 | 0.7 |

Thus, we know not only the direction of inequality but that the quantitative difference lies between 1.1 and 4.3 percentage points. Since the difference between the rates of output increase is 2.4 percentage points (Table 2), the decline in the rate of productivity increase accounts for a substantial amount of the decline in the rate of output increase—for most or all of it so long as $a \geq .05$.

B. Because the average annual rates of increase depend only on initial- and terminal-year values, one might be concerned that the results are strongly influenced by: (a) the selection of 1951 as the initial year of the first period, given 1958 as the dividing year between the two periods; (b) the selection of 1958 as a dividing year between the two periods, especially when the capital value for that year had to be interpolated; or (c) the selection of 1963 as the terminal year of the second period, especially when the output index might have been unduly influenced by the absolute decline in 1963 agricultural output. Accordingly, I have calculated the critical values of a as in Panel I of Table 4 for each of the following alternative pairs of periods: (a) with 1958-62 and 1958-63 as period 2, 1951-58 or 1953-58 or 1954-58 as period 1; (b) with 1959-62 and 1959-63 as period 2, 1951-59 or 1953-59 or 1954-59 as period 1. In all cases the results are the same: all possible capital shares yield an average annual rate of productivity increase in period 1 exceeding that in period 2.

C. Is it possible that the decline in the rates of productivity increase is simply a continuation of past trends and, therefore, of no particular significance? The entries in Panel I point to the uniqueness of the decline. With 1951-53 as period 1 and 1953-58 as period 2, the values of a for which $\bar{A}_1 > \bar{A}_2$ are $a > +1.10$; with 1928-40 as period 1 and 1951-58 or 1951-63 as period 2, the critical values of the capital share are $a > +2.35$ or $a > +1.46$. For these comparisons, *all possible* capital shares yield average annual rates of increase of factor productivity that are *greater* in period 2 than in period 1. (To complete the picture for the earlier periods, note from Panels II and III that the rate of increase of factor inputs clearly declines between the prewar and postwar periods, that the direction of change between 1951-53 and 1953-58 is ambiguous,

and that factor productivity increases within each of the periods represented.)

D. Because of the conjectural nature of several aspects of the index of transport and communications output, it is certainly legitimate to ask whether the observed decline in the rate of increase of factor productivity is anything but a numerical consequence of particular and sometimes arbitrary "solutions" to data problems. Although I am unable to comment on this directly, I have undertaken similar computations for industry, agriculture, the nonagricultural economy and the economy as a whole. In each of these cases: (a) the rate of output increase declines between 1951-58 and 1958-63; and (b) the search for critical values of the capital share leads to the conclusion, as here, that for all possible values of the capital share the rate of increase of factor productivity declines between 1951-58 and 1958-63. These results will be submitted in a subsequent paper.¹²

¹² In that paper I proceed in a somewhat different fashion. I assume a Cobb-Douglas linear homogeneous production function with neutral technical change. With these assumptions, the index of technical change is formally identical with the index of factor productivity as constructed here and, indeed, all the equations and inequalities used here are identical with those arising from the production function assumptions. The major difference between the two approaches is the economic meaning of a and $1-a$. With the production function assumptions, a and $1-a$ are constant distributive shares or constant proportional marginal productivities. In the present construction of an index of factor productivity, a and $1-a$ are fixed weights for capital and labor weights whose appropriate definition may be distributive shares or proportional marginal productivities but which refer only to the weight-year.

Here, I have treated the problem as a straightforward matter of index-number construction for two reasons: (a) as an economy of exposition; and (b) as an analgesic for any who might be restive with the production function assumptions or their application to transport and communications. In so doing I have lied by omission but not really very much as the following remarks are intended to show.

1. I have used the geometric form of an index of factor productivity precisely because it is consistent with a Cobb-Douglas linear homogeneous production function with neutral technical change.

2. On the other hand, the geometric form represents a perfectly legitimate index number in itself. In principle, one should check index numbers for sensitivity to alternative weights but this is not necessary in my use for I obtain results independent of the weights. Some may observe that I never specified the year to which the weights refer and that the algebra in (fn. 10), seems to imply 1951 as the weight-year when 1955 weights are used for the output index. Note, however, that: (a) an extension of the algebra in that footnote would preserve the results for 1955 weights throughout, and (b) when index numbers are compared over more than one period, it is inevitable that terms appear with weights that refer to neither year in at least one of the periods. Note, also, that the problems which arise from an admixture of arithmetic and geometric methods of aggregation (in the output and productivity indexes, respectively) arise in both the index number and production function approaches.

3. Although the geometric form of the index number is legitimate, it is less frequently used than the arithmetic form. However, the arithmetic form of a productivity index also has implicit production function assumptions and, perhaps, less credible assumptions than Cobb-Douglas: namely, a production function in which the marginal product of either factor does not depend on the quantity of the other, a production function with infinite elasticity of substitution.

4. Whatever the relative merits of the geometric and arithmetic indexes, my results do not

depend on the choice I have made. Define indexes of factor productivity, A'_1 and A'_2 , in arithmetic form as follows:

$$A'_1 = \frac{X_1}{aK_1 + (1-a)L_1}; \quad A'_2 = \frac{K_2}{aK_2 + (1-a)L_2}$$

where X_1 , X_2 , K_1 , K_2 , L_1 , L_2 , and a have the same meanings as above where periods 1 and 2 are 1951-58 and 1958-63, respectively. Inserting the values for X , K , and L , taking logarithms and dividing by N_1 and N_2 , one can determine by numerical methods that $\bar{A}'_1 > \bar{A}'_2$ for a ≥ -0.40 , approximately. Recall the comparable figure in Table 4: $a > -0.34$.

ALTERNATIVE INTEREST RATES AND THE DEMAND FOR MONEY: THE EMPIRICAL EVIDENCE

By TONG HUN LEE*

Despite voluminous literature on the influence of various interest rates on the demand for money, opinions vary widely as to which interest rate or subset of alternative interest rates is a relevant determinant of the demand for money. Eisner [6] and Latané [19] [20] favor an interest rate on long-term bonds, since Keynesian economics links a long rate to investment and income through the demand for and supply of money. Brunner and Meltzer [3] and Hamburger [15] argue that the demand for money should be treated in a theory of broader portfolio selection and suggest that the demand for money depends on the yield on equities as well as on bonds. Bronfenbrenner and Mayer [2], Teigen [24], Heller [16], and Laidler [18], on the other hand, take a position that the demand for money is a function of a short-term interest rate, as the short rate indicates the opportunity cost of holding money in place of close substitutes. Gurley and Shaw [11] [12] [14] [13] take a step farther to argue that liquid assets such as savings deposits at nonbank financial institutions are closer substitutes for money and, therefore, that the demand for money depends on interest rates on nonbank intermediary liabilities.

Although the demand for money is theoretically a function of a whole spectrum of interest rates, the principal issue is an empirical one: Which interest rate approximates "the" rate of interest and exerts the most significant influence on the demand for money? An answer to this question has important implications for monetary theory and policy. Recent empirical works by Heller [16], Hamburger [15], and Laidler [18] in this area are limited to an investigation of a short rate versus a long rate or a long rate versus the yield on equities. They ignore interest rates that are relevant for other hypotheses. Moreover, these studies do not use the differentials between their interest rates and the yield on money such as demand deposits.¹

* The author is professor of economics, University of Wisconsin-Milwaukee, and a member of the Social Systems Research Institute, University of Wisconsin, Madison. He is indebted to the National Science Foundation for financial support of this research under grant GS-631. Thanks are due to Guy H. Orcutt for his constant encouragement in this research undertaking and to David A. Patterson for his helpful comments on the first draft of this paper. The constructive comments of the editor and an anonymous referee are gratefully acknowledged. The author, however, remains solely responsible for any errors and for the views expressed in this paper.

¹ Hamburger and Laidler recognize that the relevant interest-rate variables should be mea-

The present paper removes these deficiencies and shows that contrary to other claims, the yield on nonbank intermediary liabilities is the most significant interest rate variable in affecting the demand for money. The conclusion is thus consistent with my earlier results published elsewhere [21] that savings deposits at nonbank financial institutions are close substitutes for money. The present study also reveals a plausibility of the Baumol-Tobin-Whalen hypothesis [1] [26] [29] of economies of scale in holding cash for transaction and precautionary purposes. It further shows an effect of close money substitutes on measuring the rate of adjustment between the desired and the actual levels of money holdings. In addition, empirical results in this paper have some bearing on the question of the proper definition of money that is relevant for monetary theory and policy.

I. *Approach and Data*

The model employed for the analysis is a variety of Friedman's permanent income formulation [8] of the demand for money. This approach is chosen partly because recent papers [17] [4] report permanent income as a better explanatory variable than nonhuman wealth and/or current income and partly because the wealth data for the recent past is not available. The demand function is specified as

$$(1) \quad M' = f(Y_p, r')$$

where Y_p is per capita real permanent income, M' denotes per capita money stock in real terms for the traditional concept of money, and r' represents a vector of interest rate differentials between yields on other assets and the yield on money. The yield on traditionally defined money is derived as the weighted average of rates of return on demand deposits (the negative of service charges) and currency (zero). The price deflator employed for real variables is current price rather than permanent price.² This static model can be cast into a dynamic stock adjustment model of Chow [4] and Teigen [24] varieties by introducing a lagged dependent variable, M'_{-1} , as

$$(2) \quad M' = g(Y_p, r', M'_{-1})$$

Demand functions (1) and (2) for the traditional concept of money can be adjusted for Friedman's concept of money. For this purpose,

sured by the interest-rate differentials. They, however, dismiss the use of this measure for the reason that the interest-rate differentials cannot be either computed with quarterly data or extended over a long period with annual data.

² Use of permanent price as a deflator in a preliminary investigation did not alter the following conclusions to any significant extent.

money defined to include time deposits, M'' , is substituted for M' for the current and lagged variables, whereas interest rate differentials between yields on other assets and the yield on money so defined, r'' , is substituted for r' . The yield on money defined to include time deposits is measured by the weighted average of rates of return on time deposits, demand deposits, and currency. Detailed definitions and symbols used in the analysis are as follows:

| Symbols | Definitions ³ |
|--|---|
| M' : | Per capita currency and demand deposits held by the public in real terms |
| M'' : | M' plus per capita commercial bank time deposits held by the public in real terms |
| Y_p : | Friedman's permanent per capita net national product in real terms |
| r'_t : | The yield on commercial bank time deposits minus that on M' |
| r'_{s1} : | The yield on savings and loan association shares minus that on M' |
| r'_s : | The yield on four-to-six month commercial paper minus that on M' |
| r'_1 : | The yield on twenty-year corporate bonds minus that on M' |
| r'_e : | Moody's dividend yield on common stocks minus the yield on M' |
| r''_{s1} ; r''_s ; r''_1 ; r''_e : | The respective yields minus the yield on M'' |

The short rate, the long rate, and the yield on equities above are chosen primarily because they are the variables that Laidler [18] and Hamburger [15] used in their tests to show the relative importance of interest rates in affecting the demand for money. The choices of these variables among other relevant measures are not of crucial importance in yielding the following results.⁴

The period covered in this study is from 1951 to 1965, a period of relatively homogeneous institutional settings, following the 1951 Federal

³ Money stock series are the simple averages of the recently revised monthly series obtained from the 1966 September issue of the *Federal Reserve Bulletin*. The yields on demand deposits and time deposits that are required in computing the interest rate differentials are obtained from issues of the *Annual Report of the Federal Deposit Insurance Corporation*. The yield on savings and loan association shares comes from the 1966 *Savings and Loan Fact Book*. Permanent per capita net national product in current dollars is computed by the same method as that used by Friedman and Schwartz [10] and is deflated by implicit price index for gross national products.

⁴ In a preliminary investigation, interest rates on short-term and long-term government securities were used rather than those on four-to-six month commercial paper and twenty-year corporate bonds. The results from this experiment did not differ from those reported in this paper.

Reserve Accord with the Treasury and the 1950 revision of the Federal Savings and Loan Insurance Corporation insurance regulations.⁵ It also captures the characteristics of money-demand function associated with the revival of monetary policy.⁶ It can be assumed that during this period the supply schedule of money has been shifted by a Federal Reserve policy less reliant on movements of interest rates and the needs of trade. Although what is known as the identification problem in econometrics is not completely resolved in this study, use of this particular period should help to identify the effects of interest rates and permanent income on the demand for money.⁷

II. *Empirical Results on Money Substitutes*

Log-linear forms of equations (1) and (2) for the traditional concept of money are fitted to the data by the least squares method, using single interest rate differentials of alternative rates. The results in Table 1 show that regression equation (1.2) or (1.7) with the yield on savings and loan shares performs the best in terms of \bar{R}^2 among respective regressions of static or dynamic formulation. Hence, regressions are recomputed in Table 2 with two interest rate differentials using both the yield on savings and loan shares and the yield on other assets. These results indicate that in all of the regression equations, the coefficients of the yield on savings and loan shares remain highly significant. The yield on time deposits appears to have a modest effect on the demand for money, but the elasticity of time deposit rate is smaller than that of the yield on savings and loan shares in regression equations (2.1) and (2.5). Regressions were also recomputed with three interest rate differentials by utilizing the yield on savings and loan shares, the yield on

⁵ In 1950 the insurance provisions of the Federal Savings and Loan Insurance Corporation were revised and made more liberal than before in the event of default of an insured savings and loan association. As I have shown elsewhere[21], the revised insurance provisions have since made savings and loan shares more comparable in quality to demand and time deposits. Therefore, if a role of near-money in affecting the demand for money is to be compared with that of other assets, one should focus attention on this period.

⁶ The data for various interest rates used in the analysis are available for years after 1933, but Friedman's permanent income series based on recently revised national statistics can only be computed for the years after 1938. The reason for the latter is that Friedman's scheme of weighting the present and past values of net national products involves 11 years and the revised net national product series goes back only to 1929. Omitting the World War II years and the bond price support years out of 1939-65 period, the available observations that are left out of this analysis are the two-year observations of 1939-40. An experiment including these two observations, however, did not alter the conclusions drawn in the following analysis.

⁷ That the identification problem is not a crucial factor affecting the following results is demonstrated by the fact that my earlier cross-sectional estimates from the household survey data [21] conform to the following results concerning the substitutability of nonbank intermediary liabilities for money. As is well known, the demand function of individual households estimated from micro-cross-section data is not likely to pose a serious identification problem.

TABLE 1—LOG-LINEAR REGRESSION EQUATIONS FOR THE TRADITIONAL CONCEPT OF MONEY USING INTEREST-RATE DIFFERENTIALS: ANNUAL DATA, 1951-1965

| (1.10) $M' = -.131 + .208 Y_p + .063 r'_s + .939 M'_{-1}$ (1.05) (.810) (5.92)** | $\bar{R}^2 = .938^{**}$ | $DW = 2.08^*$ |

Note: Numbers in parentheses are t statistics. The symbol * or ** on the t statistics and \bar{R} indicates that the relevant statistic is significantly different from zero at the 5 per cent or 1 per cent level, respectively. The symbol * or ** on the Durbin-Watson statistics indicates that the null hypothesis of residual independence in the relevant equation cannot be rejected at the 5 per cent or 1 per cent level of significance. The tests of the Durbin-Watson statistics are based on the Theil-Nagar testing procedure [25].

time deposits, and still another yield on the rest of other assets. Although not reported in the paper, the results are the same as before: savings and loan shares are the closest substitutes for money, whereas time deposits at commercial banks are modest substitutes for money. Stepwise regressions were computed in this manner adding successively one more interest rate differential, etc., but the results indicated the same conclusion as before. Finally the regression equations with all the interest rate differentials enumerated above were computed with or

 \end{aligned}$$

where all variables are in natural logarithms and figures in parentheses

are t statistics. The coefficients of the yield on savings and loan shares remain highly significant while those on time deposits now melt away after introducing all other yield variables.⁸ It is quite evident through these successive tests that savings and loan shares are the closest substitutes for money among time deposits, short-term paper, long-term bonds, and equities.⁹

The estimated demand functions for Friedman's concept of money with single and two interest rate differentials are reported in Tables 3 and 4 respectively. They again show similar results that savings and loan shares are the closest money substitutes among alternative types of assets. The upshot of this evidence can also be seen by the following regressions:

$$(5) \quad M'' = 2.65 + .670 Y_p - .688 r_{s1}'' - .037 r_s'' + .037 r_1'' - .050 r_e''$$

(2.97)* (6.93)** (1.86) (.535) (1.28)

$\bar{R}^2 = .933^{**}$
 $DW = 1.28$

$$(6) \quad M'' = 1.71 + .531 Y_p - .553 r_{s1}'' - .044 r_s'' + .049 r_1''$$

(2.09) (3.59)** (2.13) (.715)

$$- .050 r_e'' + .265 M_{-1}''$$

(1.29) (1.14) $\bar{R}^2 = .934^{**}$
 $DW = 1.18$

One must then conclude that, no matter which definition of money

⁸ Although the coefficients of the yield on time deposits become weak in above regression equations, the yield on time deposits may still be an important variable in affecting the demand for money. In regression equations (2.1) and (2.5) the yield on time deposits as well as on savings and loan shares exerts significant influence on the demand for money while in regression equations (2.2)–(2.4) and (2.6)–(2.8) the yields on other assets do not. In regressions (3) and (4), the inclusion of the yields on other assets as regressors blurs the effect of time-deposit rates on the demand for money, but the coefficients of the yields on other assets again turn out to be insignificant. The weak effect of time-deposit rates in these equations may, therefore, be partly due to the increased noise of statistical multicollinearity when the apparently insignificant variables are added as regressors in the annual time-series analysis. Another partial cause may be the use of time-series data containing the period of the 1950s in which time deposit rates were kept substantially lower than other interest rates through maximum rate control on time deposits under Regulation Q. My cross-sectional estimates covering this period [21] indicate insignificant effects of time-deposit rates on the demand for demand deposits. Thus, the present result may have been heavily weighted with annual observations of the 1950s, while changes in the yield on time deposits may, in fact, have significant effects on the demand for money in a more competitive rate structure of the 1960s.

⁹ Reasonably stable regression coefficients on the yield on savings and loan shares in the successive tests actually demonstrate that the results are not distorted by statistical multicollinearity. The use of lagged dependent variables usually removes a time trend from the regression analysis, but it does not affect the present conclusion.

is used, the demand for money is highly sensitive to changes in the yield on savings and loan shares, and savings and loan shares are the closest substitutes for money. The first of the two conclusions above can also be confirmed by my previous study [21] in which I used cross-sectional aggregate data by states as well as household survey data and employed time-series data with a limited number of interest rate variables. These findings, therefore, reject such other claims that: (1) long-

III. Implications for Other Related Hypotheses

The present study has important bearings on a number of controversies connected with monetary theory and policy. One of them is related to "the" proper definition of money. Traditionally, money is defined to include currency and demand deposits for the reason that these assets represent means of payment. On the other hand, Friedman and Schwartz [10, p. 650] propose to broaden the definition of money by arguing that the term, money, should "refer not solely to a medium of exchange but also . . . to a temporary abode of purchasing power. . . ." Thus, Friedman and his associates [8] [9] [10] adopt a broad concept of money to include time deposits with the assumption that time deposits are close or even perfect substitutes for currency and demand deposits while savings and loan shares are not. The findings of the preceding section do not support their assumption. My earlier results from cross-section data reported elsewhere [21] also indicated that savings and loan shares were closer substitutes than were time deposits.

Laidler [18] among others argues that Friedman's concept of money is superior to the traditional one, since the predictability of the money demand function for Friedman's concept is better than that for the traditional concept. Comparisons of \bar{R}^2 for the relevant regressions of the preceding section show that when Laidler's criterion is used, Friedman's concept of money works much worse than the traditional concept of

money.¹⁰ Laidler further argues that the estimated demand functions for Friedman's concept of money are much stabler over time than those for the traditional concept of money. Although this may be one of the criteria for choosing a particular definition of money, the stability question cannot be answered from regression analysis unless the money demand function is correctly specified. The demand functions investigated by Laidler do not incorporate the yield on savings and loan shares as an independent variable. Moreover, as Heller [16] shows, the tests of the stability of regression estimates from annual time series are misleading. In fact, using quarterly data, Heller concludes that Friedman's as well as the traditional concept of money yields equivalently stable money demand functions. Heller's conclusion cannot be investigated in this study owing to the lack of quarterly data on the yields on savings and loan shares and time deposits. But it is clear that Friedman and his associates as well as Laidler are not able to justify their reasoning for proposing the broad definition of money. Although the proper definition of money relevant for monetary theory and policy is an open question, if their criteria are used, the results in this paper provide evidence against Friedman's definition of money.

The estimated coefficients of lagged dependent variables in this study also have some implications for the question of how rapidly income responds to money-supply changes. Tucker [27] in a recent article shows under a dynamic Keynesian framework that if distributed lags in the demand for money in response to changes in interest rates exist, the money-demand lag tends to offset long distributed lags in investment in response to changes in interest rates. Thus, utilizing the money-demand lag and other parameters estimated by prior studies, Tucker attempts to show that the money-supply changes affect income and production rather rapidly. The money-demand lag used by Tucker and those estimated by others, however, do not reflect the speed of adjustment when there are close substitutes for money such as savings and loan shares. In all of the functions estimated for both the traditional and Friedman concepts of money, the coefficients of lagged dependent variables become statistically insignificant whenever the yield on savings and loan shares and/or the yield on time deposits are introduced in the demand functions. This result is not surprising. When money holders can substitute highly liquid assets for money without incurring much time, effort, and transaction costs, as is likely to be the case for savings deposits, the behavioral lags of actual money holdings in response to

¹⁰ Although not reported in the paper, the standard errors of estimates of the regression equations for Friedman's concept of money are larger than those of the corresponding regression equations for the traditional concept of money. It should also be noted that the former regressions do not show the independence of residual disturbances while the latter regressions do in the relevant cases.

changes in yields on savings accounts may be quite small or even zero.¹¹ If this is the case, a quick response of income and production to monetary policy has to be explained through other channels of financial behavior rather than the offsetting effect of money-demand lag on the lags involved in investment.¹²

Recent theories on the holdings of cash balances indicate that when money balances are held for transaction and precautionary purposes, there exist economies of scale in holding money balances. Baumol [1] and Tobin [26] show that optimal transaction demand for cash varies less than in proportion to changes in the volume of transactions or income. Whalen [29] on the other hand shows a similar relationship between optimal precautionary demand for cash and the volume of transactions. Money defined to include currency and demand deposits especially for the period of this analysis is likely to consist of cash balances held for transaction and precautionary purposes rather than for speculative purposes. Since cash balances held for speculative purposes are not tied to current needs of transactions, they can easily be siphoned into liquid, riskless, and interest-bearing assets while awaiting the opportunities for reinvestment in long-term securities. Such liquid assets yielding relatively high rates of return have indeed become more available since 1950. Savings and loan shares became more liquid and secure than before [see footnote 5] and their yields have been kept substantially higher than they were before [see 21]. Moreover, rates on time deposits became more competitive with other market rates in recent years, and an active use of negotiable certificates of deposit in the 1960s would have added to the temporary investment media for speculative demand for cash balances. Therefore, if permanent income is regarded as a measure of the volume of transactions, it is not surprising to find that the permanent income elasticity of the demand for money exclusive of time deposits is less than unity. The estimated permanent income elasticities for the traditional concept of money are significantly less than unity in the relevant regressions (1.2), (2.1)–(2.4), and (3), whereas those for Friedman's concept of money are not statistically

¹¹ Use of quarterly rather than annual data may exhibit a lagged relationship of the money demand function, even when rates on savings and loan shares and time deposits are introduced in the demand functions. Unfortunately, quarterly data on these rates are not yet available. Evidence from annual time series here, however, is sufficient to indicate that the quarterly estimates of time lags in the demand for money reported in other studies [24] [5] are likely to contain considerable upward biases. Hamburger [15] uses a framework which differs from the present one to estimate the time lags involved in household responses to changes in interest rates, but he uses neither the yields on savings and loan shares and time deposits nor the interest rates on short-term securities.

¹² Tucker actually carries out his arguments on the basis of linear rather than log-linear models. Experiments with the linear money-demand functions did not affect the present conclusion. They, in fact, did not affect the other findings of this paper to any great extent.

different from unity in the regressions (3.1), (4.1)–(4.3), and (5).¹³ One may, therefore, observe that there has been improved cash management at least since 1951, not only as a result of an increasing availability of liquid assets but also as a result of higher interest rates on such assets. The world of cash management postulated by Baumol, Tobin, and Whalen, when they emphasized the role of opportunity cost in holding cash balances, may after all depict the financial practices of a modern era.¹⁴

IV. *Conclusions*

Empirical results of this paper show that the relative importance of savings and loan shares with respect to other assets as money substitutes is the most outstanding. This is so whether money is defined to include or exclude time deposits. The evidence is consistent with the substitution hypothesis of Gurley and Shaw and also with my empirical results shown elsewhere that nonbank intermediary liabilities are close substitutes for money.

Since the demand for money is highly sensitive to changes in the yield on nonbank intermediary liabilities, monetary economists henceforth ought to pay more attention to the developments of nonbank financial intermediaries and to their role in affecting the demand for money and the velocity movement in the short run as well as in the long run. The importance of the existence of such institutions should

¹³ One may note that the permanent income elasticity for Friedman's concept of money for the period after 1950 is smaller than, though not significantly different from, unity, whereas the elasticity for the period including earlier years was significantly greater than unity in my previous estimate [21, p. 445]. The postwar rise in income velocity which Friedman *et al.* [8] [10] cannot explain may partly be accounted for in terms of an improved cash management after 1950. Friedman *et al.* explain the postwar rise in velocity with the ad hoc argument of the public's favorable economic expectations concerning postwar economic stability [10, pp. 637–75]. Although Friedman *et al.* may be correct in attributing the velocity rise during the 1946–50 period to postwar economic stability (see for example [21, p. 446]), such an explanation cannot solely account for the rise in velocity for such a long period after 1950. Instead, it can be argued that a more efficient cash management coupled with the increasing attractiveness of nonbank intermediary liabilities is responsible for a reversal after the war of, what Friedman *et al.* call, the secular velocity decline. The evidence that an increasing attractiveness of nonbank intermediary liabilities can account for the postwar rise in velocity is shown in my earlier paper [21, pp. 446–47].

¹⁴ A number of empirical studies in the past [8] [23] [22] [16] [28], however, report conflicting evidence as to the presence of economies of scale in holding money balances. Although space limitation precludes detailed comparisons with the present estimates, they differ mainly in three or more of the following respects: (i) the period of analysis does not conform to that of present analysis; (ii) interest rates on liquid assets are not incorporated in the statistical demand function; (iii) an opportunity cost measured by the differential between the yield on alternative assets and the yield on money is neglected; (iv) the definition of money includes time deposits; (v) permanent rather than current price is used in deflating money stock series; and finally (vi) wealth or current income rather than permanent income is used in measuring the relevant elasticity.

also be reflected in the current theories of the term structure of interest rates. The relevant issue in the term structure theory may be the relationship between the yield on nonbank intermediary liabilities and the long-term or the short-term interest rate rather than that between the short-term and the long-term rates.

The results in this study do not support the rationale used by Friedman *et al.* for the broad definition of money. The study also shows evidence that distributed lags of the demand for money in response to interest rate changes are negligible when the yields on close cash substitutes are incorporated into the money demand function. The evidence, therefore, does not support Tucker's explanation that a speedy reaction of economic activities to money-supply changes can take place through the offsetting forces of lags in investment and lags in money demand within a simultaneous economic system. This study, contrary to empirical results by others, further shows a plausibility of the Baumol-Tobin-Whalen hypothesis that there are economies of scale in holding cash for transaction and precautionary motives.

The several questions posed in this paper can generally be explained in terms of an increasing availability and attractiveness of close cash substitutes. There are other obvious ramifications in these questions that cannot be handled in a short paper. Nevertheless, this paper shows that liquidity should be an important consideration in studying the demand for money and a significant degree of the liquidity is generated by the presence of nonbank intermediary liabilities of recent years.

CHANGES IN THE COSTS OF TREATMENT OF SELECTED ILLNESSES, 1951-65

By ANNE A. SCITOVSKY*

The idea of a medical care price index based on the average costs of treatment of specific illnesses rather than on the prices of selected items of medical care as is the Bureau of Labor Statistics medical care price index has been in the air for quite a while. Some years ago, the writer gave a paper describing how such an index could be constructed and discussing its advantages over the present index [2, pp. 128-42]. The research project some of whose results this paper analyzes was the direct outcome of this discussion and had a twofold purpose: (1) to explore if it was feasible to estimate average costs of treatment of specific illnesses, and (2) if it was feasible, to estimate the average costs of treatment of a number of illnesses in two different periods and compare their cost changes with the price changes indicated by the medical care price index. The present paper is limited to this second point and concentrates on the principal factors that explain at least to some extent why the cost figures we obtained show a considerably greater increase than the medical care price index shows. To sum up the findings regarding feasibility, the cost-per-episode-of-illness approach was found workable by and large, although some illnesses lend themselves better to it than others. However, it is probably a considerably more costly method than that used by the BLS. An index of this type should therefore not be considered a substitute for the present medical care price index but a possible additional index that would be prepared every few years for purposes of comparison and evaluation of the present index.

To give a brief description of the study, it was carried out under the auspices of the Palo Alto Medical Research Foundation, and the patients studied were treated by physicians of the Palo Alto Medical Clinic in Palo Alto, California, a group practice of about 100 physi-

* The author is senior research associate at the Palo Alto Medical Research Foundation, Palo Alto, California. The research on which this paper is based was supported by U.S.P.H.S. grant No. CH00065 from the Division of Community Health Services. In a somewhat different form the paper was presented at a meeting of the American Public Health Association November 1966. The author wishes to express her thanks to Dr. Marcus A. Krupp, Director of the Palo Alto Medical Research Foundation, for his interest, encouragement and many helpful suggestions; to Mrs. Jeanne LeBrun and Mrs. Kirsten Berg who were responsible for the collection of the data; and to Julius Margolis and Bernard Saffran for their valuable comments and criticisms of the manuscript in various stages of completion.

cians in 1964. Data on treatment and costs were collected from the medical histories and financial records of the Palo Alto Medical Clinic and of the Palo Alto-Stanford Hospital where patients of Palo Alto Medical Clinic physicians are treated when they need hospitalization; for 1964-65, some data were also obtained from the patients themselves who were contacted by questionnaire. With the help of a committee of Palo Alto Medical Clinic physicians, the following ten illnesses were originally selected for study in two periods, 1951-52 (the earliest year for which the Palo Alto-Stanford Hospital still had the patients' ledger cards) and 1964-65: otitis media in children, fracture of the forearm, acute cystitis, treated hypertension, pneumonia proved by x-ray, duodenal ulcer, coronary occlusion, maternity care, acute appendicitis, and cancer of the breast. The selection of these illnesses was guided by the following criteria: the illnesses should be common illnesses or representative of a group of common illnesses (e.g., pneumonia was chosen as an example of respiratory illnesses); the sample should include illnesses usually treated entirely on an out-patient basis (e.g., otitis media, acute cystitis), illnesses that always require hospitalization (e.g., appendicitis), illnesses treated on either basis depending on the individual case (e.g., pneumonia, duodenal ulcer), and illnesses which require both forms of treatment (e.g., maternity care, cancer of the breast); the sample should cover all age groups; and the sample should contain roughly the same number of male and female cases. Fairly early in the study, however, it became apparent that we could not get enough usable cases for 1951-52 for five of these illnesses, partly because it would have involved sampling more medical records than we could afford to sample (since the Palo Alto Medical Clinic has only a very incomplete diagnostic file, we had to get our 1951-52 cases by going through old medical records), but even more because the early medical records for these illnesses were rather poor. As a result, the study covered only five illnesses: acute appendicitis, maternity care, otitis media in children, fracture of the forearm (also in children only), and cancer of the breast.

I. Summary of Findings

In the fourteen years from 1951-52 to 1964-65, the costs of treatment of all five illnesses covered by the study (with one minor exception) increased more—some of them substantially more—than the BLS medical care price index. The medical care price index for the United States as a whole rose by 55 to 59 per cent during this period (55 per cent for 1964, 59 per cent for 1965). By contrast, we found the following increases:

TABLE 1—PERCENTAGE INCREASE IN AVERAGE COSTS OF TREATMENT, 1951-52 TO 1964-65

| Illness | Percentage Increase |
|---|---------------------|
| Acute appendicitis | 87 |
| Maternity care | 72 |
| Otitis media in children | 68 |
| Cancer of the breast | 106 |
| Fracture of the forearm ^a | |
| 1. Splint only | 75 |
| 2. Cast only | 55 |
| 3. Closed reduction, physician's office | 110 |
| 4. Closed reduction, hospital | 167 |
| or: | |
| 3. Closed reduction, local or no anesthetic | 87 |
| 4. Closed reduction, general anesthetic | 315 |

^a The cases are grouped by degree of severity as indicated by type of treatment. The second grouping of the cases in categories 3 and 4 is more meaningful because in 1951-52 category 3, "Closed reduction, physician's office," included some cases severe enough to require a general anesthetic which was, however, given in the physician's office, a practice no longer followed in 1964-65.

The differences between the BLS index and our indexes become slightly less if instead of the overall medical care price index we use the BLS index for medical care excluding health insurance, which is more appropriate for this comparison and which rose by 59 to 63 per cent, respectively. Furthermore, according to the BLS, the medical care price index for San Francisco rose slightly more than the national index. Even if we add, say, another five percentage points, the differences would still be pronounced.

II. *Factors Contributing to the Differences Between our Indexes and the BLS Index*

Analysis of our data shows that at least a partial explanation of the differences between the BLS index and our indexes lies in the fact that our cost figures take account of a number of factors affecting costs which the BLS index does not take account of, and most of which make for a greater difference in costs than that measured by the BLS index. (This is not to say that the BLS index *should* take account of all of these factors; this question will be dealt with later.) The importance of these factors varies between different illnesses. Wherever possible, we have tried in our analysis to give at least a rough idea of the order of magnitude of their effect on costs of treatment and hence on the indexes of the illnesses covered by the study.¹

¹ It might be expected that because in our figures for the illnesses requiring hospitalization (appendicitis, maternity care, breast cancer, and forearm fractures treated in the hospital), hospital costs of room and board have a greater weight than they do in the BLS index (11-35 per cent as against 4-9 per cent), this would account for some of the

Changes in Treatment

The most obvious of these factors is changes in treatment which our figures reflect but the BLS index not only does not reflect (except very partially at the occasion of periodic revisions) but deliberately excludes,² since its purpose, like that of the whole Consumer Price Index, is "to measure only the change in price for items of the same quality and quantity customarily bought by urban wage-earner and clerical worker families" [1, p. 1057]. Some of these changes in treatment raised costs (e.g., an increase in the number and variety of laboratory tests or x-rays, or an increase in the use of private or semi-private rooms in place of wards); others, while they did not actually lower costs (at least in our study we did not come across any that did), kept costs from rising as much as they would have risen as a result of price rises only (e.g., a decrease in the average length of hospitalization, or a decline in the percentage of home visits). We found that in the case of appendicitis, breast cancer, and forearm fractures requiring a general anesthetic, the *net* effect of changes in treatment was to raise costs more than they would have risen if only prices had changed. In other words, part of the differences between the BLS index and our indexes for these conditions is due to changes in treatment.³

differences between our indexes for these conditions and the BLS index since the hospital room rate has shown the sharpest rise of all medical care items (139 per cent according to the BLS, about 117 per cent according to our findings). Actually, it does so to a very limited extent only. Changes in treatment and prices raising the relative importance of other medical services, combined with a decrease in the average length of hospitalization in the case of maternity care and breast cancer (i.e., a decrease in the weight given to the hospital room rate as against a constant weight in the BLS index) explain why this factor is relatively unimportant. The increase in costs *exclusive of costs of hospital room and board in both periods* would give us the following increases in costs of treatment during the period covered by our study:

| | |
|--|------------------------|
| Appendicitis | 74% (instead of 87%) |
| Maternity care | 70% (instead of 72%) |
| Breast cancer | 121% (instead of 106%) |
| Forearm fractures requiring hospitalization | 168% (instead of 167%) |
| Forearm fractures requiring a general anesthetic | 297% (instead of 315%) |

² The periodic revisions of the BLS index to take account of changes in family spending do not give full weight to the effect of changes in treatment since additional items are linked in so as not to affect the level of the index at that time. We are using the term "treatment" in a very wide sense, covering not only medical items such as physician visits, laboratory tests, x-rays and length of hospitalization but also type of hospital accommodation (ward, semi-private room or private room) and type of physician visit (office call, home call).

³ In the case of otitis media, the net effect of changes in treatment was to have slowed down the rise in costs resulting from price increases, almost entirely because of the drastic reduction in the percentage of home visits from 35 per cent to 3 per cent of all physician visits; if treatment had remained as in 1951-52, average costs of treatment would have

If treatment in 1964-65 had been the same as in 1951-52, average costs of treatment of appendicitis would have risen by 81 per cent instead of 87 per cent⁴ and those of breast cancer by 78 per cent instead of 106 per cent. In the case of forearm fractures requiring a general anesthetic, the effect of changes in treatment is much more dramatic, accounting for about one-half of the 315 per cent increase in costs of treatment. For in the earlier period, physicians still quite frequently administered a general anesthetic in their office when setting a fracture whereas now this is always done in the hospital.

Medical Care Items Not Priced Separately in the BLS Index

Another factor contributing to the differences between the BLS index and our indexes is the inclusion in our cost data of a number of medical services at their actual prices which the BLS until the 1963 revision of the index did not price separately. The most important of these services are laboratory tests and x-rays in and out of the hospital, use of the operating room and delivery room in the hospital, and anesthesiologists' services. To take account of these items for which it did not collect prices, the BLS assumed that their prices changed by the average amount of all medical care items (exclusive of health insurance) for which it did collect prices. For the period 1951-52 to 1964-65, this is 59 to 63 per cent.⁵ According to our findings, however, the prices of these ancillary services rose considerably more. We found that the prices of laboratory tests rose by 50 to 100 per cent, with an average of 60 to 70 per cent; the prices of x-rays by 55 to 100 per cent, with an average of 60 to 70 per cent; and the operating room and delivery room rates by 108 and 122 per cent, respectively.⁶ Table 2

risen by 105 per cent instead of 68 per cent. In the case of maternity care, the net effect of changes in treatment was neutral, the cost of additional services (mainly laboratory tests) being just about offset by the savings due to the reduction of the average length of hospitalization by almost one day. Treatment of forearm fractures not requiring a general anesthetic was the same in both periods; see, however, pp. 1189-90 below.

⁴ Another factor raising costs above what they would have been as a result of price rises only is the increase in the incidence of perforated cases from about 5 per cent of all cases in 1951-52 to almost 15 per cent in 1964-65; in the latter period, average costs of treatment of these cases were about 64 per cent higher than those of simple acute cases. If both treatment and incidence of severe cases had been the same in 1964-65 as in 1951-52, costs of treatment of appendicitis would have risen only 70 per cent.

⁵ Anesthesiologists' fees were assumed to change like the average fees for physician services for which the BLS collected data. For the period covered by our study, this would mean an increase of about 54 per cent. Our data show a rise of 80 to 90 per cent.

⁶ Operating room charges as they appeared on hospital ledger cards rose by only about 64 per cent, and delivery room charges by 33 per cent. However, in 1951-52 these charges included anesthesia supplies for which there was a separate charge in 1964-65. The above figures of 108 and 122 per cent refer to the increase in operating and delivery room charges including anesthesia supplies. We found that this practice of breaking up charges into separate items has become considerably more common in recent years and has to be watched for when making price comparisons between different years.

TABLE 2—RELATIVE IMPORTANCE IN AVERAGE COSTS OF TREATMENT OF ITEMS NOT PRICED SEPARATELY IN THE BLS MEDICAL CARE PRICE INDEX, BY ILLNESS, 1951-52 AND 1964-65

| Illness | Percentage of Average Costs | |
|---|-----------------------------|---------|
| | 1951-52 | 1964-65 |
| Appendicitis | | |
| Anesthetist fee | 7.2 | 7.5 |
| Laboratory tests | 4.0 | 7.5 |
| Operating room (and post-operative room in 1964-65) | 12.2 | 15.0 |
| Intravenous solution | .5 | 1.8 |
| Total | 23.9 | 31.8 |
| Maternity care | | |
| Anesthetist fee | 7.0 | 5.3 |
| Laboratory tests | 1.9 | 5.6 |
| Delivery room | 10.3 | 13.1 |
| Total | 19.2 | 24.0 |
| Cancer of the breast | | |
| Anesthetist fee | 6.4 | 5.4 |
| Laboratory tests | 4.7 | 4.8 |
| Operating room (and post-operative room in 1964/65) | 8.6 | 10.7 |
| x-rays, diagnostic | 1.0 | 2.3 |
| Radiation therapy | 3.7 | 14.2 |
| Medical/surgical supplies | 4.1 | 1.9 |
| Total | 28.5 | 39.3 |
| Fracture of the forearm, splint only | | |
| x-rays | 36.1 | 43.5 |
| Fracture of the forearm, cast only | | |
| x-rays | 32.3 | 36.8 |
| Fracture of the forearm, closed reduction, physician's office | | |
| x-rays | 36.1 | 26.6 |
| Fracture of the forearm, closed reduction, hospital | | |
| x-rays | 21.4 | 16.5 |
| Operating room | 7.2 | 8.0 |
| Anesthetist fee | 12.0 | 10.0 |
| Total | 40.6 | 34.5 |

gives an idea of the relative importance of these items in our cost data for the different illnesses in the two periods. As the table shows, these items accounted for 19 to 40 per cent of total costs of treatment, depending on the illness. It goes without saying that their relative impor-

tance in total medical care costs would be considerably less; we shall deal with this briefly later on.

*Differences Between Customary Fee and Average Fee:
the Closing Gap*

The difference between the BLS method of estimating changes in physicians' fees and our way of arriving at them is yet another reason why our figures show a greater cost increase than the BLS index. When the BLS compares physicians' fees for the same service in two periods, it compares the fees physicians report as their customary fees. By contrast, in our study we compared actual average fees at different times. We found considerable evidence not only that in the past there was much more variation around this customary fee than there is today, but also that the actual average fee charged often was substantially below the customary fee, whereas today the two either coincide or are very close. To put this differently, there is evidence that in the past physicians adjusted their fees more to patients' ability to pay, with discounts having been more general (and possibly more substantial) than higher charges. As an example, the table below shows pediatricians' customary and average fees in the two periods which we found in our study of otitis media, and the increase in customary as against average fees.

TABLE 3—CUSTOMARY AND AVERAGE FEES FOR OFFICE AND HOME VISITS
BY PEDIATRICIANS, OTITIS MEDIA, 1951-52 AND 1964-65

| | 1951-52 | 1964-65 | Percentage Increase |
|---|---------|----------------------|---------------------|
| Customary fee for office visit | \$ 4.00 | \$ 7.50 | 87.5 |
| Average fee for office visit | \$ 2.74 | \$ 6.70 | 144.5 |
| Customary fee for home visit | \$ 6.00 | \$12.00 ^a | 100.0 |
| Average fee for home visit | \$ 5.33 | \$12.33 | 131.3 |
| Average fee for office visit as a percentage of customary fee | 68.5 | 89.3 | — |
| Average fee for home visit as a percentage of customary fee | 88.8 | 102.8 | — |

^a This was the customary fee in the daytime. After hours and on weekends it was \$15.00. This explains why the average fee as a percentage of the customary fee for home calls was more than 100 per cent in 1964-1965.

As the table shows, the customary fee for an office visit rose by 88 per cent while the average fee increased by 145 per cent; similarly, the customary fee for a home visit doubled while the average fee rose by 131 per cent. Other examples, although less striking, are surgeons' fees for an appendectomy and their fees for a mastectomy. While the custo-

mary fee for an appendectomy was \$200 in 1951-52 and \$250 in 1964-65, an increase of 25 per cent, the actual average fee in 1951-52 was \$182 (or 91 per cent of the customary fee) as against \$251 (about the same as the customary fee) in 1964-65, an increase of 38 per cent. The corresponding figures for the mastectomy fee are an increase of 43 per cent from \$350 to \$500 in the customary fee, and 58 per cent from \$314 (about 90 per cent of the customary fee) to \$495 in the average fee.

While we did not find this difference between customary fee and average fee, and a diminishing gap between the two, in all the illnesses we covered (for example, in the case of maternity care the two fees roughly coincided in both periods), we nevertheless believe it to be quite an important factor. For it should be pointed out that when calculating average fees we did not count charges that physicians were unable to collect as zero charges: we counted actual charges, whether or not they were paid. Our study of patient ledger cards indicates that the percentage of uncollectable charges has diminished considerably over the period covered by our study. If we took this additional factor into account, therefore, the difference between customary and average fees would have been even larger in 1951-52 and hence the increase in fees and in average costs of treatment greater than our figures show.

Increased Specialization in Medicine

A further factor affecting relative costs in the two periods which is reflected in some of our indexes but not in the BLS index is the increased use of specialists. In our study, this played an important role in raising the costs of treatment of forearm fractures. We found that in the early 1950s, about 60 per cent of such cases were treated by orthopedic surgeons and 40 per cent by other physicians (mainly general practitioners and general surgeons); by 1964-65, orthopedic surgeons treated 89 per cent of all cases, and the remaining 11 per cent treated by other physicians were only the simplest cases requiring a splint only. We also found that in 1951-52—and in 1964-65 in the case of the one form of fracture still treated by physicians other than orthopedic surgeons—fees of orthopedic surgeons for treating a given type of fracture were considerably higher than those of other physicians. For example, in 1951-52 the fee for a closed reduction in the physician's office was about 75 per cent higher if it was done by an orthopedic surgeon rather than by a general practitioner or general surgeon. Similarly, in 1964-65, the fee for treating a fracture requiring a splint only was about double if the attending physician was an orthopedic surgeon rather than a nonspecialist.⁷ To give a rough idea of the effect of this factor on relative costs in the two periods, we have estimated that the

⁷ Actually, we should say a "less specialized specialist" since these days almost every physician is a specialist.

cost of treatment of a forearm fracture requiring a general reduction in the physician's office would have risen by about 56 per cent instead of 110 per cent had it not been for this change-over to specialists. This agrees pretty well with the 55 per cent increase in costs which we found for cases requiring a cast only, all of whom happened to be treated by orthopedic surgeons in both periods.

Change in City Status of Palo Alto

Finally, there is one factor which may have affected our indexes to some extent, causing them to show a greater increase than the BLS index, and that is the change in the status of Palo Alto (where, as mentioned earlier, our study was carried out) from relatively small-town to city status during the period covered by our study. The prices of many goods, including many medical services, tend to be higher in large than in small cities. As a city grows in size, therefore, we would expect these prices to rise quite apart from any general price increases or changes in quality. This may have happened in Palo Alto which in the early 1950s still had some small-town characteristics but by the mid-1960s had not only doubled in size but become part of the metropolitan San Francisco area.

We have little data with which to substantiate this theory, much less to evaluate its importance. The BLS has some data for 1965 that show that physicians' fees for a number of services are higher in large than in small cities. We did a little investigation of pediatricians' fees in Palo Alto and San Francisco in 1951-52 and 1964-65 which showed that in the earlier period the customary fee for a routine office visit apparently was \$4.00 in Palo Alto and \$5.00 in San Francisco while today it seems to be the same in both cities. In other words, the increase was 50 per cent in San Francisco and 87 per cent in Palo Alto. In view of the informality of our investigation, however, we would hesitate to regard these findings as conclusive, especially since we found some evidence that the fees for some other medical services were the same in both cities in both periods; for example, the customary fee for a routine office visit by an internist seems to have been \$5.00 in both Palo Alto and San Francisco in 1951-52, and \$7.50 in both cities in 1964-65, an increase of 50 per cent. Moreover, the same BLS data just mentioned show that many drugs are cheaper in large than in small cities, undoubtedly because of the greater prevalence of cut-rate drug-stores in the former. In view of our lack of adequate data, all we can say is that this factor may possibly have caused some of our indexes to overstate the increase in costs. We doubt, however, that this factor was very important since in both periods Palo Alto was a relatively high-income community where prices probably were pretty much like those in San Francisco.

III. *Evaluation of the BLS Medical Care Price Index in the Light of Our Findings*

What, if anything, can we say about the medical care price index in the light of our findings? It may be presumptuous to attempt even a tentative evaluation on the basis of such a limited study as ours, but we believe a few general statements can be made.

Leaving aside for the time being the problem of quality change (i.e., changes in treatment and the increase in specialization), let us see

TABLE 4—PERCENTAGE INCREASE IN THE PRICES OF SELECTED ITEMS OF MEDICAL CARE,
BLS INDEX AND OUR INDEXES

| | BLS Index 1951-1965 | Our Indexes 1951-52-1964-65 |
|---|--------------------------|--------------------------------|
| Physician fee for office visit ^a | 53.6 | 144.5 (87.5) ^b |
| Physician fee for home visit ^a | 60.3 | 131.3 (100.0) ^b |
| Surgeon's fee for appendectomy | 22.5 ^c | 38.1 |
| Obstetrical case | 63.6 | 56.9 |
| Hospital room rate | 139.2 | 117.1 |
| Drugs and prescriptions | | |
| Antibiotics | 10.1 (30.8) ^d | 31.7 ^e |
| Other drugs | | 31.0 ^e |

^a Fee of family doctor in BLS index, of pediatrician in ours.

^b The figure in parentheses refers to the increase in the customary fee, the other figure to that of the average fee.

^c Increase 1951 to 1963; pricing of this service was discontinued in 1963.

^d The figure in parentheses refers to the increase in the drug index for San Francisco (unpublished BLS data).

^e Based on prices of drugs used in the treatment of otitis media. "Other drugs" are mainly antihistamines, ear and nose drops, and cough medicines.

what we can say about the BLS index, accepting its basic principle of measuring only changes in price, holding the quality and quantity of goods bought constant. Table 4 presents the percentage increase in the prices of a number of medical services as shown by the BLS index and by our indexes.

To take these up item by item, it can be seen that the two sets of indexes are not too far apart on two items: the fee for obstetrical care and the hospital room rate. The same is true for drugs and prescriptions if we compare our index with the (unpublished) BLS drug index for San Francisco which rose by 30.8 per cent rather than with that for the United States as a whole. The difference in the increase of the fee for an appendectomy would probably be somewhat smaller if the BLS figure were for 1965 instead of 1963 (at which time the BLS stopped pricing this service); moreover, what is more important, as was pointed out earlier, the 38.1 per cent increase shown by our data refers to the increase in the actual average fee while we found that the cus-

tomy fee had risen by only 25 per cent, i.e., almost the same amount as shown by the BLS index. It is quite possible, therefore, that as a result of comparing customary instead of average fees, the BLS index for this service understates the increase.

The differences in the indexes for physicians' office and home visits are more difficult to evaluate. Even if we compare the BLS indexes for these services with the indexes we obtained for customary rather than average fees, the differences in the increases shown are substantial (87.5 per cent for our index as against 53.6 per cent for the BLS index in the case of an office visit). As mentioned earlier, we have some reason to believe that pediatricians' fees for office visits, having been lower than those of other physicians in 1951-52 and having caught up with them by now, rose more than those of other physicians. However, assuming that customary fees rose by only 50 per cent (i.e., the probable increase in internists' fees in Palo Alto), our figures would still show a greater increase than the BLS figures if we compare average rather than customary fees; for example, if we assume that the average physicians' fee was 10 per cent lower than the customary fee in 1951-52 (a conservative estimate, in our opinion) but the same as the customary fee in 1964-65, our index would show an increase of 67 per cent as against the BLS figure of 53.6 per cent. Taking everything into account, therefore, we tend to believe that the BLS index for physician visits is on the low side.

To the above possible downward biases of the medical care price index must be added that caused by the BLS method (before the 1963 revision) of estimating changes in the prices of ancillary services; as stated earlier, the BLS index assumed that they rose by 59 to 63 per cent respectively whereas our data indicate that they rose, on the average, by 60 to over 100 per cent. While expenditures on these services are not a major item in family expenditures on medical care, they are not negligible. According to the 1950 survey of consumer expenditures (the latest for which published data are available) [3, p. 10], they accounted for 6 to 14 per cent of average family expenditures on medical care in San Francisco.⁸ An underestimate of their price increase, therefore, would be important enough to be reflected in the medical care price index.

⁸ Data are published by city, and no national averages are given. According to this survey, expenditures in San Francisco on the ancillary medical services included in our data (laboratory tests, x-rays, and operating room) accounted for about 6 per cent of average family medical expenditures, while expenditures for *all* ancillary services accounted for about 14 per cent. The most important additional item included in the latter figure is nursing care which accounted for about 4 per cent of family medical expenditures. So far as we have been able to find out, fees of private nurses, like the prices of ancillary services for which our study has data, have also risen more than 59 to 63 per cent, the increase imputed to them in the BLS index. It seems reasonable, therefore, to conclude that the BLS index underestimated the increase in the average price of ancillary services.

To sum up, we are inclined to think that, accepting what the BLS index sets out to measure, it probably underestimates the increase in the costs of medical care over the fourteen-year period from 1951 to 1965, although we cannot say by how much. In the future, however, it should be a reasonably accurate measure of changes in medical care costs, again accepting its aim and assuming that the health insurance component of the index is accurate. For since the 1963 revision, the major ancillary medical services are priced directly, and the difference between customary and average fees is likely to be of very little importance since it has practically disappeared already.⁹

We can now turn to the problem of changes in treatment and the increase in specialization. As pointed out earlier, both of these factors are not only not taken account of by the BLS index but deliberately excluded on the grounds that they represent changes in quality. What we want to present very briefly in concluding is the case for taking account of them in a medical care price index.¹⁰

Before doing so, a few words should be said about the probable effects of these two factors on medical care costs in general. There is little doubt that increased specialization has raised costs in the past, and the examples we cited from our study are by no means unique. Even physicians would probably agree, justifying the higher fees by the additional training undergone by specialists. The importance of this increase in specialization may be illustrated by the fact that in 1951 the physicians at the Palo Alto Medical Clinic represented 12 fields; by 1964, they represented 21 fields, a change not entirely explained by the growth of the Palo Alto Clinic. For Palo Alto as a whole, the corresponding figures were 18 and 37, respectively. There is every evidence that this trend toward greater specialization will continue, with ever more subspecialization in many fields. Just as today most general surgeons no longer perform orthopedic, gynecological, or thoracic surgery, in the future orthopedic surgeons, for example, will probably split into subgroups, each group specializing on a special part of the body.

⁹ We should like to add, however, that in the future the average fee actually charged may well be higher than what physicians report as the customary fee. Fee schedules are becoming more and more detailed and are distinguishing between services rendered during regular office hours and on weekends or evenings, the fees for the latter being higher. (In our study, we found that this distinction had not yet been made in the early 1950s, though it has been common for some time now.) The customary fee reported would be the regular daytime fee since the majority of visits would be at this fee. As shown in Table 3, as a result of after-hours and weekend visits, the average fee for a house call by a pediatrician was about 3 per cent higher than the customary fee.

¹⁰ Perhaps it should be noted that the writer has completely reversed herself on this point, having argued when originally discussing a medical care price index based on costs-per-episode-of-illness that one of its advantages would be that it would facilitate correcting for quality changes.

The effect on costs of changes in treatment is much less clear-cut and more difficult to evaluate. As mentioned earlier, we found in our study that on balance such changes had raised costs in the case of appendicitis, breast cancer, and forearm fractures requiring a general anesthetic, while in the case of otitis media their net effect was to have slowed down the rise in costs, and in the case of maternity care their net effect was neutral. It would take a much more comprehensive study than ours to estimate the net effect of *all* changes in treatment over the past 14 years. Many physicians have maintained that the medical care price index has overstated the increase in costs by not taking account of changes in treatment, citing the decline in the average length of hospitalization as their main evidence. If forced to make a guess, we would say that the net effect of changes in treatment, at least over the past 14 years, has been to raise costs, and hence that the medical care price index, if it had taken account of such changes, would have shown a greater rise than it did. However, we might get quite different results if we compared costs of treatment in the early or mid-1930s with costs in the mid-1940s. For during this period two dramatic changes in treatment occurred which may well have actually lowered costs: the use of antibiotics and the practice of getting surgical patients on their feet (and out of the hospital) as soon as possible.

To answer the question whether a medical care price index should or should not take account of quality changes, we must ask ourselves what we want such an index to measure or, to put it differently, what use we want to make of it. One of the main uses of the CPI, including the medical care price index, is in labor-management contracts to adjust wages to enable workers to maintain their standard of living. On the whole, it seems reasonable therefore to hold the quantity and quality of items in such an index constant, at least in the short run. When it comes to a medical care price index, however, this is not nearly so reasonable. In the case of most though not all goods, the consumer has a choice between different qualities of the same item. In the case of medical care, his choice is infinitely more limited. He can choose his physician, although today, with the increasing standardization of fees, the price range from which he can choose is narrow; furthermore, even if he decides to consult a general practitioner, he may well get referred to a specialist. He can go to a ward instead of a more expensive room if he has to go to the hospital. He can buy his drugs at a cut-rate drug-store instead of the more convenient corner drugstore. But that just about covers all the choice he has. By and large, we can say that at any given time he can only buy the current quality of medical care. To come back for a moment to the case of the forearm fracture requiring a general anesthetic mentioned earlier, there is no doubt that the pa-

tient is better off if he is given such an anesthetic in the operating room of a hospital equipped for all contingencies than in the physician's office where the risk is much greater. When the question is how much more he has to earn to have his fracture treated than he needed ten or fifteen years ago, however, it does not make much sense to answer this by comparing costs 15 years ago with the estimated costs of the identical treatment today when it is no longer available. The fact that the present treatment is better will increase his welfare; it still leaves him with the problem of how to pay for it.

The above argument can, of course, be extended to other necessities included in the CPI where there has been a forced substitution of a more expensive for a less expensive variety of a product. It does not apply when we consider the other main purpose of the CPI, i.e., its use as a general economic indicator. For this purpose, the present type of index seems preferable. To serve both purposes, therefore, if forced substitution of a higher-quality for a lower-quality commodity is at all common, we might well want two types of CPI, one reflecting price changes only, the other price and quality changes; or alternatively, we might rely on other existing measures of economic activity and let the CPI reflect both price and quality changes. This is a question, however, which goes beyond the scope of the present paper.

DEBT INSTRUMENTS IN BOTH MACROECONOMIC THEORY AND CAPITAL THEORY

By EARL A. THOMPSON*

Economic theorists have always treated the debt instrument as a *deus ex machina*, never fully integrating either governmental or private debt creation into general equilibrium theory. In particular, the literature contains, at best, only incomplete theoretical statements of both the effects of and rationale for debt financing. This paper attempts to complete these statements for worlds not complicated by transaction or information costs.

To do this, the paper raises and offers answers to three questions. First, as regards the effects of debt financing by the government, what tax-subsidy policy is equivalent to a policy of replacing current taxes with government debt? Our answer will serve to specify the exact impact of debt financing on aggregate demand and will point out some fallacies in various modern attempts to introduce government bonds into macroeconomic theory.

The second and third questions concern the rationale for debt financing. The second question is: Does there exist a class of full, general equilibria for which some governmental debt financing policy would improve the allocation of resources in the standard Paretian sense? Our answer is affirmative. Our class of Pareto nonoptimal general equilibria contains as a special subclass that class of golden-age equilibria in which the rate of interest is below the rate of growth. This special subclass has been called "inefficient" in several recent papers on capital theory (the first of which was by Samuelson [18] and the most complete by Phelps [17]). The authors of these papers uniformly purport to demonstrate that perfect competition can readily generate such inefficient equilibria. Our third and final question directly challenges the "demonstrations" of these authors. Its answer, which states that genuinely perfect competition cannot generate such nonoptimal equilibria, will introduce a rationale for the *private* creation of debt instruments in perfectly competitive markets which has been heretofore ignored in standard economic theory.

The second and third inquiries, aided by the results of the first inquiry, will serve to generalize, respectively: (a) Fisherine necessary

*The author is assistant professor of economics, University of California, Los Angeles. He is indebted to his colleague, Armen Alchian, and to a referee of this journal for several comments on previous drafts of this paper.

conditions for Pareto optimality and (b) Fisherine theories of interest rate determination under conditions of perfect competition. These generalizations will amend portions of the results of most of the recent literature on the allocation over time in infinite horizon, general equilibrium settings.

I. *The Effects of Debt Financing by the Government*

A. *The Tax-Subsidy Equivalent*

Our own analysis can be built upon the general analysis of debt financing of Buchanan [3], [4, ch. 28], and Bowen, Davis, and Kopf [2].¹ These authors decompose governmental debt financing, i.e., the replacement of current taxes with new issues of government bonds, into the following two components: (1) a tax component—a replacement of *current* taxes with future taxes of equal present value, and (2) a bond sale component—a current sale by the government of an amount of bonds equal in value to the above reduction in current taxes. The authors utilize their analysis to expose a major fallacy in the textbook doctrine that debt financing cannot shift the real tax burden of a current government expenditure onto future generations. For this first inquiry, we utilize their decomposition, specialized by two assumptions stated below, to derive a simple tax-subsidy equivalent of debt financing. This equivalent exposes what appear to be fallacies in modern attempts to integrate bonds into macroeconomic theory and permits a specification of the exact mechanism whereby debt financing affects current aggregate spending.

Our assumptions are: (1) all taxes, present and future, are lump-sum in nature and perfectly foreseen, and (2) the market in present bonds is perfectly competitive.

Our first assumption serves to restrict the meaning of the tax component of debt financing. The government's replacement of current *lump-sum* taxes with future *lump-sum* taxes would obviously induce no substitutions between real goods so that the only possible changes in the demands for or supplies of real goods resulting from the tax component are due entirely to changes in individual wealths. Since the *aggregate* future tax increase is equal in present value to the *aggregate* current tax reduction, these possible changes in individual wealths can amount to at most a redistribution of wealth among the domestic taxpayers.

While the tax component of debt financing does not induce any sub-

¹ Accordingly, money, a medium of exchange, is excluded from our definition of debt. A debt asset is any financial asset which is valued solely for its interest return. Our assumption of zero transaction and information costs insures that the money rates of interest, or "marginal efficiencies," on all nonmonetary assets are equal.

stitutions between real goods under our assumption of lump-sum taxation, it does induce an increase in the demand for bonds at the initial set of prices (over and above any change in demand which might result from the possible redistribution of wealth). This increase in demand for bonds is exactly equal in value to the tax reduction—given our second assumption that the market for present bonds is perfectly competitive. An explanation of this equality is as follows: Since, before accounting for the possible redistribution of wealth between the various taxpayers, the reduction in each individual's current lump-sum tax payment and equal expansion in his liability for future lump-sum tax payments simply amount to a net loan to the individual, and since the individual had already chosen his optimal borrowing-lending pattern in the perfectly competitive market for present bonds, each individual will put his extra disposable current income from the tax reduction into bonds in order to restore his previously optimal amount of borrowing. This increase in the *demand* for present bonds—taken in conjunction with the equal increase in the *supply* of present bonds which makes up the entire second component—implies that debt financing does not disequilibrate a competitive market for present bonds at the initial set of prices and distribution of wealth. Thus, taking both components together, debt financing has absolutely no effect upon the allocation of resources in the absence of a redistribution of wealth—i.e., in the absence of a difference between the present cost of the extra taxes which any citizen expects to be paying because of the service charges on an increased national debt and the decrease in his *current* tax bill made possible by the debt financing. For with no one's wealth affected at the same prices and rates of interest, excess demands for all goods would be unaltered by the policy. Moreover, when debt financing does redistribute wealth, the economy is affected only because of the redistribution.

Hence, with perfect markets for present bonds and neutral, perfectly foreseen taxes, debt financing is equivalent to either no change or a policy of lump-sum transfer between domestic taxpayers. The gaining citizens, if any, are those taxpayers whose net tax liabilities are reduced due to the government's substitution of future for current taxes; the corresponding, losing citizens are those taxpayers whose net tax liabilities are increased.

B. Application to the Literature on Government Bonds in Macroeconomic Theory

One might think, following an American tradition begun by Hansen [9, pp. 135-222] and carried on into practically every modern textbook discussion of fiscal policy, that an increase in current aggregate

consumption expenditures results from the increase in current aggregate disposable income from the current tax reduction involved in debt financing. But this thought would be basically fallacious, for it completely disregards the equal decrease in aggregate wealth due to the increased future tax liabilities. One might similarly think, following Patinkin [14, ch. 12], [16, ch. 12] or Tobin [20], for example, that debt financing, by increasing the supply of government bonds, would by definition increase the aggregate real wealth of the community. This hypothesis would also completely ignore the liability of future tax payments,² a liability which is exactly equal in value to the new financial asset to each citizen when there are no distribution effects.³ Finally, one might think, following Modigliani [13] or Tobin [20], for example, that the increased supply of government bonds would force a substitution of bonds for real assets and consequently increase the rate of interest on bonds. But this would also be fallacious, for, in the absence of distribution effects, the reduction in current taxes and equal increase in future tax liability increase the value of the demand for bonds at the original interest rate by an amount equal to the increase in the value of the supply of bonds. This is because, at this interest rate, with wealth unchanged, planned streams of expenditures and receipts on the purchases and sales of real assets remain unchanged so that the additional funds required in the future in order to

² As the following inquiries in this paper show, there does exist a special class of imperfectly competitive economies for which a special debt refinancing program will allow some increase in debt to amount to an increase in aggregate wealth. Nevertheless, the types of studies criticized above both assume perfect competition and fail to specify anything like the requisite kind of refinancing operation.

³ Patinkin [14, Ch. 12], referring to the paper of Christ [6], has recently amended his position to allow for some discounting of future tax liabilities. Nevertheless, he maintains that, because of a "distribution effect," at least part of an increase in the supply of government bonds can still represent an increase in aggregate wealth because of an incomplete accounting for future tax liabilities. Following the unfortunate precedent set by Metzler [12], Haberler [8], and Johnson [10], Patinkin specifies neither the kind of redistribution involved nor the method whereby a redistribution gives rise to an incomplete accounting for the future tax liabilities.

It is not difficult, following our own analysis, to produce this missing information. First, since the above authors are discussing open market bond sales rather than debt financing, the current tax decrease in the analysis above must be replaced with an equal increase in the real value of those cash balances which are not used to purchase the bonds. Thus (with real bonds and no money illusion), an individual is a net gainer at the original prices if and only if the increase in the real value of his cash balances exceeds the increase in real value of his future tax liability. For what it is worth, my guess is that sales of *long-term* securities would typically redistribute toward those with the higher marginal propensities to consume out of wealth (viz., those in the older half of the population who will not live long enough to pay a full share of the future taxes), thereby *increasing* the interest rate; but sales of *short-term* securities would redistribute toward those with relatively low marginal propensities to consume out of wealth (viz., the younger adults, who have relatively low taxable incomes), thereby *decreasing* the interest rate.

finance the increased tax liability must be obtained by spending the extra disposable income from the tax reduction on bonds (utilizing the future receipts from these bonds to pay the future tax liability).

C. *Debt Financing and Aggregate Demand*

An immediate implication of the analysis is that, with perfect bond markets and neutral taxes, the popular policy of reducing taxes and expanding the national debt in a recession is completely ineffective in the absence of distribution effects. However, as we now illustrate, such a policy is typically expansionary because it *does* redistribute wealth toward those citizens with high marginal propensities to consume out of wealth: When the older generation succeeds in receiving a current real tax reduction in excess of the present cost of its future real tax payments on the increased debt, the older generation clearly gains at the expense of those who suffer present costs of increased future tax liabilities which exceed their current tax reductions. This kind of redistribution through debt financing is typical in most economies because the old generally share in an income tax reduction but do not live to share in the servicing of new debt. Such a redistribution will increase current aggregate consumption, for an older generation has a marginal propensity to consume out of *wealth* which is close to unity while the younger (and unborn) generations, whose permanent incomes are mere fractions of their wealths, have marginal propensities to consume out of *wealth* which are mere fractions of unity. The resultant decrease in aggregate savings increases interest rates and lowers future wage rates, but the reallocation of resources and price changes occur only because of the wealth redistribution between internal taxpayers.

D. *Introduction to the Next Section*

A government policy that is purely redistributive (via lump sums) is typically regarded by economists to be irrelevant to the Paretian efficiency of a general equilibrium. That is, in general equilibrium, any purely redistributive policy is supposed to make a person better off only by making some other person worse off. Since, as we have seen, debt financing is purely redistributive, it would be conventional to conclude that debt financing is irrelevant to the Paretian efficiency of a general equilibrium—to conclude that if debt financing makes someone better off, it must concurrently make someone else worse off. However, as the following inquiry shows, there is a wide class of general equilibria for which a certain national debt policy will lump-sum redistribute between generations in such a way as to always benefit at least one person without harming any other person.

II. *Debt Financing, Intergenerational Transfers, and the Pareto Nonoptimality of a Class of General Equilibria*

A. *Assumptions and Definitions*

Before specifying the Pareto nonoptimal class of general equilibria and a debt financing policy which leads to optimality, some simplifying assumptions and definitions of relevant concepts are in order.

1. While our results will hold as long as successive generations coexist for some positive amount of time, the discussion below will be restricted to a life-cycle environment in which two and only two successive generations coexist at all times (Cf. Samuelson [18], Diamond [7], and Cass and Yaari [5]). With a constant age of reproduction for all generations, this restriction implies that the length of time that any individual spends in each of the two generations is the same. This length of time is taken to be the length of one "period." New national debt has a debt maturity of one period and all consumptions and fiscal operations are concentrated at the beginning of each period.

2. The rate of interest for a given period is defined as the marginal rate of return over cost, the marginal rate of time preference of the younger generation, and, if an international capital market exists, the international market rate of interest. Hence, all lifetime consumption patterns are assumed to satisfy the usual Fisherian optimality conditions, conditions which will be seen to comprise only *part of* the set of necessary conditions for a Pareto optimal allocation over time.

3. Consumable wealth is defined as that part of wealth (evaluated in terms of current consumer goods) which is marginally transformable at the current rate of interest into current consumer goods. Consumable wealth of the younger generations would be equivalent to the aggregate wealth of the younger generations if, for example, (1) a perfect international market exists for the conversion of claims into current consumer goods, or (2) no resources owned by the younger generations are specific to future production processes. Obviously, consumable wealth can never exceed wealth proper.

We can now proceed to the economic analysis.

B. *The Class of Pareto Nonoptimal General Equilibria*

Consider the class of general equilibria for which the *present* value of the *aggregate* consumable wealth of each younger generation alive an infinite amount of time from now is *infinite*. Because infinity minus a constant is still infinity, a transfer of wealth from the infinitely wealthy generations to the current generation—if such a transfer is technically feasible—would not reduce the present value of the wealth of any generation. As we are about to see, this "transfer" is indeed

technically feasible, at least in a special case, through the use of an appropriate national debt policy.

The special case which we consider here is one in which each period's current interest rate falls short of the percentage increase in the aggregate consumable wealth of next period's younger generation over that of the current period's younger generation by at least some positive constant. This broad class of general equilibria is not further restricted to any particular economic environment; there may exist, for example, any patterns of population growth and technical change, government expenditures and taxation, nonconstant returns to scale, or market imperfections. A simple present value calculation shows that, in this class of general equilibria, the present value of the aggregate consumable wealth of any younger generation alive an infinite time from now is infinite.

What we wish to show is the following: When the percentage increase in the aggregate consumable wealth of the next period's younger generation over that of the current younger generation forever exceeds the real rate of interest in each future period by at least some positive constant, then there exists a debt financing policy which satisfies a Pareto condition—i.e., which makes someone better off without making anyone else worse off.

C. *A Note on a Generalized Theorem*

Before proceeding to our nonmathematical demonstration of this, it should be noted that it is mathematically demonstrable [19]⁴ that, under plausible regularity conditions,⁵ *any* time there exists an infinite present value of the aggregate wealth of all generations born an infinite time from the present, there exists a debt financing policy (e.g., the one described below) which satisfies a Pareto condition. The condition that the interest rate always falls short of the percentage increase in the wealths of the successive younger generations by at least some positive constant is only a special case of the general infinite wealth condition. Nevertheless, this special case—a special case of which has been mathematically established as Pareto nonoptimal by Koopmans and Phelps [17]—will be seen below to be amenable to nonmathematical

⁴ This is available upon request from the Institute of Government and Public Affairs, UCLA, Los Angeles, California, 90024.

⁵ These conditions are: (1) that the intertemporal utility and transformation functions for each generation are continuously differentiable, (2) that there exists a positive constant such that for all generations, the elasticity of substitution of at least one of these functions exceeds this constant, and (3) that all growth rates and interest rates in the pre-policy allocation over time are bounded by some positive constant from above and some constant greater than -1 from below. The latter two conditions also apply to the analysis of the present paper.

examination. My paper [19] shows that if there is also strict convexity of the standard Fisherine intertemporal utility and production-possibilities sets, then the above infinite wealth condition is *necessary* as well as sufficient for the existence of an intergenerational redistribution program satisfying a Pareto condition. (It is also seen that if it is always the case that one of the two Fisherine intertemporal functions is not strictly convex but, instead, representable by a straight line, then the necessary and sufficient infinite wealth condition stated above is replaced by the weaker condition that the present value of the wealth of all younger generations exceeds some positive constant.)

D. The Curative Debt Financing Policy

Our debt financing policy is first to raise the level of national debt, giving tax relief (or direct subsidies) only to the older generation, and then to increase the debt and old-age benefit level in each succeeding period at a percentage rate equal to the real rate of interest in that period. The consequent increase in consumption of the current older generation does not reduce the present value of the consumption of the current younger generation, who will be compensated for their initial loss of consumable assets with both principal and interest by tax relief (or direct subsidies) in their later years financed by the succeeding, as yet unborn, younger generation, who will in turn be compensated like their forefathers through a tax reduction in their old age achieved by the flotation of a still larger amount of national debt. With the ratio of the national debt to the consumable wealth of taxpayers ever decreasing because of the relatively rapid rate of growth of consumable wealth, the process can continue on forever. The current older generation gains and no other generation will lose.

With reduced amounts of consumable assets available to them while they are young, every younger generation will either (1) consume less while they are young, thereby raising their marginal rate of time preference, (2) carry over a smaller stock of consumable assets into their old age, thereby raising the marginal rate of return on cost, (3) import consumable assets, thereby bidding up the world market rate of interest, or (4) choose some weighted combination of the above three actions. Whichever the case, each period's rate of interest rises as a result of our policy. Clearly, the larger the increase in the initial level of the debt, the larger the rise in each period's interest rate.

Once the initial level of the national debt has jumped to a level which forces the resulting rates of interest forever above the corresponding rates of increase of the consumable wealths of successive younger generations, our conventional theorems of the Pareto optimality of a competitive equilibrium become applicable; the present value

of the wealth of generations alive an infinite time into the future is zero. At these rates, we can no longer specify a policy which makes one generation better off without making another generation worse off; any policy such as that suggested above is physically impossible. For a further rise in the initial level of national debt would have to be followed by percentage increases in this debt which are equal to the real rates of interest in order to hold all of the succeeding generations on their original indifference levels; but since this implies that the national debt forever grows relative to the consumable wealth of the young, sooner or later the time would come when the consumable wealth of the young would be less than the national debt and therefore insufficient to cover this generation's real tax bill. In other words, there would be some future older generation that could not hope to increase the national debt and have its real taxes reduced (or subsidies increased) because it would be physically impossible to collect the appropriate taxes from the younger generation. It would therefore be physically impossible to compensate *this* older generation for the consumable assets which it had to surrender in tax payments in order to keep the immediately preceding generation from being made worse off.

Thus, when rates of interest forever exceed corresponding percentage increases in the aggregate consumable wealths of successive younger generations, changes in the national debt serve only to redistribute the finite current wealth between the various taxpayers. But when the opposite relation holds—when the percentage increase in the aggregate consumable wealths of successive younger generations forever exceeds the corresponding rate of interest by at least some positive constant—appropriate increases in the national debt can, in the standard Paretian sense, improve upon the allocation of resources. This is done by redistributing wealth away from generations which will exist an infinite time from now.

E. Application to the Literature on Steady-State Equilibria

Applying our general result to the modern growth model discussion, a steady-state equilibrium, or "golden-age," with an interest rate below the steady-state growth rate of the economy is not only "inefficient" in the "golden-rule" sense, a very special sense which requires a social welfare function that completely ignores the utilities of all nongolden-age generations. It is "inefficient" in the standard Paretian sense, a sense which can be based upon any Bergson Social Welfare Function, a function which counts the utilities of all generations.

Several other authors have also noted that a steady-state with a rate of interest below the rate of growth of aggregate income can be improved in something resembling a Paretian sense (e.g., [1] [5] [18]).

Applied to the steady-state case, our model above is unique in that it shows that the economic problem is necessarily one of the intergenerational distribution of wealth. At the same time, our model both (1) specifies a familiar economic policy which will simultaneously satisfy a Pareto condition and remove the inefficiency by raising the interest rate⁶ and (2) shows why standard analyses of efficiency and equilibrium apply once the interest rate exceeds the growth rate. Most important, an understanding of the distributional nature of the problem is essential in the following inquiry.

III. *The Pareto Optimality of a Genuinely Perfectly Competitive Equilibrium*⁷

A. *The Implications of a Perfect Market in Bond Futures*

The above was not restricted to any particular institutional setting. Nevertheless, in an institutional framework of genuinely perfect competition, it is impossible for the rate of interest to forever fall short of the corresponding percentage increase in the consumable wealths of successive younger generations by at least some positive constant.

The reason is that if interest rates *were* forever this low, *private* firms would proceed to bid up interest rates by issuing new debts to finance current new expenditures in the same way that our optimizing government above issued new debts to finance its current subsidy to the aged. That is, under these circumstances the corporate firm, an institution with an infinite legal life, would rationally adopt the following policy: (1) presently buy real assets by issuing new corporate debt; then, (2) in the next period finance *both* principal and interest on this debt by issuing a correspondingly larger amount of debt; and (3) repeatedly expand the corporate debt in this way, i.e., by selling bonds in return for the consumable assets necessary to service and retire the previous issue. The current stockholders in the corporation could thereby freely acquire current real assets. Since the percentage increase in the consumable wealth of the successive, debt-purchasing younger generations would never fall below the interest rate, each group of younger generations would readily absorb the firm's debt flotation. Hence, with no injured parties, there would be no legal objection to the firm's explicit financial policy. This opportunity to acquire

⁶ Our national debt policy, in contrast to those examined by Diamond [7], satisfies a Pareto condition and therefore *demonstrates* the Pareto nonoptimality of the class of general equilibria described above, a class which contains that specified by Diamond. Diamond does not demonstrate the Pareto nonoptimality of his "inefficient" equilibria, and his suggested policies merely redistribute wealth between *finitely* wealthy generations so as to raise the interest rate. This kind of policy is analogous to redistributing all wealth away from the consumers of a monopolistically sold product in order to remove a familiar monopoly-misallocation.

⁷ Jack Hirshleifer contributed helpful comments on an earlier draft of this inquiry.

current assets at zero cost leads to increases in the amount of *private* borrowing until interest rates are brought to levels sufficiently high that any such financial policy simultaneously fails to satisfy a Pareto condition and would lead to bankruptcy, which is not allowed in a perfectly competitive system.⁸

An orderly method of allotting property rights to the limited number of feasible interest-and-principal refinancing programs, or contracts promising the delivery of future bonds, could be one organized on a first-apply, first-receive basis. For example, an application for a property right could be considered complete once the refinancing plan is made known in bond indentures or the corporate charter.⁹

B. Applications to the Literature on Capital Theory

A straightforward, powerful application of this property of perfectly competitive institutions is that there never can be a negative rate of interest in a perfectly competitive stationary state. For example, this property completely alters the results of the stationary model of Samuelson [18], a purportedly perfectly competitive model which generates social inefficiencies because of negative rates of interest. More generally, rates of interest below golden-age growth rates, i.e., Samuelson-Phelps-type inefficiencies, are impossible in any *genuinely* perfectly competitive equilibrium. Again, when such inefficiencies are present, there are positive profits to private borrowing, with repayment accomplished through a plan of continual refinancing of both principal and interest. Such inefficiencies are simply inconsistent with the existence of perfectly competitive markets in future bonds.

Most other modern growth models, while perhaps of less direct policy relevance than those discussed above, also admit steady-state solutions in which the "competitive" interest rate is below the growth rate.

⁸ In the case that the bankruptcy implies that creditors of the corporation at the time of bankruptcy are not paid off, *no generation* would buy the bonds of the company. This is because creditors in the period immediately preceding any period of bankruptcy depend for *their* repayment on bond sales to creditors who will not buy at any positive price because the company is going bankrupt. In this way, the zero value of the bonds of the company is transmitted from the future to the present. I owe this point to my colleague, Joseph Burns.

⁹ Armen Alchian has suggested an alternative to a market in bond futures. He asserts that the rational family will accomplish the same intergenerational transfer as the futures market. This does appear to be true, at least for a case in which some "family" units always contain members from both generations and the ratios of the consumable wealths of the younger generations of some such family to the corresponding aggregates of consumable wealth of the younger generations are always above some positive constant. Alchian offers as an example the custom, prevalent in many Oriental families, in which the elderly members of the family are supported largely by younger members. Examples of the mechanics of such intra-family, intergenerational transfer systems can be found in Meade [11].

These models should be formally altered by the inclusion of a competitive market in future bonds. This would amputate an entire class of steady-state equilibria from these growth models.

C. *An Empirical Example*

An example of a market in bond futures is found in the establishment and operation of a modern-day "pension fund." In the United States, several insurance companies, industrial corporations, and labor unions set up these funds through "retirement plans" for their workers (or customers in the case of insurance companies, customers purchasing term life insurance). Members of these plans are, in effect, buying bond futures from their companies. A firm offering a retirement plan is typically a "growth company" in that its wage bill (or the total income of its customers in the case of an insurance company) is expected to grow steadily at rates at least approximating market rates of interest. (Such growth policies would not be sustainable if the growth rates of the aggregate consumable wealth of the younger generations were always below the interest rates, for then any such company would sooner or later reach the size of the entire economy and its previous growth policy would be subsequently impossible.) A contributor to such a retirement plan can expect payment of both principal and interest, the source of such payments being a pension fund formed out of earmarked future income, the income generated by the contributions of succeeding generations of contributors. The companies, of course, use the initial contributions for the enrichment of the stockholders, whose aggregate consumption drives interest rates up to the point that any additional pension fund would eventually go bankrupt. In most cases, a license to establish and operate a pension fund is required by a state, an institution responsible for bankrupts.

D. *Policy Implications of an Imperfect Market in Bond Futures*

Introducing market imperfections characteristic of the real world, it may well be that the private transaction costs in effecting transfers from the currently infinitely wealthy generations sometimes exceed the administrative costs of having an efficiently operating government do the same job. In such cases, the efficient government would have the role given to it in the second inquiry. That is, if it were estimated in an actual economy that the present value of the transferable aggregate wealth of the generations born an infinite time from now were infinite, *and* if it were estimated that the transfer benefits in effecting an appropriate policy exceeded the administrative costs of the government policy, then the efficient government would effect a transfer policy such as the debt financing policy specified in the preceding inquiry.

IV. *Conclusions*

Debt financing by the government in any economy with lump-sum taxation and a perfectly competitive market for present bonds is equivalent to a policy of either no change or lump-sum wealth redistribution between the country's internal taxpayers. The consistent application of this equivalency in our macroeconomic models would yield theoretically correct analyses of the expansionary impact of debt financing and open-market operations and would prevent our falling into various, peculiar intellectual traps. In particular, we could not, following Patinkin [14, Ch. 12], [16, Ch. 12], and Tobin [20], for example, believe that debt financing creates only an asset, government debt, which is an additive component of the total wealth of a perfectly competitive economy. We could not, following Modigliani [13] and Tobin [20], for example, believe that governmental debt financing creates a "substitute for real assets," thereby forcing up the rate of interest on these latter assets. Finally, we could not, following Hansen [9, pp. 135-222] and most American textbooks, believe that governmental debt financing increases consumption expenditures simply because the policy increases *current* disposable income.

Despite the fact that any debt financing policy is at most just redistributive, there exists a debt financing policy which makes someone better off without making anyone else worse off in a broad class of general equilibria. Such a policy is to first raise the level of national debt, giving tax relief (or direct subsidies) only to the older generation, and then increase the level of national debt and tax-relief-to-the-aged in every succeeding period at a percentage rate equal to the real rate of interest in that period. The class of general equilibria for which this type of debt financing policy will benefit someone without harming anyone else is the class for which there exists an infinite *present* value of the aggregate consumable wealth of the generations born an infinite time from the present.¹⁰ A general subclass of this class of Pareto non-optimal general equilibria is that characterized by future rates of interest which forever fall short of the corresponding percentage increases in the aggregate consumable wealths of the successive younger generations by at least some positive constant. A special subclass of this subclass of Pareto nonoptimal general equilibria is the class of economies demonstrated to be "inefficient" by Koopmans and Phelps [17]. Another special subclass is the class of "inefficient" golden-age

¹⁰ This general proposition, which holds under the strict convexity of intertemporal production and preference sets, is demonstrated in [19]. Under weak and not strict convexity of at least one set for future periods, the *infinite* wealth condition above is seen to be replaced by an analogous, *positive* wealth condition.

growth paths of Samuelson [18], Diamond [7], Cass and Yaari [5], and Aaron [1], paths characterized by golden-age interest rates which are below golden-age growth rates. All of these "inefficient" economies are Pareto nonoptimal because of faulty distributions of wealth between presently living generations and generations born an infinite time from the present.

Our general class of Pareto nonoptimal general equilibria cannot be perfectly competitive because, in such equilibria, positive marginal profit exists to any corporation that buys additional real assets by financing its purchase through a private debt issue followed by continual interest-and-principal refinancing through future debt issues. Hence, for example, the allegedly perfectly competitive models noted above (i.e., [1] [5] [7] [17] [18]), models which generate explicitly inefficient golden ages, are in fact inconsistent with the existence of a perfectly competitive market for private debt instruments. Most other modern growth models are similarly defective in that they also are allegedly perfectly competitive but generate the class of non-perfectly-competitive, steady-state solutions in which the rate of growth of the economy exceeds the rate of interest. All of these models suffer from the omission of a market in bond futures.

The general methodological implications of our second and third inquiries for the study of perfectly competitive allocations over time can be summarized as follows: We should (1) add to the standard Fisherian necessary conditions for Pareto optimality the requirement that under strict convexity there is a finite present value of the aggregate wealth of some generation born an infinite time from the present, and (2) add to the standard set of perfectly competitive institutions a perfectly competitive market for future debt instruments.

A PRIVATE OWNERSHIP BIAS IN TRANSIT CHOICE

By ROGER SHERMAN*

The continuing defection of public transit riders in big cities suggests that eventual dominance by private automobiles may be inevitable [7, pp. 267-69]. A Chicago survey has indicated that only a very large subsidy would persuade a significant number of auto travelers to switch to public modes [8]. There remains a question, however, whether the private auto is gaining ascendancy by genuine consumer choice or because private costs differ sufficiently from social costs to produce a misallocation of resources in favor of autos. A. A. Walters attempted the difficult analysis of auto travel's social cost using data from several studies and concluded: "In order to make private costs approach social cost we suggest that a *minimum* fuel tax of 33 cents a gallon must be raised" [9, p. 67].¹ C. O. Meiburg raised another allocation issue by pointing out tendencies toward overinvestment in highways through our political decision process, which builds highways to relieve congestion but also distributes them free so that congestion is inevitable [5]. Such studies suggest that present institutional arrangements may not enable consumers to choose the allocation of transit resources they prefer.

On the reasonable assumption that costs decrease for each transit mode, we demonstrate in Section I a bias in consumer choice that favors private autos over public transit. The bias arises as a result of an auto traveler's commitment to auto ownership, which forces a choice between auto and other modes and also makes the average price he pays per mile vary with his usage while for public modes it does not. Also, constant prices for decreasing cost public transit modes can prevent optimal allocation among them, thereby making them a less effective substitute for auto travel. Section II describes one way of financing public transit that will avoid this particular allocation bias.

* Assistant professor of economics, University of Virginia. This research was begun under a Graduate School of Industrial Administration Fellowship at Carnegie Institute of Technology. I am grateful to Professors James M. Buchanan, Kalman J. Cohen, Otto A. Davis, and Allan H. Meltzer for criticism and advice. Any remaining errors are mine.

¹ Walters argues further that railroad fares are greater than the marginal cost of the service they purchase (except for peak periods on commuter services). This argument, combined with evidence that private auto costs are less than their marginal social cost, makes the allocation bias complete. M. B. Johnson calls for more precise pricing, after reaching similar conclusions regarding private and social costs [3]. William Vickrey has long advocated more precise pricing and has proposed several practical means for achieving it [10].

I. *Private Choice: Automobile, or Public Transit?*

Broadly, there are two alternative travel means, the private automobile and public means, including bus, railroad, taxi, airplane, or rental vehicles. We should expect a consumer to choose either automobile or public transit, not both, because auto ownership carries with it a substantial commitment to the automobile as a means of travel. If used-car markets were perfect this might not be so, for a consumer could then buy a car for one trip and sell it afterward. But transaction costs in automobile markets are high. Not only does the purchase of an automobile require time and effort, its sudden sale at an inopportune time will result in financial sacrifice. A tendency of persons to travel either by auto or public transit is evident in data from a Chicago study of commuters [6, pp. 138-41]. Of those who owned cars (85 per cent owned cars), four out of five used the car in traveling to work, three out of four traveling all the way into the city by car. Of those who did not own cars, 85 per cent traveled to work via public transit.

Over a short period, the marginal cost of auto travel will be very low for an auto owner while for a nonowner, transaction costs make short-period marginal cost very high. Thus, the short-run choice between public and private transit will depend on whether the chooser already owns an automobile. Analysis of choice must extend over a time period long enough to permit an effective choice, enough time for a consumer to purchase or sell an automobile and satisfactorily amortize his transaction costs. The average period of automobile ownership in the United States is a little more than three years [11], and we shall assume that the auto-traveling consumer bases his choice on an estimate of his auto travel costs over that period. To avail himself of such long-run costs, however, he must commit himself to auto travel for the period. Failing such commitment, he will have to confine his travel primarily to the public mode.

Some costs of auto travel vary with time (e.g., insurance, licensing, garaging, some depreciation) and others vary with miles traveled, so traveling more miles over a given time period will lead to a lower average cost per mile. Notice that the cost per auto mile, or consumer price per mile, will therefore be different for different consumers, depending on how many miles they travel. The effect of miles traveled on price per mile will, in turn, affect the consumer's decision regarding the number of miles he travels. By thus affecting planned travel miles, marginal cost exerts an influence on the eventual average price per auto mile, making the average cost lower for consumers who travel more. Average cost per mile also decreases with more miles traveled via public transit. In the public transit case, however, there can exist

one average cost per mile, when fixed costs are allocated over the total number of passenger miles traveled. As a consequence of such cost allocation a single, constant price per mile can be charged users of public transit and related to the cost per passenger mile.² Since we wish to examine allocation in the absence of subsidies, and because we consider a combination of public modes some of which are not subsidized, we shall assume that cost and price per mile are equal. In the public transit case, then, one consumer's price is not affected by his usage. To see the difficulties this arrangement causes for resource allocation among transportation modes, consider the consumer's utility-maximizing problem.

Well-known conditions for the consumer to maximize his utility require that his marginal utility from each good divided by its marginal price be equal for all goods and services consumed, this ratio of marginal utility to marginal price being the consumer's marginal utility of income. In planning his possible auto travel over a three-year period, the consumer must first reduce income available for all goods by making fixed payments associated with auto ownership. Consumption of all goods (ignoring inferior goods) is reduced as a result. At the same time, a lower marginal price is used to evaluate auto miles traveled, and this invites the consumer to travel more than he would if he paid a constant average price per mile. In planning possible public transit travel, in contrast, the consumer bases his usage on a constant average price which equals average cost but is greater than marginal cost. The private auto arrangement has an advantage for utility maximizing that can be illustrated easily. Regard as private transit an automobile, privately purchased. Consider as a public transit alternative an automobile that can be rented, the rental rate per mile for one person being regulated at an average price equal to average cost. If a person is given a private or public choice in these terms, he will always prefer the private alternative, for he can reach the same consumption goods mix that is available to him under the public arrangement and because of a lower effective marginal price can reach a preferred position as well (assuming only that the marginal rate of substitution between travel and other goods diminishes).

When this example is extended to a genuine public transit service, there will be only one average price for all public transit consumers rather than a different one for each consumer. That single average price is affected not by one's own usage of the service, but by the usage of all other consumers combined. Those whose marginal utility from

² The charge may only approximate a price equal to cost per passenger mile because of administrative problems in fare collection, but we regard the pricing of public transit as on a fee-per-mile basis.

travel diminishes rapidly are then likely to prefer public transit because the price per public transit mile is lower than they can achieve privately. Those who travel much, however, will face a lower cost per mile via auto travel. It is this effect that is troublesome in decreasing cost industries, where long-run average cost can be lowered by higher rates of usage. The commitment that will enable an individual to achieve the benefits of his own higher usage is a commitment to automobile ownership, which will simultaneously reduce the usage of public transit services. It does so because the auto owner enjoys a low marginal price per mile by auto once he commits himself to ownership, and is therefore less likely to seek public transportation at a price equal to its average cost. Thus, if benefits of higher usage are available only through the private auto transportation mode, that mode will be made more attractive, while passenger miles lost to it from public modes will raise the average cost of service via those modes.

The allocation problem is further aggravated by the presence of many separate public transit modes. From the utility-maximizing model we know that in choosing among public transit modes, a consumer's marginal utility from each mode divided by its marginal price must be equal for every mode that is used. If marginal costs of public transit modes are not proportional to average costs,³ consumers who face prices equal to average cost are sure to reach an equilibrium that is nonoptimal. Exchanges among the consumers, at marginal costs, could improve their welfare. Thus, the coordination of different public modes through single, fixed prices is imperfect. And failure to achieve an optimal combination of the different modes reduces the effectiveness of public transit as a substitute for auto travel.

II. *Avoiding Ownership Bias*

One way to achieve an efficient combination of public transit services, and at the same time offset the advantage of marginal cost influence in private auto choice, is to subsidize all public transit modes so that they may price at marginal cost. Unfortunately, this will not solve the problem completely, for it makes inefficiencies necessary elsewhere in order to finance the subsidy. More important, it implicitly raises the question: should an automobile be given to every family as well, so that only short-run marginal costs will influence the choice between public and private transit? The costly duplication that would result from such a scheme reveals the importance, shown clearly by R. H. Coase [2], of affording long-run as well as short-run choice; consumers must take into account all costs when expressing their prefer-

³ We are not suggesting that proportionality to marginal cost is a satisfactory price criterion. It is surely not satisfied by public transit modes.

ence, not just short-run marginal costs. But to cover all costs, the fees would have to be in two parts: one for short-run marginal costs, and another for fixed costs which depend on time rather than usage.⁴

Since coordination of public transit modes is needed to make public transit effective as an alternative to the private automobile, a collective institution such as a public transit club would offer genuine advantages. Membership fees could correspond to fixed costs of the modes chosen by the member. Non members could still have access to the public modes but at higher prices per mile than members, who would pay only marginal costs. The club could of course serve as a credit institution as well, for it would be a billing and collection agency. Fixed fees could be distributed among the modes by the club, dividing the fee among different firms within each mode in proportion to the direct services provided by the firms. To be sure, allocating investment risks and fixed costs of the modes among members in the form of fixed fees is not easy. The degree of commitment to an automobile is evident to any owner; he makes an investment in an auto and he assumes risks of ownership. Unlike the automobile case, public transit investment does not occur in separate parts that are identified with each user. Nevertheless, the fixed costs of a public transit mode, e.g., vehicles, roadbed, and structures, will depend on the number of passengers it must be capable of carrying, not just on passenger miles. Indeed, the number of rush-hour passengers has repeatedly been revealed to be a crucial determinant of costs for different public transit modes.⁵ And if members can influence their average price per public transit mile by making a fixed payment and then paying a marginal price equal to marginal cost, the bias in favor of automobiles will be eliminated.⁶

It would be possible to accommodate many variations in a membership institution. When several agencies offer service by the same mode, differences in variable fees are possible and would enforce competition

⁴According to W. A. Lewis [4] a "two-part tariff" was first proposed by Dr. John Hopkinson in 1892 in a recommendation for fixed and variable prices of electric power in England.

⁵See, e.g., [6] and [10].

⁶This proposal does not guarantee ideal resource allocation beyond the transportation sector. In particular, it may favor transportation generally, for it lets consumers evaluate their own effect on the price they pay per transportation unit, while prices for non-transportation goods and services are held constant (See [1]). If these other goods and services are produced by perfectly competitive industries, however, their marginal costs should equal their prices and so no misallocation need arise. Alternative goods supplied by public utilities such as telephone and electricity are often priced in a manner that reflects usage, and this proposal only offsets their former advantage.

It should be noted that two-part price arrangements, often called incentive prices, have been applied to transit in a number of places with varying degrees of success. Some communities forbid their use. While such prices would tend to reduce the bias examined here, they have not been broad enough in scope to significantly offset it.

within those modes. Classes of service could also be distinguished, in fixed or variable fees or in both. Where different services share fixed costs jointly it might be desirable to grant access to both services, at appropriate prices per mile, for only one fixed fee. Peak load pricing can be accommodated, too. For example, limited memberships which deny rush hour access might be offered at lower fees.⁷ Our purpose is only to register feasibility, and so we shall not elaborate further on these possibilities. Fortunately, large, established public transportation institutions already exist. Thus, the major problems would be those that accompany transition to an institutional form which would unify pricing, not problems associated with the initiation of new transit agencies or modes.

Organizing such an institution is not a simple matter, to be sure. Especially difficult is the question of its geographic scope. It seems most appropriate for individual cities, yet one of its advantages is coordination of all transit modes into an effective consumer service including intercity railroads and airlines, which would suggest national scope. The most practical form might be a federation of metropolitan Riders' Clubs, each serving major urban centers in the country. Whether the Riders' Clubs be public or private enterprises is an interesting issue we cannot open here. Our objective is only to sketch an alternative institution which might enhance the effectiveness of consumer choice and of the competitive process among those who provide transportation services.

III. *Summary*

A resource allocation bias can favor private autos when an ownership commitment encourages an either/or choice between private and public modes, assuming that all transit is characterized by decreasing costs, and that public transit must cover its costs and uses single, constant prices to do so. Possible misallocation among the public transit modes was also demonstrated. To compensate for these allocative biases, we proposed a collective institution to implement fixed and variable fees. The proposed institution would enable each consumer to plan his transit usage, taking account of approximate marginal social costs, and on that basis make a forward commitment either to private or public transit means. In this way investment in transit resources, as well as short-run usage, can be coordinated. The rise in alternative transit modes makes this approach more appropriate than the traditional regulation of separate monopolies. The argument is relevant primarily

⁷ A family could possess one membership with rush hour privileges and limited membership for all other family members. Occasional rush hour travel could still be made, of course, but at higher nonmember prices.

for urban areas, where substitution possibilities are greatest, where necessary organizing is most feasible, and where transit resource allocation problems are most urgent.

Price Elasticity of Demand as an Element of Market Structure

Is price elasticity of demand an important element of market structure. Jesse Markham says it is and cites the conduct of the producers of rayon and copper in support of his contention [6]. Richard Caves agrees that elasticity is an element of structure but apparently not a very important one. He cites no empirical evidence for his views but gives a simple theoretical argument which will be expanded upon momentarily. He also cites with approval a paper by Franco Modigliani which contains a convincing theoretical argument that elasticity of demand helps determine barriers to entry [3, pp. 30-31] [7]. In his book *Industrial Organization*, Joe Bain does not even list demand elasticity in a miscellaneous category of dimensions which "might offer added explanations" of market conduct but which are not of major significance [1, pp. 264-65.]. Robert Clodius and Willard Mueller go further, suggesting by implication that elasticity is definitely not to be considered an element of structure in industrial organization research [4].

Perhaps enough has been said to show that our initial question involves unsettled issues. In this brief note, we argue on theoretical grounds that elasticity of demand may well be an extremely important dimension of market structure where by structure we mean the set of environmental elements that influence market conduct and performance.¹

I

Consider two industries with the same market structure except that the first has a highly elastic demand curve and the second, a highly inelastic demand curve. Caves argues, and rightly so it would seem, that in the first case a firm would be more likely to resort to price cutting in order to increase its market share because total industry sales would increase even if other firms decided to follow suit. The same cannot be said in the case of inelastic demand where the firms in total might end up selling about the same output at a lower price. It might be noted in addition that the greater the elasticity of demand, the greater the probability that firms will not recognize their interdependency and the greater the probability that any chiseling on some form of collusive agreement will go undetected.

In many ways the argument is akin to that used to show the relevancy of concentration. When concentration is high, a change in the market policy of any one firm is said to have a pronounced impact on the performance of the market and on the profit accounts of all other firms. At issue is oligo-

¹ The elasticity of supply confronting a procurement industry has been considered a structural element by Helmberger and Hoos using arguments similar to those adduced here [5].

polistic interdependency—when is it recognized and under what conditions does it lead to collusive market conduct? Intuitively, the impact of a change in one firm's output of market price reflects not only that firm's market share but also the elasticity of market demand. Intuition does not get one very far, however, in ascertaining the sensitivity of market price to changes in a single firm's output depending on that firm's market share and the elasticity of market demand. At this juncture a bit of mathematics renders significant results.

II

Consider an industry, comprised of n firms, producing a homogeneous product. Let Q equal total industry output and X_i the output of the i^{th} firm. Of interest is the impact on market price of a change in the output of the i^{th} firm when the output of all other firms in the industry remain constant.² Assuming that the change in the i^{th} firm's output is given by cX_i , where c is some number, the change in industry output may be expressed as the total differential of Q :

$$(1) \quad dQ = cX_i$$

Using the formula for price elasticity of demand, (2), and substituting (1) into (2), a rearranging of terms yields (3):

$$(2) \quad -E = \frac{dQ}{dP} \cdot \frac{P}{Q}$$

$$(3) \quad \frac{dP}{P} = - \frac{cS_i}{E}$$

where S_i is the market share of the i^{th} firm, X_i/Q . To facilitate exposition, let $dP/P = K$. Then, treating c as a variable,

$$(4) \quad \frac{\partial K}{\partial c} = - \frac{S_i}{E}$$

Thus, given market share and elasticity, the impact of output change on price is constant for a unit change in output. The relationship depends on market share and elasticity but not on the level of output change. Consider briefly two limiting cases. If $S_i = 1$ then a monopoly exists and the effect of changes in output on price is inversely related to elasticity. On the other hand, as the market share of the firm decreases, i.e., as S_i approaches 0 in the limit, the other limiting case of perfect competition is approached. As expected in this case, equation (4) indicates that changes in the firm's out-

² Alternatively, we could assume that all other firms hold prices but not quantities constant. This assumption plays a crucial role in the models of monopolistic competition and kinky demands where elements of product differentiation are present. The very notion of the responsiveness of market output to changes in market price becomes ambiguous where product differentiation is present. For this reason we assume homogeneous outputs; the results seem less applicable the greater the degree of differentiation.

put will have no impact on market price. In this situation, elasticity is obviously irrelevant to an explanation of market conduct.

A similar relation holds for changes in the firm's share of the market, as shown by

$$(5) \quad \frac{\partial K}{\partial S_i} = - \frac{c}{E}$$

which indicates that given c and E , the impact on price of changes in market share is constant. The price effect is independent of the share of the market held by the firm but is inversely related to the market elasticity.

Finally, the impact of change in elasticity on price is given by

$$(6) \quad \frac{\partial K}{\partial E} = \frac{cS_i}{E^2}$$

Equation (6) is very significant. It shows that the price effect is very sensitive to changes in E .

The same conclusion follows from evaluation of (7) and (8) below:

$$(7) \quad \frac{\partial^2 K}{\partial c \partial E} = \frac{S_i}{E^2}$$

$$(8) \quad \frac{\partial^2 K}{\partial S_i \partial E} = \frac{c}{E^2}$$

These equations show that the impacts of changes in output and market share decrease at an increasing rate with increases in the magnitude of the elasticity. A numerical example will help. Let $c = .1$. Then, a firm with a 20 per cent share of the market where $E = -.3$ has about the same effect on market price as would a firm with a 60 per cent share of a market where $E = -1.2$!

III

A number of important implications for research may be drawn from the above analysis.

1. There is little reason to suppose that elasticity of demand is even roughly the same from one industry to the next. Indeed, the evidence suggests considerable variation [8] [2]. Where cross-section data are used in searching for associations between market performance (profit rate, e.g.) and market structure, exclusion of elasticity of demand as a structural dimension may lead to biased results. Though inclusion of an elasticity variable may be very difficult, if not impractical in many cases, we ought at least be aware of the possible consequences associated with its exclusion.

2. At first blush, one might suppose that, in cross-section analysis, concentration and elasticity of demand might well be collapsed into a single variable using equation (3) above. While experimentation along this line might be worthwhile, there is a compelling reason why the number of

(large) firms is important per se: it is likely to be easier to secure an agreement among three people than among six. The same holds for enforcement of an agreement reached earlier. Thus, at the extremes of market structure, either collusion or independent conduct is all but assured by the number and size distribution of firms. The same cannot be said with much confidence for the intermediate cases, and this is precisely where the search for associations between market structure and performance has proved so fruitless.

3. If demand elasticity is an important dimension of structure, one might first look for performance consequences in industries characterized by extreme elasticity or inelasticity. Case studies of such industries might provide interesting evidence on the empirical validity of the hypothesis at hand.

A Note on Economic Rent

Although the concept of economic rent has been widely used by professional economists for many years, as yet no clear consensus concerning its meaning exists. At present two very different versions of the rent idea are usually encountered. The origin of one can be traced through Marshall and Mill back to Ricardo while the other had its beginnings in the works of Pareto. Unfortunately many writers do not recognize the dissimilarity between these concepts and use them interchangeably, while others see the difference but fail to derive

any worthwhile advantages from the use of two rent definitions rather than one.¹

The crux of the definition issue is this. Economic rent is defined by the followers of Ricardo as the excess amount earned by a factor over the sum necessary to induce it to do its work. The Paretian rent concept is the excess earnings over the amount necessary to keep the factor in its present occupation [6, par. 745-55]. Clearly these are very different definitions. In the first the test is whether the factor is supplied at all or not; the second is concerned with where it is supplied. In the latter case it is obvious that opportunity costs created by the competitive uses must be met as a condition of holding the factor in its present use.² Only the surplus over these opportunity costs would be rent in this sense.

The first of these definitions had its origin in Ricardo's concept of differential surplus. In essence, it is the same as Taussig's "producer's surplus" [8, p. 63] and Marshall's "scarcity rents" [4, pp. 422-30]. It is oriented to the motives and behavior of the supplier of resources and presumably may serve as the basis of moral judgments approving or condemning their rewards.

Pareto's definition is user oriented. Because of the use of the present occupation test, it differentiates payments generated by the industry or firm employing productive resources from those imposed in the market by the competition of other firms or industries. As a result multiple rent concepts appear. First is rent from the point of view of the economy, which coincides with the Ricardian type of definition. Next, however, is rent from the point of view of the industry, which is any payment made by the industry to a factor in excess of the opportunity costs created by other industries. These extra payments are made necessary by the industries' contribution to the total demand for the factor. Finally, rents from the standpoint of the firm are payments by the firm in excess of what other firms in the same industry would offer the agent for its services.

The existence of two significantly different but widely used approaches to the concept of economic rent is obviously unfortunate. It is appropriate, therefore, to examine critically the relative merits of the two types of definitions in order to determine whether significant simplification is possible and desirable.

The concept of economic rent is encountered most frequently in two important areas of economics, the theory of distribution and the theory of cost. Consequently the merits of the two types of rent concepts can appropriately be

¹ Even Boulding in his excellent recent revision of *Economic Analysis*, offers two definitions, one following Ricardo and the other patterned after Pareto without explicitly mentioning that these definitions are different and that they may lend themselves to different uses [1, p. 265 and p. 512]. An examination of the latest editions of most leading intermediate and advanced texts shows this situation to be quite general [7] [3].

² At times a distinction is made between the payment needed to hold a factor in its present occupation and the return it could earn in other uses [5]. These could, of course, be different because of nonpecuniary elements involved in different lines of work. This distinction is not employed here because it introduces another, and for our purposes extraneous, variable into the problem. Although we must admit the validity of this contention, it should be ruled out by the simplifying assumption that the net nonpecuniary advantages of the occupations in question are the same.

tested by the contributions they make to these theories and their applications.

The traditional approach which views rent as the excess payment received by a factor over the minimum required to induce it to do its work passes the distribution theory test with flying colors. This is not unexpected since the concept had its origin in early formulations of distribution theory and was an integral part thereof. In its early as well as its present form it was designed to explain the income received by factors of production. It was first used in connection with the return paid to natural resources where no elasticity of supply was believed to exist. Since the compensation of such a factor generated no increase in productive effort it was viewed as a surplus payment. Even when this line of reasoning was later extended to other types of agents, the term rent continued to be used to explain all or part of the income shares they received. Here the rent or surplus designation was applied to that part of the compensation of the factor in excess of the payment necessary to bring forth its services. This was true both of the excess over the minimum necessary to get the factor to work at all and the excess over the payment needed to induce each additional increment of performance by the factor. In modern terms, of course, this concept views "economic rent" as the part of the compensation of the factor graphically depicted by the area between the supply curve to all uses of the factor and the horizontal line representing the rate pay received by the factor.

In addition to being a clear-cut distribution concept the traditional view of rent has the great conceptual merit of being closely related to the basic causes of scarcity. Rent in this sense exists because the supplies of the factors are less than perfectly elastic. This in turn is occasioned by those fundamental forces which cause the services of factors to be available in limited quantities only. When applied to factors other than land this approach forces us to focus on the behavior of factor suppliers. As a result the study of scarcity must be related to and draw upon the findings of other behavioral sciences.

The traditional rent concept also enables us to divide, conceptually at least, factor compensation into two parts, payments which induce factors to work and surplus which only confers a greater reward for work which would have been done anyway. In classical terms it distinguishes payments made to overcome "real costs," labor pain, abstinence, etc., from unnecessary bounties. Although we no longer subscribe closely to a "real cost" doctrine, it is still worthwhile to have a conceptual separation of those payments which are a necessary condition of production and those which are not. This is particularly important in applied economics where moral judgments are passed and policies suggested.

Pareto's approach has little to contribute to distribution theory. At best the set of concepts which ascribe individual rents to each of the industries or firms using an agent might enable us quantitatively to identify where the components of the total factor rent came from. If available and valid this information might be interesting, but it would contribute nothing that a thorough demand analysis would not provide. However, this type of compilation would be conceptually incorrect. Paretian rent from the point of view of any individual user of a factor is determined by how his demand influences the price of a fac-

tor assuming the demands of all other users to be *present in the market*. It is clear that the sum of these influences is not necessarily the same as the sum of the consequences when all of the individual demands are added to or subtracted from the market at the same time. Hence the total individual user rents would in all probability differ greatly from the total rent received by the factor. This difference would be especially large where supply is highly inelastic. In addition we must remember that, when any user adds his demand to the factor market, the price rise he produces generates "rents" not only for himself but also necessitates additional payments by all other users of the agent.

We should also point out that the multiple-rent concepts are of no value whatsoever when the theory of distribution is used in applied economics. Certainly no moral significance or basis of policy formation can be found in firm or industry rents. It should be clear, therefore, that the Pareto approach is a misfit from the standpoint of distribution theory and must justify itself, if at all, on other grounds.

When the theory of cost is considered, Pareto's approach fares somewhat better. The traditional concept draws its lines of division between necessary and unnecessary payment at the social level. What is necessary or unnecessary for the firm or the industry, however, is far different. Opportunity costs are real and must be met even though from the social point of view most of these payments are rent. Nevertheless this does not justify separate rent concepts for industries or firms. All that is required by the theory of cost at either firm or industry level is that the conditions of supply of the factor to the firm or the industry be known. Here the concepts of supply curves to industries or firms are entirely sufficient. In situations where a firm or industry can control the market sufficiently to influence costs, the theories of monopsony or oligopsony are adequate. As a result rent concepts at the firm and industry levels that identify and name the income generated by firms or industries are totally unnecessary to the theory of cost. They are worse than useless, however, because they confuse elements of cost and distribution theory. The distribution concept of rent is needlessly brought into the theory of cost while the cost-oriented user classification complicates the theory of distribution without enhancing our knowledge of factor income determination.

It should be clear from what has been said that on theoretical grounds the traditional concept is vastly superior. There is also no suggestion that the multiple-rent concepts are of any practical importance for either the businessman or the social planner. That they are lacking in moral significance and provide no meaningful policy guides should be evident as well. Consequently, the foregoing analyses suggest that economic rent is best defined as the surplus over the payment needed to induce a factor to do its work, and best defined in this way alone.³

One final argument in favor of the Pareto concept merits separate attention. Economists have long debated the role of rents in price making, some contend-

³ The suggestion that rent be defined as the opportunity cost of land (or for that matter of any other factor) and that any payment in excess of this amount be designated "factor profits" [9, pp. 269-75] must also be rejected. Under conditions of pure competition such a distinction is unimportant. On the other hand, when individual firms play a significant role in the market it is at least misleading and often clearly incorrect.

ing that rents are price determining while others argue that they are price determined. The multiple rent concepts of Pareto's followers seemingly permit a neat compromise which allows one to say that rents are from one stand-point price determined yet from another price determining. The argument proceeds somewhat as follows. Although rents in the sense of payments in excess of the minimum amount needed to induce factors to work are a result of the structure of prices and therefore price determined from the standpoint of the economy as a whole, many components of these payments are price determining to particular industries or firms. This is because the competitive bidding of other industries has built the parts of those rents not generated by the specific industry itself into opportunity costs which the industry must meet and which must be covered in the price of the product. Hence those components of "rents from the standpoint of the economy" which are embodied in opportunity costs are price determining from the standpoint of the industry while rents generated by the industry itself are price determined. Similarly, payments which are rents from the standpoint of the industry are often included in the market price of agents purchased by the firm and are price determining at that level.

This somewhat persuasive line of reasoning, however, misses the basic point in the entire price-determined price-determining controversy. In essence the controversy arises from a misleading statement of the problem. In fact under properly constructed sets of assumptions it is easy to prove that rent is either price determined or price determining. For example, consider a factor X , which is used in the manufacture of product A . Let us assume that X is used in the production of other products and the manufacture of A requires other agents. If now the conditions of supply of all of the agents are treated as given, as well as the technical coefficients and the preference patterns for all products except A , a change in the preference pattern concerning A will alter the price of A . This in turn will lead to a change in the demand by the producers of A for X and therefore a change in the price of X , of which the part in excess of the minimum supply price is rent. Consequently the change in the price of A changes or "determines" the rent of X . On the other hand, if every basic determinant of the system is treated as given, except the supply of X , a change in the supply of X will alter its price including its rent and, in consequence, the price of A . Here rent might be said to be price determining.

In reality, of course, economists have long known that rent is neither price determining nor price determined since neither rent nor price is a basic determinant of the system. They are co-determined as the result of the interaction of more fundamental forces. We know from Cassell's simple general equilibrium model that these forces are the condition of supply of the agents, the technical coefficients, and the preference patterns of consumers [2, pp. 134-55]. Their simultaneous interaction determines the prices of all products and factors, as well as the quantities of all goods produced and the allocation of resources. Rent along with price is a result not a causal factor.⁴ The validi-

⁴ It is true that autonomously determined rents or prices might themselves be basic elements in a more complex model. This however, is not the point at issue in this classical controversy.

ty of this basic viewpoint is not significantly altered when more sophisticated assumptions are introduced to the system.

Consequently, even this last argument fails to justify the confusion now existing with the rent concept.

Drawings on an Old Envelope: Short-Run and Long-Run Average Cost Curves

Jacob Viner's path-breaking analysis of cost curves [6] taught the profession to relate long-run and short-run average costs (LAC and SAC) by means of an envelope curve, showing a set of SAC curves perched on the LAC curve. Viner's presentation, however, implies a cost function such that short-run total costs decrease as output increases and short-run marginal costs (SMC) are negative. Viner's diagram is reproduced here as Figure 1. Many widely used texts have followed Viner's example, some "improving" on its tidiness by making the SAC curves more nearly identical.¹ Negative marginal costs are inconsistent with the usual assumptions of efficient output and continuity of functions, and we doubt that the authors intended to depict them as negative.

The requirement that SMC not be negative sets a limit to the curvature of the downward-sloping portion of SAC . The limiting case would be one of constant short-run total cost, producing a rectangular hyperbola for its SAC . Any SAC curve drawn with steeper slope than the rectangular hyperbola passing through minimum SAC will imply negative marginal costs. As an illustration, Figure 1 shows such a hyperbola superimposed on SAC .²

¹ See, *inter alia*, Bain [1, p. 119], Chamberlin [2, p. 233], Due and Clower [3, p. 168], Samuelson [4, p. 469], and Stigler [5, pp. 131, 139, and 161].

² The interested reader is invited to measure the vertical and horizontal coordinates of selected points on the SAC curve and establish, as we did, that the implied SMC functions (except SAC 1) are negative.

FIGURE 1

If the *LAC* curve is flat or nearly flat, the hyperbolic limits to successive *SAC* curves must become increasingly flat as one moves to successively larger scales of operation. For relatively simple pedagogical production functions, it can be shown that any *SAC*₂, representing a larger scale of output, tends to be wider and shallower than *SAC*₁, representing a smaller scale. (The width can be measured along a line some given distance above the minimum point.)

Consider a production function with equally spaced isoquants of identical curvature. Provided that the long-run expansion path is linear, the *SMC* curves will have the same shape and slope for any Q_m (where Q_m is the output at which *SAC*₁ is at a minimum). The shallowness and width of *SAC* is determined by the absolute change in total cost divided by the proportionate change in quantity. Since the absolute change in total cost associated with a given change in output will be invariant with Q_m , but the denominator will be negatively related to Q_m , identical *SMC*'s will necessarily yield flatter *SAC*'s as Q_m increases. For successive *SAC*'s not to become shallower and wider, the *SMC*'s must become steeper as Q_m increases; this will require that the isoquants become progressively more tightly curved as output level increases, so that the increased cost due to the curvature exceeds the effect of the increase in the denominator. When the long-run expansion path is nonlinear, limits can be shown to exist which will enforce the general tendency for *SAC*'s to become ultimately shallower and wider.

We can show algebraically the tendency for *SAC*'s to become shallower and wider as Q_m increases for the simple production function

$$Q = a^{1-x}b^x \quad (0 < x < 1)$$

Assume that a short-run production function can be identified by substituting some specific value b^* for one input. The quantity of the other input can

then be expressed as

$$(1) \quad a = \left(\frac{Q}{b^{*x}} \right)^{1/1-x}$$

The short-run total cost function (*STC*) is determined by multiplying the quantity of each input by its price, the two terms in the equation representing fixed and variable cost respectively. Dividing each term by Q yields the functions for *AFC* and *AVC*:

$$(2) \quad AFC = \frac{P_b \cdot b^*}{Q}$$

$$(2') \quad AVC = P_a \cdot \left(\frac{Q}{b^*} \right)^{x/1-x}$$

For any given value of b^* , there is a Q_m at which *SAC* is minimized. This can be determined by setting equal to each other the derivatives of *AFC* and *AVC* with respect to Q .

$$(3) \quad \frac{P_b \cdot b^*}{Q^2} = \left(\frac{P_a}{b^{*x/1-x}} \right) \left(\frac{x}{1-x} \right) Q^{(2x-1/1-x)}$$

Solve for Q and let the solution represent Q_m

$$(4) \quad Q_m = b^* \left[\left(\frac{P_b}{P_a} \right) \left(\frac{1-x}{x} \right) \right]^{1-x}$$

Let us assume that input prices are given and that we define units of input so that $P_a = P_b = 1$. *SAC* can then be expressed in terms of Q_m :

$$(5) \quad SAC = \left(\frac{Q_m}{Q} \right) \left(\frac{x}{1-x} \right)^{1-x} + \left(\frac{Q}{Q_m} \right)^{x/1-x} \left(\frac{1-x}{x} \right)^x$$

For any given value of x , *SAC* is a function of Q/Q_m . As a result, the width of *SAC* at any given height is proportional to Q_m . For instance, when $x=9/10$, *SAC* has a value of 6.2 when $Q/Q_m=0.2$ and 1.5, approximately. The width of each *SAC* at the height 6.2 is about 1.3 Q_m . Similar results follow for other values of x .

The Foundations of the "War on Poverty" Reexamined

How rapidly will economic growth and full employment acting alone reduce the proportion of people living in poverty? In his communication "The Foundations of the 'War on Poverty'" [2] Lowell Galloway argued that the percentage of families living in poverty would decline to considerably lower levels by 1970 or 1980 than had previously been estimated by the Council of Economic Advisers [8].

Galloway regressed the logarithm of the percentage of families with incomes below \$3,000 in 1963 dollars on median family income and the unemployment rate. From his basic equation, Galloway estimated poverty rates in 1970 and 1980 under two assumptions regarding growth of median family income and unemployment rates. These results are shown in Table 1. His estimates of poverty rates in 1980 were a bit over half of those previously published in [8]. From these results Galloway concluded [2, p. 130] "In short, the case for substantial anti-poverty programs of a selective character is weakened by the findings of this paper. Rather, greater consideration should be given to the role which economic growth can play in eliminating poverty." Because Galloway's results have an obvious and important bearing on matters of considerable economic and political significance, they merit careful scrutiny, which this article attempts to provide. The following are the major conclusions.

1. Aggregate poverty statistics are inherently incapable of providing evidence for or against the backwash thesis—the thesis that poverty will not largely disappear with growth.

2. Galloway's results are sensitive to the functional form of his regression, and, in particular, the semilogarithmic transformation tends to overstate the impact of rising incomes on the poverty percentage.

3. Galloway's results are sensitive to the data he uses. Both Galloway and the CEA used poverty estimates based on a \$3,000 family income cutoff. If the semilogarithmic regression is run separately for the percentage of white and nonwhite families living in poverty, it appears that white family poverty is more sensitive to economic growth, but less sensitive to the unemployment rate than is nonwhite family poverty. On the other hand, the definition of poverty appears not to affect results significantly. Use of aggregate poverty statistics based on the definition of poverty developed by Mollie Orshansky for the Social Security Administration [6]

TABLE 1—REGRESSIONS OF POVERTY RATES ON MEDIAN FAMILY INCOME AND UNEMPLOYMENT RATES AND ESTIMATES OF POVERTY RATES IN 1970 AND 1980

| Model | Constant | Median Income (<i>M</i>) | Unemploy- ment Rate (<i>U</i>) | \bar{R}^2 | Predicted Poverty Rates (percentage of families) | | | |
|-----------------------------------|----------|-------------------------------|--|-------------------|---|-------------------|-------------------|-------------------|
| | | | | | 1970 ^a | 1970 ^b | 1980 ^a | 1980 ^b |
| 1. CEA estimates ^a | | | | | | | 10 | 13 |
| 2. Galloway estimates semi-log | 1.945100 | -.000121 (.000003) | .005086 (.001431) | .99+ ^a | 12.6 | 14.2 | 6.4 | 8.7 |
| 3. White poverty semi-log | 1.909827 | -.000116 (.000004) | .003723 (.002825) | .9847 | 10.8 | 11.6 | 5.4 | 6.7 |
| 4. Nonwhite poverty semi-log | 2.151410 | -.000090 (.000008) | .006249 (.005002) | .9138 | 30.6 | 32.8 | 18.8 | 21.4 |
| 5. Galloway estimates double logs | 6.306461 | -1.332623 (.035155) | .043557 (.020980) | .9919 | 14.3 | 15.1 | 9.7 | 10.9 |
| 6. White poverty double logs | 6.535934 | -1.410371 (.041096) | .037398 (.024526) | .9902 | 12.0 | 12.6 | 8.0 | 9.0 |
| 7. Nonwhite poverty double log | 5.805022 | -1.114743 (.109364) | .071077 (.056989) | .9082 | 32.9 | 34.8 | 23.8 | 26.5 |

^a Assumes that growth in median income occurs at the same rate as during the period 1947-56 and the unemployment is 4 per cent.^b Assumes that growth in median income occurs at the same rate as during the period 1957-63 and that unemployment is 6 per cent.^c As reported in Lowell Galloway, "The Foundations of the War on Poverty," *Am. Econ. Rev.*, March 1965 [2].^d It is not clear from the source whether or not this correlation coefficient is corrected for degrees of freedom.

[7]¹ yields substantially the same results as those based on the \$3,000 cutoff that Galloway uses, as far as the impact of economic growth on poverty in the aggregate is concerned. Unemployment rates are not related to poverty rates in a statistically significant way for the period 1959-64. Using the Orshansky poverty numbers, it is possible to carry out regressions of poverty rates on median income and unemployment for several population groups. This was done for seven groups, broken down by location of residence (farm, nonfarm), race (white, nonwhite), and sex of family head. These results provide further evidence that poverty is heterogeneous and should be disaggregated to be understood. Poverty among some groups seems highly sensitive to economic growth (e.g., white farm households); other groups are barely affected by it (e.g. nonfarm, nonwhite, female headed families). The case for special programs aimed at "disadvantaged groups" is strengthened by these results.

Since Orshansky also compiled statistics on the near poor,² the relationship between the number of poor and near poor (the "needy"), on the one hand, and median income and unemployment rates, on the other, was also examined. The chief result here is that the number of needy households is significantly related to median income, but not, in most cases, to unemployment. For most groups, the impact of higher median income is weaker on the number of needy households than on the number of poor households.

These results will be discussed in more detail below.

I. *The Need for Disaggregation*

The aggregate approach is inherently incapable of testing the backwash thesis. This thesis asserts that some disadvantaged groups benefit to a far smaller extent from growth than does the remainder of society. In the extreme case, assume that there are two groups: A, in which poverty rates decline linearly with growth in real income; and B, in which poverty rates are unaffected by growth in real income. Thus

$$(1) \quad {}^A P_t = a - bM_t,$$

$$(1a) \quad {}^B P_t = c,$$

where ${}^A P_t$ is the poverty percentage for group A at time t , M_t is median family income at time t , and a , b , and c are all parameters. The relation of the aggregate poverty rate, ${}^{A+B} P_t$, to median income would be

$$(2) \quad {}^{A+B} P_t = (a + c) - bM_t$$

Even if the fit were perfect, as Galloway's very nearly is, the results would be no evidence against (or for) the backwash thesis. Extrapolation implies

¹ The poverty threshold is defined on the basis of the Department of Agriculture's "economy" food budget for families of various sizes, adjusted downwards for farm families and for the aged. The resulting food budget is multiplied by factors determined on the basis of budget studies to get the poverty threshold. There are 108 thresholds depending on family size, age and sex of head, and location. See [6]

² Near poor families have incomes greater by from \$305 in 1963 dollars, for one-person family, to \$1,305, for a family of seven or more persons, than do poor families. See [6]

that the poverty rate goes to zero, but by assumption the poverty rate will not fall below c (assuming negative poverty rates for group A to be impossible). To examine the backwash thesis it is necessary to examine the relationship of poverty to family income and unemployment for the groups to which the backwash thesis might reasonably apply. In so doing, it should be kept in mind that even if economic growth seemed to erode poverty rapidly for every subgroup, the backwash thesis might still be valid, since within each subgroup there could be sub subgroups analogous to A and B just described.

II. Specification

Galloway's basic equation was of the form $P_t = ab^M c^U e_t$, where P_t is the percentage of families with incomes below \$3,000 in 1963 dollars in year t , M_t is median family income in year t , U_t is the national, average unemployment rate in year t , a , b , and c are parameters, and e_t is an error term. The estimated equation is shown as equation (2) in Table 1. By plugging in assumptions regarding growth of median income and unemployment rates, one may extrapolate the trend in the poverty rate. Galloway projects the poverty rate to 1970 and to 1980, as did the CEA using another model before him. The CEA's results, as reported by Galloway, are shown as equation (1) in Table 1.

The question arises of why the semilogarithmic transformation was chosen rather than some other form. Richard Muth has shown, in an unpublished paper [3], that the semilogarithmic form produces estimates which overstate the rate at which increases in income will reduce the percentage of families with incomes below any constant cutoff if incomes are distributed approximately log-normally. In that case the poverty percentage P is shown by

$$(3) \quad P = \int_{-\infty}^C \frac{1}{\sigma\sqrt{2\pi}} \exp - \frac{1}{2\sigma^2} (X - \mu)^2 dX$$

where C is the log of the poverty cutoff, X is the log of family income, and μ and σ are the first and second moments of the log normal distribution. Equation (3) implies

$$(4) \quad P = f\left(\frac{C - \mu}{\sigma}\right) = f\left(\frac{C - \log M}{\sigma}\right), \quad \text{or}$$

$$(4a) \quad \log P = g\left(\frac{C - \log M}{\sigma}\right),$$

where M is median family income, since $\mu = \log M$. Totally differentiating (4) and (4a) yields

$$(5) \quad dP = -\frac{f'}{\sigma} \left[\frac{dM}{M} + \left(\frac{C - \log M}{\sigma} \right) d\sigma \right]$$

$$(5a) \quad d \log P = -\frac{g'}{\sigma} \left[\frac{dM}{M} + \left(\frac{C - \log M}{\sigma} \right) d\sigma \right]$$

$$(5b) \quad \frac{\partial P}{\partial M} = \frac{f'}{\sigma M}$$

$$(5c) \quad \frac{\partial \log P}{\partial M} = -\frac{g'}{\sigma M}$$

$$(5d) \quad \frac{\partial P}{\partial \log M} = -\frac{f'}{\sigma}$$

$$(5e) \quad \frac{\partial \log P}{\partial \log M} = -\frac{g'}{\sigma}$$

Muth evaluated the partial differentials in (5a) and (5b) using a poverty cutoff of \$2,650 in 1959 dollars with adjustments to the cutoff for farm families. Since increases in income (M) will tend to reduce the value of the partial derivatives in (5b) and (5c), unless offset by decreases in σ (i.e., greater income equality), which seems unlikely, regression of P or $\log P$ on $\log M$ seems preferable to regression on M . In addition, Muth evaluated the partial derivatives (5b) through (5e) and found only (5e) roughly constant over time, indicating that double log regression would be more satisfactory than regressions of the poverty rate or its logarithm on median income.

The results of a double-logarithmic regression, where $P = aM_i^{-b}U_i^ce_i$ and the poverty rates are the percentages of families with income below \$3,000 (1964 dollars), are shown as equation (5) in Table 1. The estimated poverty rates are higher than those which Galloway obtained for 1970 and much higher for 1980. In fact, under the more favorable assumptions regarding growth and unemployment, the double-log results differ little from the original CEA estimate which Galloway criticized.

III. Categories of the Poor

The percentage of families with incomes below \$3,000 (1964 dollars) broken down by white and nonwhite families was obtained from Census. Both the semi-log and double-log models were fitted for these two groups. The parameter estimates are shown as equations (3) and (4), and (6) and (7) in Table 1, and the poverty rates are extrapolated to 1970 and 1980. In both models, the nonwhite poverty rate is less sensitive to median income and roughly twice as sensitive to unemployment rates as is the white poverty rate. The goodness of fit for nonwhite poverty rates is markedly lower than for white poverty rates. The greater sensitivity of nonwhite poverty to unemployment no doubt is caused by the fact that more nonwhites than whites are near poverty even when full employment conditions prevail, and, hence, are pushed under the line when economic activity slackens. No similarly obvious explanation for the lower value of the coefficient of median income in equations (4) and (7) in Table 1 is apparent. But,

whatever the reason, the difference is statistically significant, and the forecasts which emerge from those equations give a far less sanguine picture of the disappearance of poverty than do Galloway's estimates. After 15 years of full employment and high growth, between 18.0 per cent and 23.8 per cent of nonwhite families would be in poverty in 1980, about three times the white percentage.

The above findings suggest the desirability of still other breakdowns of the poverty population to ascertain whether economic growth affects in differing degrees various other subgroups among the poor. Accordingly the Orshansky poverty numbers were used for further regressions of the percentage of poor households on median income and unemployment. Because the poverty thresholds developed by Orshansky [7] [8] vary, depending on family size, location, and age, the more comprehensive household statistics can be used.

Unfortunately, poverty indices based on these definitions have been computed only for the years 1959-64. On the other hand, these data are available for subgroups, and statistics on the near poor have also been compiled. The semilogarithmic form of the model was fitted for poverty data on households (families plus unrelated individuals) in the following groups.³

A. All households

This regression was run to determine whether the Orshansky poverty numbers led to substantially different parameter estimates than did the longer series based on the \$3,000 poverty cutoff. The coefficients of median income are remarkably similar in the two instances. When the new definition and the shorter time span are used, the coefficient of the unemployment rate is not significant and the sign is negative. However, since in the long run changes in the unemployment rate have little effect on poverty rates relative to income growth, this problem is minor. The insignificance of the unemployment coefficient may perhaps be explained by the relatively narrow limits within which the unemployment rate fluctuated in the period 1959-64.

The impact of changes in median income on the number of needy (N = poverty plus near poverty) households is smaller than the impact on the number of households in poverty. This finding is explained by the fact that when income rises the ranks of the near poor neither grew nor shrank. As some near poor graduated into higher brackets, some previously poverty stricken households moved into the near poor category.⁴

These results suggest that neither the use of a different definition of poverty, nor the use of an index of poor households rather than poor families, will explain any large differences in the coefficients of median income for particular groups from those for the whole population.

³ The semilogarithmic form is used to evaluate the indictment of the backwash thesis on the most favorable terms.

⁴ If $P_{t-1} - P_t = N_{t-1} - N_t$ but $N_t > P_t$, then $\log P_{t-1} - \log P_t > \log N_{t-1} - \log N_t$. Hence, the resulting parameter estimates.

B. Nonfarm, white, male headed households

This group contained 67.0 per cent of all households and 35.4 per cent of all poor households in 1964—10.5 per cent and 17.6 per cent of all households in this group were classified as poor and needy respectively in 1964, the lowest for any group examined here. The results suggest that poverty in this group is more responsive to rises in median family income than is poverty for the nation as a whole. If the higher assumption regarding economic growth is employed here, the percentage of poor and needy will fall to 7.3 per cent and 13.7 per cent respectively in 1970; the numbers for 1980 will fall to 3.2 per cent and 7.8 per cent respectively. The coefficient for unemployment is disregarded because its sign is contrary to expectation and is insignificant. If these rates were applicable to all other groups, the case for special poverty programs would indeed be weakened.

C. Nonfarm, white, female headed families

This group contained 18.4 per cent of all households and 34.8 per cent of all poor households in 1964. The poverty and needy rates were 40.3 per cent and 47.6 per cent respectively in 1964. Changes in the percentage of households living in poverty are significantly correlated with changes in median family income, but the effect of a rise in median income on the poverty rate is smaller for this group than for male headed families discussed above. This smaller effect is quite consistent with a priori expectations based on the lower participation rates of women. If high economic growth persists, then the poverty rate in this group will fall to 34.6 per cent in 1970 and 24.7 per cent in 1980.

D. Nonfarm, nonwhite, male headed households

This group included 7.0 per cent of all households and 11.1 per cent of all poor households in 1964. The percentage of households living in poverty is significantly correlated with median income. However, the relation is weaker than for white households (group B above), both in the sense that the coefficient is smaller and in the sense that the fit is looser. In this group 31.6 per cent and 42.8 per cent of households were classified as poor or needy in 1964. Under the assumption of high growth and low unemployment the poverty and needy percentages will fall to 22.8 per cent and 36.1 per cent in 1970 and to 11.3 per cent and 22.5 per cent in 1980.

E. Nonfarm, nonwhite, female headed households

This group included 3.1 per cent of all households and 10.2 per cent of all poor households in 1964; 64.6 per cent were poor and 72.8 per cent were needy. The coefficient of median income is rather small and the fit is rather poor in each case, suggesting that economic growth has little impact on the poverty rate in this group. According to these equations, by 1970 the percentage of households classified as poor or needy would have fallen to 56.2 per cent and 67.3 per cent respectively; by 1980, to 43.8 per cent and 60.1 per cent respectively. However, little weight can be accorded to these esti-

mates, because none of the coefficients is significant. The proportion of poor falls more rapidly than the proportion of needy.

F. Farm, white, male headed households

This group included 4.8 per cent of all households and 6.0 per cent of all poor households in 1964; the poverty rate was 25.0 per cent and the needy rate was 34.4 per cent, both rates up sharply from 1963. If 1964 is excluded, the goodness of fit would be substantially improved and the coefficient of median income would be higher. A generally loose fit between farm poverty

and median income is to be expected because of the dependence of farm income on transfer payments which are only loosely correlated with changes in median income. If a separate series of median family income in agriculture were used, the relationship for 1964 would be less out of the ordinary, because median family income in agriculture remained virtually unchanged between 1963 and 1964, while median family income in general rose by 3.3 per cent. On the other hand, the coefficient is biased upward somewhat by the use in 1963 of a stricter definition of poverty than was used in other years. In any case, three of the most important influences on farm income are excluded, namely crop yields, the rate of out-migration, and the level of farm support outlays.

G. Farm, white, female headed households

This group included 0.5 per cent of all families and 0.8 per cent of all poor households in 1964; 35.5 per cent were poor and 44.7 per cent were needy; these rates were up only slightly from 1963. The coefficients of median income are significant and larger in absolute size than were those for male headed households (group F above). If high growth persists, then in 1970 the proportion of these families which are poor and needy will be 15.2 per cent and 22.9 per cent respectively and in 1980, 2.8 per cent and 5.9

Sources: [4] [5]

per cent. The estimates for 1980 are probably excessively low since they imply lower poverty rates than for nonfarm, white, male headed families (group B above).

H. Farm, nonwhite, male headed households⁵

This category included 0.5 per cent of all households and 1.7 per cent of all poor households in 1964; 69.6 per cent were poor and 75.9 per cent were needy. The superior fit of the regression involving the needy rate is due to the use of a special definition of poverty for agriculture in 1963 which caused many families to be classified as near poor in that year who would have been classified as poor in other years. If high economic growth and employment

⁵ There are too few farm, nonwhite, female headed households to permit separate estimation.

persist, then the needy rate for this group will fall to 57.5 per cent in 1970 and to 24.7 per cent in 1980. In general, the evidence is not inconsistent with a hypothesis that agricultural poverty and near poverty will fall rapidly as economic growth proceeds, and no doubt also, as the out-migration, which depends on favorable nonfarm economic opportunities, continues. However, the evidence is also not inconsistent with the hypothesis that the farm poor remain poor even after they move off the farm, and should not be construed as evidence that poverty programs aimed at today's farm poor may not be necessary to prevent the mere transfer of poverty from the farm to the city.

IV. Summary

The rather optimistic view of the impact of economic growth on poverty advanced by Galloway is unwarranted. (1) Aggregate data cannot be used to test the backwash thesis. (2) His results are sensitive to the form of the model which he used. (3) If disaggregated data are used, a much gloomier picture emerges. Finally, it should be remembered that even if disaggregated data in every case yielded large negative coefficients for median income, a proponent of the backwash thesis could argue, and the data would not refute him, that within each category there exists a group of hard core poor, untouched by economic progress, whose presence justifies the passage of antipoverty legislation. And the debate about such programs would have to be resolved with other evidence than simple, or even multiple, regressions of the kind reviewed here.

The Foundations of the "War on Poverty": Reply

Henry Aaron has indeed made a useful contribution to our knowledge of the incidence of poverty in the United States. For this we should be grateful and while I do not agree completely with his interpretations and conclusions let it be clearly stated for the record that I concur in his essential premise, viz., that the double log regression form is superior to the semi-log from the standpoint of shedding light on the relationship between poverty and economic growth in the United States. In fact, if anything, Aaron has been too modest in stating his case. Basically, he argues on conceptual grounds that the double log form is superior. This is, admittedly, a meaningful criterion. In addition, though, there are other criteria which might be employed in judging which of the two functional forms is more appropriate, viz., success in (1) explaining the past relationship between poverty and growth and (2) predicting the impact of growth on poverty levels.

The first of these criteria is a simple "goodness of fit" concept and on this score it is difficult to choose between the two regression forms. In fact, with this criterion a simple linear relationship performs quite well. However, the second criterion affords the possibility of a stronger test of the usefulness of the double log form vis-à-vis the semi-log. Essentially, this can be conducted by fitting both semi- and double log regressions to part of the data and using the result to predict the remaining observations.¹ I conducted such a test by fitting semi- and double log regressions to the 1947-59 data and from these predicting the 1960-64 poverty rates.² The results are shown in Table 1 and clearly indicate that the double log regression does a better job of predicting the 1960-64 poverty rates. Further, the bias in the semi-log predictions is in the direction of understating the actual amount of poverty.

The systematic tendency for the semi-log regression form to underpredict poverty in the 1960-1964 period casts doubt upon my earlier projections of future poverty rates. Aaron's projections seem much more reasonable. Those projections are in substantial agreement with those of the Council of Economic Advisers which is not surprising in that the poverty elimination rate dP/P used in those projections is perfectly consistent with the double log form of the relationship between poverty and aggregate economic conditions. Specifically, differentiating Aaron's double log equation yields the following:

$$(1) \quad \frac{dP}{P} = b \frac{dM}{M} + c \frac{dU}{U}$$

where P denotes the poverty rate, M median family income, and U unemployment. Thus, with constant unemployment dP/P depends solely on the

¹ This was done in part in my earlier paper [2] but only for purposes of predicting the 1963 poverty rate.

² I used Aaron's income series to make these projections. The income series in my original paper was erroneously labeled as being in 1963 prices. Actually, it is in 1957-59 prices.

rate of growth in median family income which is consistent with what the Council estimates had in mind.

On the basis of his double log poverty projections Aaron argues that I have been too hasty in rejecting the "backwash" thesis. Let me say at this point that I was not under the impression that I had categorically rejected it. Rather, I think that I did indicate that the significance of the "backwash" thesis depended upon its quantitative importance. This seemed to be somewhat minimal on the basis of my earlier projections. However, the double log projections indicate a stronger case for the thesis. In fact, by my own ground rules (as established in my earlier paper) it must be considered to be a significant thesis.

The portion of Aaron's paper dealing with 1959-64 subgroup poverty is quite interesting in that it provides insight into what I would call the "structure" of poverty. Aaron fitted his subgroup regressions in the semi-

TABLE 1—ACTUAL AND PREDICTED POVERTY RATES, 1960-1964

| Year | Predicted Rates | | Actual Rate |
|------|-----------------|------------|-------------|
| | Semi-Log | Double Log | |
| 1960 | 19.9 | 20.3 | 20.9 |
| 1961 | 19.7 | 20.1 | 20.9 |
| 1962 | 18.7 | 19.3 | 19.7 |
| 1963 | 17.5 | 18.3 | 18.5 |
| 1964 | 16.4 | 17.5 | 17.6 |

log form but I have taken the liberty of fitting them in double log form and predicting 1980 poverty levels for those subgroups in which the fit is significant at at least the five per cent level. These are four in number: white male nonfarm, white female nonfarm, white female farm, and nonwhite male nonfarm. The resultant projections are shown in Table 2 and indicate quite clearly that substantial changes are likely to take place in the composition of the poverty group in the United States over the next decade-and-a-half. Among these four subgroups, which account for over 90 per cent of 1964 households and 80 per cent of the 1964 poverty group, the white nonfarm females account for 42 per cent of the poverty group in 1964. By contrast, on the basis of the 1980 projections this group will account for 57 per cent of the poverty among these subgroups.³

These projections imply that the poverty problem in the future is likely to be more heavily concentrated among households with a female head. Thus, the "backwash" thesis appears to be most valid for the female household subgroup which, from the policy standpoint, argues for selective

³ These results are quite consistent with W. H. Locke Anderson's findings [1]. Further, if a projection is made for the female nonwhite nonfarm subgroup it also shows a building up of poverty. Thus, the general pattern of increasing female poverty is found in this group also.

programs aimed at improving the relative income status of this group. Further, these results are suggestive of the very real possibility that the "backwash" thesis is operative primarily in those groups whose attachment to the labor force tends to be relatively weak. This would not be surprising on a priori grounds for the greater the degree of labor force attachment among a subgroup the more likely they are to be affected by variations in general levels of economic activity. While this seems quite obvious it has very significant conceptual ramifications in that it implies that the validity of the "backwash" thesis does not depend upon any significant change in the relationship between work effort and income, i.e., the work-income nexus. In those subgroups whose labor force participation is high (males for example) there is little indication of a deterioration in the work-income relationship. Even among the male-nonwhite-nonfarm subgroup the 1980 favorable growth poverty projection indicates that between 50 and 60 per cent of poverty in this group can be eliminated by favorable growth condi-

TABLE 2—1964 ACTUAL AND 1980 PREDICTED POVERTY RATES, SELECTED SUBGROUPS

|-------------------------|-------------------|-----------------------------|
| Male, white, nonfarm | 10.5 | 4.4 |
| Male, nonwhite, nonfarm | 31.6 | 14.2 |
| Female, white, nonfarm | 40.3 | 28.0 |
| Female, white, farm | 35.5 | 4.9 |

tions. And, this assumes that the 1959-64 degree of discrimination against nonwhites and white-nonwhite educational differences exist in 1980.

In summary, Aaron's paper offers some very persuasive evidence as to the validity of the backwash thesis. At the same time it also suggests that the backwash thesis does not depend for its validity upon any assumption of a deterioration in the traditional work-income nexus in the United States. Rather, the backwash phenomenon seems to occur in precisely those subgroups in which the work-income relationship does not have the opportunity to function as strongly due to low labor force participation rates.

On a Debt-Income Model of Consumer Instalment Credit Growth: Comment

The purpose of this note is to show that the controversy between F. R. Oliver and Alain Enthoven in their exchange in the June 1964 issue of this *Review* [3] [2] about the constancy of the borrowing-income ratio seems unnecessary on one point and yet still open to question on another. The exchange revolved around Section II of Enthoven's paper [2]. Enthoven's model can be summarized as follows:

$$(1) \quad Y(t) = Y(0)(1+r)^t,$$

where Y denotes income, r its constant relative rate of growth, and t the number of years which have elapsed since the base year. Then if $B(t)$ and $R(t)$ are new borrowing and repayments in year t ,

$$(2) \quad B(t) = bY(t),$$

and

$$(3) \quad R(t) = L[B(t), \dots, B(t-n)],$$

where b is constant and L represents some linear combination. By definition,

$$(4) \quad D(t) - D(t-1) = B(t) - R(t).$$

Using (2) and (3) in (4)

$$(5) \quad D(t) - D(t-1) = by(t) - L[bY(t), \dots, bY(t-n)].$$

As Oliver states, Enthoven assumes for the sake of definiteness that repayments are complete by the end of the third year; thus, (5) becomes:

$$(5a) \quad D(t) - D(t-1) = a_1Y(t) + a_2Y(t-1) + a_3Y(t-2) \\ = aY(t)$$

by using (1). Summing,

$$D(t) = \sum_{n=1}^t aY(n) + D(0) \\ = \frac{a(1+r)}{r} Y(0)[(1+r)^t - 1] + D(0).$$

Hence follows his basic conclusion:

$$(6) \quad \frac{D(t)}{Y(t)} = \frac{a(1+r)}{r} - \left[\frac{a(1+r)}{r} - \frac{D(0)}{Y(0)} \right] (1+r)^{-t},$$

and $D(t)/Y(t)$ appears to be approaching $a(1+r)/r$ as t tends to infinity.

In his model, Enthoven assumes that income grows by a constant proportion each year in (1), that borrowings in each year are a constant propor-

tion of income in (2), and that repayment conditions are constant in (3). Oliver argues in both words and algebra that under these restrictive assumptions, especially the last of the three, the debt-income ratio tends to a limit only in a "trivial" sense (our quotation); it always equals the "limit." He then points out that the constancy of the debt-income ratio implied by Enthoven's model is not found empirically, especially before the mid-1950s.

Enthoven replied that equations (2) and (3) were unnecessary for his model and only (1) and (4) were needed to maintain the conclusion. He conceded that Oliver's criticism was correct, but of no consequence, since he can afford to throw away (2) and (3). He then went on to demonstrate numerically that his model had performed well.

We have used the aggregate time series of borrowing, repayment, personal income, and disposable personal income¹ to estimate a few empirical relations between them. The following is what we found.

The aggregate time series of instalment credit extended, namely, new borrowing for each year 1946 through 1965, is very highly correlated linearly with either personal income or disposable income. The empirical results are as follows:

$$(7a) \quad \hat{B}(t) = -19.36 + 0.1730Y(t) \quad \text{with } r = 0.9921 \\ (1.66) \quad (0.0048)$$

$$(7b) \quad \hat{B}(t) = -20.94 + 0.2016Y'(t) \quad \text{with } r = 0.9937 \\ (1.63) \quad (0.0054)$$

where $B(t)$ is new borrowing during year t , $Y(t)$ personal income, and $Y'(t)$ disposable income (the numbers in parentheses under the coefficients are the respective standard errors). It is obvious from (7a) and (7b) that new borrowing is *not* proportional to income although certainly related linearly. These empirical results do not support Enthoven's postulate (2), $B(t) = bY(t)$, in that the constant (i.e., the intercept in billions of dollars) is definitely not zero. The t -ratio of the estimated intercept to its standard error is either -11.6 or -12.8 , both of which are highly significant, depending upon whether personal or disposable income is the regressor.²

Dividing both sides of (7a) by $Y(t)$ gives the following result:

$$\frac{\hat{B}(t)}{Y(t)} = -\frac{19.36}{Y(t)} + 0.173.$$

Both Oliver and Enthoven have observed that the borrowing-income ratio has been rising at a decreasing ("absolute") rate since 1946. This is due to the simple fact that the increasing $Y(t)$ over time reduces the magnitude of the ratio $-19.36/Y(t)$. The result is a borrowing-income ratio $B(t)/Y(t)$

¹ The data for these and all other calculations in this discussion are taken from [4]. The income data are personal income and disposable income from Table C-14, p. 226. The instalment credit data are from Table C-50, p. 269. The borrowings and repayments are from Table C-51, p. 270.

² If $B(t)=0$ in equation (7a), then $Y(t)=112$ which naively interpreted, simply means that there would be no new borrowing if personal income dropped back to 112 billion dollars.

increasing at a decreasing rate and approaching the constant 0.173 from below.

On the basis of the empirical finding, let Enthoven's postulate (2), the borrowing-income relation $B(t) = bY(t)$, be modified as $B(t) = k + bY(t)$ where $k \neq 0$. Would this modification impair his debt-income growth model? To answer this question, let

$$(2') \quad B(t) = k + bY(t),$$

$$(3') \quad R(t) = L[B(t), B(t-1), B(t-2)],$$

and

$$(4') \quad D(t) - D(t-1) = B(t) - R(t)$$

$$\begin{aligned} D(t) - D(t-1) &= k + bY(t) \\ &\quad - L[k + bY(t), k + bY(t-1), k + bY(t-2)] \\ &= k' + a_1Y(t) + a_2Y(t-1) + a_3Y(t-2) \\ &= k' + aY(t) \end{aligned}$$

where

$$k' = k - L[k] = L'[k] = 1k,$$

i.e., k' is proportional to k . Then

$$\begin{aligned} (5') \quad D(t) &= k' + aY(t) + D(t-1) \\ &= k' + aY(t) + k' + aY(t-1) + D(t-2) \\ &= \dots \\ &= tk' + a \sum_{n=1}^t Y(n) + D(0) \\ &= \frac{a(1+r)}{r} Y(0)[(1+r)^t - 1] + D(0) + tk'. \end{aligned}$$

The debt-income ratio (not borrowing-income ratio) is

$$\begin{aligned} (6') \quad \frac{D(t)}{Y(t)} &= \frac{\frac{a(1+r)}{r} Y(0)[(1+r)^t - 1] + D(0) + tk'}{Y(0)(1+r)^t} \\ &= \frac{a(1+r)}{r} - \frac{a(1+r)}{r(1+r)^t} + \frac{D(0) + tk'}{Y(0)(1+r)^t} \\ &= \frac{a(1+r)}{r} - \left[\frac{a(1+r)}{r} - \frac{D(0)}{Y(0)} \right] (1+r)^{-t} \\ &\quad + \frac{tk'}{Y(0)(1+r)^t}. \end{aligned}$$

This is the same as equation (6) above (or Enthoven's original equation (9) in his 1957 article in this *Review*) except that the last term here is new and comes about precisely from the nonzero intercept. The term $tk'/Y(0)(1+r)^t$ is a ratio of two functions of t . Will the term vanish as t tends to infinity? In other words, $\lim_{t \rightarrow \infty} tk'/Y(0)(1+r)^t = ?$ It is a so-called indefinite form of ∞/∞ . By l'Hospital's rule,

$$(7) \quad \lim_{t \rightarrow \infty} \frac{tk'}{Y(0)(1+r)^t} = \lim_{t \rightarrow \infty} \frac{d(tk')/dt}{d[Y(0)(1+r)^t]/dt}$$

$$\lim_{t \rightarrow \infty} \frac{k'}{Y(0)(1+r)^t \log_e t} = 0.$$

Thus, the limit of Enthoven's debt-income ratio remains intact even with the empirically determined non-zero intercept, that is

$$(8) \quad \lim_{t \rightarrow \infty} \frac{D(t)}{Y(t)} = \frac{a(1+r)}{r}.$$

The finding and argument above seem to explain the increasing borrowing-income ratio and yet support Enthoven's conclusion. However, we have found a rather poor empirical relation between the annual increase in debt as a function of income:

$$(9) \quad \Delta D(t) = -0.4957 + 0.01132 Y(t) \quad \text{with} \quad r = 0.5602$$

where

$$\Delta D(t) = D(t) - D(t-1).$$

This is an empirical estimation of equation (4) above (or Enthoven's original equation (6) in his 1957 article): $D(t) - D(t-1) = aY(t)$. Replacing $\Delta D(t)$ by its three-year moving averages as the regressand yields a simple correlation of 0.7063 which is not much better than 0.5602. Adding a $Y^2(t)$ term as a second regressor to the regression of $\Delta D(t)$ on $Y(t)$ merely improves the correlation from 0.5602 to 0.6647. These empirical results are particularly disappointing in view of the observed close³ relation between repayment and borrowings, current and lagged:

$$(10) \quad \hat{R}(t) = 0.588 + 0.371B(t) + 0.387B(t-1) + 0.213B(t-2),$$

with

$$R = 0.9995.$$

This corresponds to equation (3) above (or Enthoven's original equation (ii) in footnote 18 of his 1957 paper).

Oliver's concern about "a breakdown in one or more of Enthoven's assumptions, in particular, the constancy of the borrowing-income ratio" [3, p. 417], is borne out empirically. Enthoven's equation (4) is stated as:

³ The extremely high correlation of 0.9995 is partly spurious due to the high multicollinearity among the regressors.

$$(4) \quad D(t) - D(t-1) = aY(t)$$

and states in effect that the absolute increase in the stock of debt outstanding each year is proportional to a variable which grows at the same rate as income. In his *Reply* to Oliver, Enthoven presents (in Table 1) some empirical evidence to suggest the relative stability of "a" in equation (4) above. The empirical findings are based upon three-year averages; when values of "a" are computed for each of the post-World War II years, a significantly different pattern of stability (or instability) is in evidence.

TABLE 1—INDIVIDUAL VALUES OF THE RATIO OF CHANGE IN DEBT TO INCOME

| Year | $a(t) = \frac{D(t) - D(t-1)}{Y(t)}$ | Year | $a(t) = \frac{D(t) - D(t-1)}{Y(t)}$ |
|------|-------------------------------------|------|-------------------------------------|
| 1946 | .00957 | 1956 | .00854 |
| 1947 | .01319 | 1957 | .00612 |
| 1948 | .01095 | 1958 | — .00062 |
| 1949 | .01253 | 1959 | .01421 |
| 1950 | .01370 | 1960 | .00895 |
| 1951 | .00231 | 1961 | .00166 |
| 1952 | .01507 | 1962 | .01018 |
| 1953 | .01249 | 1963 | .01230 |
| 1954 | .00194 | 1964 | .01140 |
| 1955 | .01715 | 1965 | .01530 |

Mean value of "a" = 0.00985. Standard deviation of "a" = 0.00510.
Coefficient of variation = 51.8%

The data in Table 1 above and the measures of dispersion computed from those data suggest that the assumption of the constancy of "a" is, as Edward H. Chamberlain might term it, an "heroic assumption." In the latter respect, we share Oliver's concern.

Enthoven also advanced an interesting argument in his 1957 paper (especially footnote 19) that the relative variance of the differences [$B(t) - R(t)$ or $\Delta D(t)$] between two series [$B(t)$, $R(t)$] may be much greater than those of the two separate series. Our computations based upon the empirical data yield the following results:

| | | |
|---------------------------------|---------------------------|------------|
| Mean of borrowings | $= \bar{B}(t)$ | $= 37.79$ |
| Variance of borrowings | $= S_{B(t)}^2$ | $= 318.21$ |
| Relative variance of borrowings | $= S_{B(t)/\bar{B}(t)}^2$ | $= 8.42$ |
| Mean of repayments | $= \bar{R}(t)$ | $= 34.55$ |
| Variance of repayments | $= S_{R(t)}^2$ | $= 276.51$ |

| | | |
|---|---|------------|
| Relative variance of repayments | $= S_{R(t)/\bar{R}(t)}^2$ | $= 8.00$ |
| Covariance of borrowings and repayments | $= S_{B(t)R(t)}$ | $= 295.22$ |
| Variance of differences between borrowings and repayments | $= S_{B(t)-R(t)}^2 = S_{B(t)}^2 + S_{R(t)}^2 - 2S_{B(t)R(t)}$ | $= 4.28$ |
| Mean of differences | $= \bar{B}(t) - \bar{R}(t)$ | $= 3.24$ |
| Relative variance of differences | $= \frac{S_{B(t)-R(t)}^2}{\bar{B}(t) - \bar{R}(t)}$ | $= 1.32$ |

Since the relative variance of the differences (1.32) is much smaller than either the relative variance of the borrowings (8.42) or the relative variance of repayments (8.00), our empirical findings are diametrically opposed to Enthoven's argument on the basis of relative variances. Thus, Enthoven's derived equation, i.e.,

$$D(t) - D(t-1) = aY(t)$$

remains open to question, and as Enthoven admits, his model comes to naught if equation (4) is abandoned.

Allocative Efficiency vs. "X-Efficiency": Comment

Professor Harvey Leibenstein's extension of the concept of efficiency to the "non-allocative" area of resource utilization within business firms [3] is a welcome addition to the literature of economics. The purpose of the present note is to comment briefly on one related issue: the limited role assigned by economists to competition as an efficiency-making force.

The burden of the evidence cited by Leibenstein is that entrepreneurs do not always maximize productive efficiency. That this is not a novel

proposition¹ in no way lessens its significance for the theory of the firm, for it undermines one of the most fundamental postulates of economic theory—the assumption that firms will combine the various factors of production in the most productive manner.

A curious double standard has always existed in microeconomic theory. While it has been assumed that the self-interest of businessmen would be an adequate guarantor of efficiency in resource use within the business firm, the competitive pressure of other firms, a force external to the firm itself, has been considered necessary to insure efficiency in the firm's dealings with the consuming public. It is this double standard which makes it necessary to distinguish between "allocative efficiency" and "X-efficiency." The difference between these types of efficiency is at bottom the difference between the market and the firm as institutions through which resources are organized and channeled for ultimate consumption.

Underlying the theory of the firm is the notion that, given the structure of the market, one firm is as efficient as another. Even the monopoly, albeit producing a smaller output and selling it at a higher price than would obtain under competitive conditions, is assumed to be producing in a "least costly" way, exactly as would the purely competitive firm. The internal efficiency of business organizations has not been challenged in economic theory. The so-called theory of the firm is, strictly speaking, not a theory of the firm at all but a theory of market structure.

Basic to the reasoning by which economists have limited the analysis of efficiency to the market is a concept of competition that has historically been limited to exchange. Despite Adam Smith's emphasis on division of labor as the fundamental element in the technique of production and the great source of economic growth, an emphasis quite in contrast to the earlier emphasis of the mercantilist writers on trade itself as the source of surplus, the mercantilist's overriding concern with price continued, with Smith and his successors, to be the central theme of economic inquiry. The purely analytical (as distinct from the ideological) function of competition was for Smith precisely what it had been for Sir James Steuart before him—to lower price to the minimum sustainable level [6, pp. 196-197], [5, Chap. 7]; not, as for Steuart, in order to stimulate exports, [6, p. 284], but rather in order to provide "cheapness of consumption" which, according to Smith, was the proper object of domestic policy [5, p. 706]. For Ricardo and the classical economists, competition served to bring market price down to long-run cost. That cost itself, however, even after economists stopped referring to it as "natural," was assumed to be minimal, and output was assumed to be produced in the most efficient manner.

¹That internal organization of firms might not be of maximum efficiency has, of course, been suggested by economists from time to time, but such suggestions have not been incorporated into the theory of the firm. Labor economists, in defending minimum wage legislation, have sometimes held that internal efficiency might be improved if firms were subjected to the "shock effect" of higher wage costs. Again, the ILO studies showing that "low productivity is frequently caused by top management's concern with the commercial and financial affairs of the firm rather than with the running of the factory," which "was frequently treated as a very subordinate task" [3, p. 406] is reminiscent of Veblen's distinction between making goods and making money [8].

Competition, in short, was exclusively with respect to price in the market; it did not relate to the technique of producing.

The incorporation into economic theory of a concept of competition enlarged to include method of production as well as price would help to bridge the gap between the two areas of economic inquiry for which Leibenstein's discussion of "X-efficiency" is most relevant: the theory of the firm and the problem of economic growth. The *Wealth of Nations*, of course, was a theory of society, not merely a theory of markets, and for Adam Smith questions of economic growth and resource allocation were integrally related both to each other and to the admixture of freedom and competition implicit in his use of the term "natural liberty." But the concept of competition was not well developed by Smith,² and its subsequent refinement came at the hands of economists whose concern was not with analyzing the changing economic structure of society but rather with developing, with mathematical rigor, the central question of resource allocation by means of a pricing system [7]. The theorist's concept of competition came increasingly to be tied to price, while questions of competition by means of productive and organizational technique, as part of the larger problem of economic change and growth, became the province of the economic historians. The latter have necessarily given a broader meaning to competition than that traditionally associated with the theory of the firm, such as developments affecting the internal organization of firms and vertical, horizontal, and conglomerate integration—developments frequently viewed by the theorist as deviations from competition.³

Any significant integration of the theory of resource allocation with the problems of economic growth—a step which would constitute a major advance in economic inquiry—must necessarily include, it would seem, an expansion of the concept of competition to take into account more fully than has so far been done the behavioral responses of firms to the internal organization of their competitors, apart altogether from market structure. In spite of the great advance made by E. H. Chamberlin [1] toward a more meaningful theory of competition, the interfirm differences that are well developed in economic theory remain differences of markets, i.e., of exchange conditions. Competition in the realm of production is still analytically unrefined—as is illustrated by the ambiguity of the "competition" and the "competitive pressures" to which Leibenstein refers at several points [3, pp. 408, 412, 413]. Despite the emphasis in recent years on nonprice competition by whatever name, it is hard to es-

² Smith was aware of the technological element in competition. Lowered prices and increased demand, he wrote "... encourages production, and thereby, increases the competition of producers, who, in order to undersell one another, have recourse to new divisions of labour and new improvements of art, which might never otherwise have been thought of" [5, p. 706]. But the essence of competition was the effort to undersell. Its subsequent development came to be limited to price, while its technological and organizational implications were "impounded" in the *ceteris paribus* assumption.

³ To the theorist, for example, the oligopolization of the meat packing industry by the big five was not a "competitive" development, for it resulted in a market structure dominated by a few firms. To the historian, on the other hand, it was the "competitive" response of Armour, Morris, Cudahy, and Schwarzschild & Sulzberger to the innovations in production and marketing introduced by Gustavus Swift [2, pp. 25-27].

cape the conclusion that the theory of the firm still rests on a concept of competition (or, as with the Chamberlinian model, on deviations therefrom) that is essentially what it was when it was developed by Jevons and Edgeworth almost a century ago.

Clearly, economic growth is the central question for our times. Equally clearly, competition "... within a rigid pattern of invariant conditions, methods of production and forms of industrial organization . . ." cannot be, as Schumpeter recognized and stressed [4, p. 84], competition that is meaningful for the analysis of economic growth. On the contrary, an economically significant concept of competition must, as he pointed out, pay increased attention to the managerial and organizational function of the firm, and "internal, especially technological, efficiency" [4, p. 106]. Leibenstein's findings that "... in a great many instances the amount to be gained by increasing allocative efficiency is trivial while the amount to be gained by increasing X-efficiency is frequently significant" [3, p. 413] is a cogent reminder of the relevance, in this respect, of Schumpeter's insight.

Allocative Efficiency vs. "X-Efficiency": Comment

In his article on "Allocative Efficiency vs. 'X-Efficiency'" Professor Harvey Leibenstein pointed out that "economic theory focuses on allocative efficiency to the exclusion of other types of efficiencies which, in fact, are much more significant" [3, p. 392 fl.]. Economic theory presumes that managers of business firms are already making optimum input decisions so consequently it tends to focus on allocation of goods and services along a production surface as opposed to movements from a less efficient production surface to a higher one.¹

¹ Though this point is not relevant to the empirical data reported in this paper, and

The purpose of this paper is to report findings that are especially noteworthy because they involve an opportunity to test the "X-efficiency" hypothesis under well-controlled conditions involving 22 separate restaurants, and the results are determinant and meaningful in reinforcing the evidence cited by Leibenstein regarding the impact of managerial performance on efficiency of business firms. The data presented by Leibenstein cover different circumstances that are impressive in their totality and general consistency. However, the basic reports he mentions reveal, on careful study, enough vagueness in the underlying figures that a skeptic might still claim he is unconvinced of the existence of "X-efficiency," or its importance. Some changes in productivity that were noted took place over a long period of time and thus became associated with other coincident activities such as the acquisition of new equipment, technological innovations of a scientific nature, or a change to a better quality of worker.

The difficulties in making careful measurements of productivity are well known. They include such problems as: How to compare output when the product mix differs; how to measure the quality of output; how to isolate the impact created by such things as new equipment; how to adjust for the fact that the use of raw materials and fuel per unit of output may not be standardized.

The authors cited by Leibenstein were certainly aware of the difficulties, so a sampling of their studies contains such cautionary remarks as: "This method gives an essentially crude comparison of output per head" [4, p. 2]. "The results . . . may be taken as a rough measure of organizational input inasmuch as other factors were, to a large degree, constant" [2, p. 303]. "But the enquiries were handicapped in all cases by the fact that the fundamental changes had been made before any steps could be taken to obtain a first-hand account of the position before incentives were introduced" [1, p. 88]. "Although the choice of industries has been governed by the need to ensure some degree of accuracy for these estimates, there is nevertheless the possibility of serious errors. The output series in particular are subject to all the hazards encountered in the measurement of long-period production movements. Index-number biases and quality changes are inescapable sources of serious errors. . . . For these reasons, it is appropriate to regard the estimates simply as indications of the order of magnitude of the changes that have taken place" [5, p. 106].

In contrast, however, the circumstances reported in the present study hold almost everything constant except a change in management. Furthermore, there are enough observations that statistical validity can be implied. Briefly, the data came from a large company that operates, primarily on a franchise

may be unnecessarily argumentative, it is interesting to consider that this possible distortion in economic theory parallels and may help explain the sometimes-noted schism between university economics departments and business schools. The economics department tends to assume that firms operate on their most efficient production surface so the only issue is one of allocative efficiency; business schools on the other hand emphasize the need to increase efficiency within the firm, and may slight questions of allocative efficiency.

basis, a string of restaurants. Because the management of this company has confidence in its ability to guide the franchisee, and because of the franchisor's desire to have a uniformly good reputation that will be associated with every eating place despite the fact that each is operated by a different owner, the parent company provides a great deal of direction. The details are too lengthy to enumerate but a few examples will suggest the extent of company supervision. The parent company prescribes each item that will be on the menu, and its head chef determines optimum recipes so that each franchisee-operator is told exactly how many pounds of coffee to use in the coffee-making equipment, how many slices of bacon go with an order of eggs, how many ounces of meat to put in an entree, etc. Not only are the menus and recipes standardized, all ingredients, down to napkins and tableware, are supplied to the franchisee-operators by the parent company. A service manual used at each restaurant standardizes service. For example, when a waitress approaches the table for the first time her introductory remarks are specified exactly. Each unit operates from a company-designed restaurant, occupied on a lease basis. The parent company uses electronic computers to record sales and cost items, and relieves the franchisee of practically all bookkeeping details by collecting weekly all expense and revenue records. The franchisor pays the itemized bills for the franchisee so that the franchisee-operator is only required, so far as bookkeeping is concerned, to deposit his cash receipts daily and sign three checks per week—the amount of each check representing the total for three major cost categories, labor, supplies, and taxes. In short, the accounting records for each restaurant are completely uniform, and so handled as to relieve the franchisee of almost all detail. The management of the franchising company believes, in fact, that its operations are so thoroughly supervised and organized that a franchisee (who typically pays approximately \$30,000 for the privilege of becoming a franchisee in a large restaurant and \$10,000 in a snack shop) is selected only from people who have not had experience in the restaurant industry. The operating company has found that those with prior restaurant experience are likely to think they know so much about the business that they try to install practices other than those specified by the franchisor.

The parent company prefers to have each of its outlets operated by a franchisee-owner, who is an independent businessman legally as well as in terms of his remuneration. But from time to time the company finds it necessary to operate a franchise outlet itself. The franchising contract contains a provision allowing the franchisee to terminate his franchise and be repaid his original investment; also the franchisor-parent company has the right to terminate, with a similar repayment clause, if it can be proved that the franchisee has not been living up to food and service standards prescribed in the original contract. As a matter of practice, termination by the franchisor has proved difficult, so most of the situations where a franchisee owner quits arise from death, illness, or other personal reasons on the part of the franchisee. Until such time as the company can find a new franchisee who will own and operate the restaurant it is necessary for the company to continue the operation itself. For this purpose it assigns to the restaurant a manager from a group who have

worked with the parent franchisor for many years and are experienced in the restaurant operations of this chain.

As a result of installing electronic data processing equipment which makes extensive reports on the sales, costs, profits, and operations of each food outlet, the management has developed an accurate record of the performance for each restaurant during periods of franchisee-ownership or franchisor-management control.

These changes involve absolutely no alteration in capital investment, materials used, production technology, layout, or accounting records; the only variation is the employment relationship of the restaurant manager to the parent company. Since this chain imposes such close control over each outlet it was presumed that there would be very little shift in the efficiency or profitability of an outlet when it was being operated by a company-installed manager instead of a franchisee owner.

Because the assets invested in the restaurant are unchanged when the supervision shifts between franchisee-owner and company-manager three measures that can be used to evaluate a change in productivity or efficiency are: profit as a per cent of sales; total sales; or total profit. From basic records made available by the franchisor, the necessary figures for these three measures were calculated and tabulated for every restaurant which had experienced a change in managership since installing computing equipment. The results are presented in Table 1.

The following explanations will make the table more understandable. The restaurants are of two types: those listed A - M are large, fairly complete, family-eating establishments, those listed N - V are smaller, quick-snack places and have correspondingly smaller investment and sales. The company is very careful to measure profit in exactly the same way under either type of management. Profit is defined as revenue less all relevant expenses except manager's salary and income tax; this means the company-manager figure for profit is identical to the profit earned by the franchisee-owner. The restaurants are located in all parts of the United States, and are of varying size and tenure-of-establishment, so even within similar types of restaurant there is considerable variation in sales. In some cases, as can be seen from the table, franchisee-ownership (F.O.) preceded company-manager supervision (C.M.); in some cases F.O. followed C.M.; in some cases there was a sequence of changes from F.O. to C.M. and back to F.O. In short, the situations cover all conditions and circumstances faced by the parent company.

Those following general conclusions can be drawn from a study of Table 1.

(a) Out of 22 restaurants where the type of management changed, the shifts in profit margins were adverse to company managers except in three cases.

(b) Considering every case where the C.M. followed an F.O., weekly sales were, on average, 99.6 per cent of the sales rate achieved by the F.O. (If the special case where a C.M. operated a restaurant for only seven weeks that happened to include a July 4th holiday is eliminated, the ratio is 92.7 per cent or sales dropped 7.3 per cent. Considering every case where the F.O. followed a period of C.M., sales rose 5.8 per cent. (Again, if the time an F.O. followed

TABLE 1^a

| Restaurant | Type of Management | Number of Weeks | Average Weekly Sales (dollars) | Average Weekly Profit (dollars) | Profit Divided by Sales |
|------------|--------------------|-----------------|--------------------------------|---------------------------------|-------------------------|
| A | F.O. | 19 | 3,463 | 124.67 | 3.6 |

| V | F.O. | 91 | 1,240 | 208.32 | 16.8 |
| | C.M. | 29 | 1,174 | 93.92 | 8.0 |

the C.M. who presided over the July 4th weekend is eliminated, the F.O.'s increased sales 19.1 per cent.)

(c) The sales-volume changes were slightly in favor of F.O.'s, but the profit patterns were more striking. The profit margins (profit ÷ sales) for F.O.'s averaged 9.5 per cent; the profit margins for C.M.'s averaged 1.8 per cent. The average weekly profit for all the restaurants during C.M. supervision was only \$56.81; under F.O.'s the profit was \$271.83, or 478 per cent greater. Only two of the 29 observations where F.O.'s were in charge showed losses; in contrast 11 of the 24 cases where C.M.'s were running the restaurants showed loss operations. These data were consistent with the beliefs of the parent company executives who said, "We don't think there is much change in sales when a restaurant is operated by a franchisee-owner instead of a company manager, but we do think profits go up. This is because franchisee-owners just watch the little things closer; they utilize the cooks and waitresses better; they reduce waste."

The evidence seems too persuasive to ignore. Despite detailed supervision which would seem to minimize opportunities for managerial initiative, restaurants operated by independent franchisee-owners outperformed those supervised by company managers, even though the company managers are paid on a basis that involves some incentive compensation for achieving profits. (The company managers can earn a bonus for profitable operation that could go as high as 33 per cent of their salary, and typically averages 15 per cent.) The impact of motivation, arising from circumstances where the franchisee-owner has invested his capital in the business and receives as income only profits, is revealed in data that strongly support the importance of X-efficiency.

Some Estimates of the Cost of Capital to the Electric Utility Industry, 1954-57: Comment

A recent paper by Merton H. Miller and Franco Modigliani [4] (hereafter MM) represents an interesting empirical extension of their earlier theoretical work, which stipulated the invariance of the cost of capital to the capital structure of a business firm, abstracting from the effects of the corporate income tax. Their previously developed theory is used to set up an econometric model from which are derived estimates of the cost of capital to the electric utility industry for the years 1954, 1956, and 1957.

We have a number of reservations as to the practical relevance of the theoretical structure from which the invariance thesis is derived; and we suggest that previous empirical testing of this thesis fails to justify its utilization as a basis for measuring the cost of capital—particularly when the cost of capital can be estimated without prejudice as to the relationship between the cost of capital and the capital structure.¹ In this Com-

¹ The most comprehensive studies known to us of the effect of capital structure on the cost of capital are those by Alexander Barges [2], William White [6], William Beranek [3], and Fred David Arditti [1]. In the first of these studies, Barges points out the serious deficiencies in the

ment, we shall indicate further deficiencies in the specific econometric model used by MM which suggest that their estimates are subject to downward bias, and we shall present an alternative approach and alternative estimates of the cost of capital. However, we should like to stress that we do not regard our results as definitive but merely as indicative of a more useful methodology, and that any estimation of the cost of capital is subject to a substantial margin of error in view of its dependence on the measurement of investor expectations.

The statistical implementation of their basic theoretical model is carried out by MM with a considerable degree of sophistication and ingenuity. However, there are substantial shortcomings in the statistical model, of which the authors do not appear to be aware. Since these generally would be expected to lead to an overstatement of the earnings multiplier and thus to an understatement of the cost of capital, there may be a significant downward bias in the estimates of the latter.

First, we take exception to the manner in which size is introduced as a possible determinant of the value of the firm. If enterprise risk (and therefore the capitalization rate, p , for a pure equity earnings stream) is independent of size, then in the no-growth case we expect value (apart from that portion due to the tax advantage of debt), $V - \tau D$, to be proportional to normalized earnings, \bar{X} , as shown by line OC in Figure 1a.² However, if p declines as size increases, through some diversification effect, and if size is not explicitly taken into account, then because of the high correlation between size and dollar earnings we will have value rising more than proportionately with earnings as in the curved line in Figure 1b. If the model enforces linearity on the value-earnings relationship and if observations fall in the range \bar{X}_1 to \bar{X}_2 , the regression line obtained will be something like AB . MM are quite correct in pointing out that a negative intercept can be interpreted as evidence of a favorable effect of size on risk class. However, the slope of AB now overstates the true effect of earnings on value, given size, which is still represented by OC for firms of average size. To avoid this overstatement, a size variable must be explicitly included.

In the relations actually fitted, MM deflate all variables by total assets in order to reduce heteroskedasticity, so that the inclusion of a constant

earlier empirical work referred to by MM. Of the four, only Beranek obtains results interpreted as favorable to the MM theory and the test here is based on the incorrect assumption that this theory implies an ultimate downturn in the equity yield curve (as a function of leverage) whereas such a downturn is inconsistent with traditional theory. (On this point see Alexander A. Robichek and Stewart C. Myers [5, pp. 34-36].) The Arditti study is in certain respects the most satisfactory of the four referred to. It covers a large continuous cross-section of firms in many different industries over the 1946-63 period, is more multivariate than the earlier studies—including a dividend effect and numerous risk variables as well as the debt-equity ratio—and as compared with the Beranek study more plausibly interprets the MM hypothesis as implying simply a positive slope of the equity yield curve as a function of leverage even after adjustment for corporate taxes. The regression coefficient of the debt-equity ratio is generally negative (frequently significantly so) and never significantly positive. Similar results were obtained by White, who uses a book rather than market debt-equity ratio to measure leverage.

² Here V is the total value of the firm, D is the face value of debt and τ is the corporate profits tax rate.

FIGURE 1a

FIGURE 1b

term is equivalent to the introduction of total assets into the undeflated equations. Thus the suppression of the constant term in the lower panel of their Table 1 may lead to an overstatement of the earnings multipliers by assigning to earnings any favorable effects of size on risk, while the relatively low earnings multipliers in the top panel are free of this error. The constant terms in the top panel are significant in two of the three years, suggesting that p does indeed decline with size.³

Secondly, the replacement of actual earnings with a linear function of dividends and other variables may lead to upward bias in the earnings coefficient. There is considerable appeal in the argument that the theoretic-

³ The significantly negative coefficients of $1/A$, the counterparts of the constant terms in the undeflated equations, suggest that the effect of size is nonlinear, as we might expect on the supposition that it is systematically related to p and should therefore enter multiplicatively rather than additively into the value-earnings relationship.

cally relevant earnings variable of the MM model, the expected average future earnings on existing assets, may be better approximated by the level of disbursements to which management has committed itself (with varying degrees of firmness) for debt service and preferred and common dividends than it is by the level of current income. However, these disbursements may have independent effects on value and may contain other information in addition to that on normalized earnings. To the extent that high payout is preferred (or disliked) by the kind of investors who buy utility stocks, dividends may have an independent effect on value, for given normalized earnings. Furthermore, to the extent that enterprise risk varies within the industry, whether because of size differences or for any other reason, we may expect that the disbursements to which management commits itself will be higher relative to normalized earnings for the lower risk firms. Thus the level of disbursements contains information about enterprise risk as well as normalized earnings.⁴ It is not clear how the positive correlation of dividends with payout would affect the estimated cost of capital,⁵ but the negative correlation of dividends plus contractual disbursements with risk (given normalized earnings) would be expected to bias the normalized earnings coefficient upward and hence the cost of capital downward.⁶

MM attempt in their Table 5 to test the strength of any independent effect of payout on valuation by adding a linear dividend term (the deviation of actual dividends from those expected on the basis of an average payout ratio) to the value regression. This is not really a satisfactory test since neither the effect of payout per se nor that of dividends as a proxy for enterprise risk is likely to be linear or even monotonic; and it is not clear what implications the nonsignificance of the dividend coefficient might have as to bias in the two-stage estimate of the earnings multiplier. When current earnings are used as the earnings variable, the effect of dividends is always found to be positive and is significant in one of the three years, suggesting that payout does indeed contribute to the explanation of value, given earnings. However, it is not certain whether its contribution arises from the information it supplies as to normalized earnings

⁴ It should be noted that dividends are by far the most important ingredient in the linear function used to approximate normalized earnings, so that the two-stage value regressions are almost, but not quite, equivalent to substituting dividends for current earnings as a determinant of value. The regressions of earnings on the instrumental variables, excluding dividends, show very small correlations, except in 1957 when a significantly negative debt coefficient makes some contribution. However, the theoretical expectation is for a positive effect here.

⁵ If utility investors in the mid-1950s preferred dividends to retained earnings, the estimated cost of capital would be biased downward; if they preferred retained earnings, the bias would be reversed.

⁶ It is of some interest that the constant term becomes insignificant in the value regressions when computed earnings based on the instrumental variables are substituted for actual earnings. MM interpret this as indicating that they were right in suppressing this term, thus implicitly excluding assets from the undeflated relationship. Our interpretation is that the instrumental variables representing the level of disbursements to which management is committed contain most of the information as to cross-sectional differences in enterprise risk which a size variable, entering linearly, has to offer (as well as information on normalized earnings), so that when these are introduced the effect of assets in the undeflated relationship is no longer significant.

or from its ability to proxy for enterprise risk or from a payout effect per se. If only the first is involved, then the use of a computed earnings variable based on dividends will not lead to an overstatement of the effect of normalized earnings. If either of the last two is involved, then bias is to be expected in the two-stage estimate of the earnings multiplier.

When the earnings variable used in the test is a computed value based on the instrumental variables, the dividend effect becomes insignificantly negative. While this suggests that the payout effect per se either is not large or (as we believe) is nonlinear, it is not convincing evidence against the proposition that the two-stage earnings variable may proxy for enterprise risk, since the instrumental variables, which include disbursements for interest and preferred dividends as well as common dividends, clearly contain all the information as to both normalized earnings and risk which the dividend deviation could possibly supply, and considerably more in addition. It is the total disbursements for interest and preferred and common dividends which we expect to be high relative to normalized earnings when enterprise risk is low; and in fact the disbursements for the first two may be expected to rise relative to the third as risk falls, if as we suspect financial leverage tends to be inversely correlated with enterprise risk.

Finally, and most important, we have strong reservations about the growth variable used. While we are not entirely satisfied with MM's theoretical formulation of the growth term, we agree that it must depend on the three components they distinguish—the rate at which assets grow, the extent to which average return on new investment exceeds the cost of capital, and the number of years for which investment opportunities at rates substantially above the cost of capital are expected to be available. The variable actually used in their regressions reflects only the first of these. However, if there are significant cross-sectional differences in the average rate of return available on new investment, it seems entirely likely that this rate will be substantially correlated with the rate of return on existing assets. But this is precisely the earnings variable used in the deflated regressions. We expect therefore that the coefficient of this variable reflects not only the multiplier for expected earnings on existing assets but also some part of the second component of the growth effect, that which is related to the average rate of return on new investment. As a result, the normalized earnings coefficient is again biased upward and the cost of capital downward.

In summary we feel that the coefficients of earnings in the lower panel of MM's Table 3 are too high (and hence the cost of capital estimates too low) because they reflect not only (1) the effect on enterprise value of expected average future earnings from existing assets, but also (2) the informational content as to enterprise risk provided by assets, dividends and interest charges and (3) the effect on value of that component of the growth term which is related to return on new investment. The increase in earnings multipliers from the values of 13.7 to 15.7 appearing in the upper panel of Table 1 to the values of 16.1 to 19.7 appearing in the lower panel of Table 3 is attributable in part to the second of these considerations and only in

part to the informational content of the instrumental variables as to normalized earnings. Both sets of estimates are presumably biased upward by the inadequacies of the growth variable used and are subject to the basic limitation of this empirical approach which makes the unnecessary and potentially dangerous invariance assumption.⁷

Direct Estimates of the Cost of Capital

A preferable approach to estimating the cost of capital is to derive separately the required rate of return on common (after corporate taxes), i_e , the required rate of return on preferred (again after taxes), i_p , the required rate of return on bonds, i_b , and to obtain a before-tax overall cost of capital (prior to adjustment for underpricing) $i' = W_e(i_e/(1-t)) + W_p(i_p/(1-t)) + W_b i_b$, where i' indicates the before-tax basis, t is the corporate tax rate and W_e , W_p , and W_b are the ratios of the market value of common, preferred, and bonds to the total value of securities. This approach abstracts from the problem of measuring the effect of capital structure on the valuation of a firm (a problem to which we have no satisfactory answer). It simply assumes that the company has a target debt-equity ratio which is close to the actual ratio and that small or temporary deviations from this ratio do not significantly affect the overall cost of capital. There is of course no real difficulty in measuring i_b , i_p , W_b , W_p , and W_e , so that the only important problem is to estimate i_e .

Now i_e can be estimated through an indirect regression approach similar to that used by MM in estimating the overall cost of capital, but to avoid the serious difficulties of such an approach, we can compute i_e much more directly if we are willing to make a few simplifying assumptions. If the investor is assumed to expect a constant growth rate (g) in annual earnings (E) during the time period (n years) the investor plans to hold the stock, and the dividend payout ratio (d) is also expected to remain constant, then the after-tax return on equity which is required by the marginal stockholder at a given time is implicit in the existing market price per share, and may be deduced from the following equation relating this price P_0 to the discounted present value of dividends and capital return:

$$(1) \quad P_0 = \sum_{t=1}^n \frac{(1+g)^t d E_0}{(1+i_e)^t} + \frac{P_n}{E_n} \cdot \frac{E_0(1+g)^n}{(1+i_e)^n}$$

since $E_n = E_0(1+g)^n$.

If we make one further assumption, that for most companies for most periods of time investors expect the price-earnings multiple at the end of the period when they liquidate their investment will be the same as when

⁷ There is no presumption as to the direction or magnitude of error which might result if the invariance assumption is in fact incorrect. MM's Table 4 suggests, at least when the earnings variable is computed from the instrumental variables, that no large error is involved; but this test is not really convincing, since leverage is introduced linearly into the valuation regression. Leverage, if it affects value, certainly cannot be expected to do so linearly. The traditional theory would lead us to expect that, for given normalized earnings, increases in debt would initially increase but eventually decrease value.

they invest, the above equation simplifies to

$$(2) \quad i_e = g + \frac{E_0}{P_0} (1 + g)d.$$

The $(1+g)$ factor in the last term, which would disappear if dividends were paid and discounted continuously at the annual rates dE_t and i_e , can be omitted for convenience resulting in a very slight understatement of the cost of capital if as is usual dividends are paid quarterly whereas g is computed on an annual basis. For convenience dE_0 will be written as D_0 or the initial dividend rate per share. The required rate of return on equity can now be written as

$$(2') \quad i_e = \frac{D_0}{P_0} + g$$

or the sum of the initial dividend yield and the expected growth rate. The first of these is directly observable, while the second must be inferred from historical growth rates or in some other way.

The only significant assumption involved in this derivation which might be questioned is whether investors normally consider that $P_n/E_n = P_0/E_0$. For the market as a whole or for any very broad industry group, this assumption seems reasonable, except perhaps at cyclical extremes. It is equivalent to assuming (though investors may or may not think of it in this way) that the growth rate anticipated for the n year holding period is expected to continue indefinitely. If this assumption is regarded as unrealistic, it is simple enough to revert to equation (1) and allow for differences in growth rates, reflecting say rates of return on investment significantly above the cost of capital for a stipulated period, n years, and a smaller growth rate thereafter. MM [4, p. 385] obtain an estimated n for the electric utilities of 1 year in 1954, 6–12 years in 1956 and 11–51 years in 1957, which seems like an unreasonably large range. If a well-known 20-year forecast of a 5 per cent annual growth in earnings per share for the electric utilities made in the early 1960s by Charles Tatham, with an initial P/E ratio of 18 and dividend payout of somewhat below 70 per cent, is taken as more indicative of investor expectations (at least for that period), then we obtain an estimate for i_e of 8.8 per cent if the growth rate of 5 per cent is expected to continue indefinitely (or if $P/E=18$ at the end of 20 years), and this estimate is reduced only moderately to slightly over 8 per cent if the growth rate is expected to revert to 3 per cent at the end of the 20-year period.

In 1954, 1956, and 1957 the actual average D/P ratios for Moody's 24 Utilities were .048, .047, and .049 respectively, and .049, .047, and .046 if three-year centered averages are used. Average annual compound growth rates in earnings of these stocks for the same years are presumably indicative to some extent of the growth rates anticipated by investors at that time. These were .045, .066, and .054 over the preceding five-year period, and .060, .043, and .047 over the preceding ten years. The corresponding growth

rates in dividends which might be regarded as smoothed earnings rates were .051, .043, and .049 over five years, and .050, .050, and .045 over ten years. These past growth rates were quite close to the forecasts made by the investment community for the period ahead.⁸ The use of any of these sets of observed growth rates in equation (2') would imply an i_e averaging in the neighborhood of .10 for the three years without too much variation from year to year, but with the precise figure derived depending on the type of growth rate used. If a growth rate of .04 is substituted for those observed, on the grounds that stock prices do not fully reflect the past or predicted growth rate in earnings or that these growth rates are not regarded as enduring over very long periods, i_e would range from slightly under .09 in 1954 to over .085 in 1957. A growth rate of .03 would imply an i_e ranging from slightly under .08 to over .075. To place these growth rates in some perspective, they might be compared with the 5.9 per cent postwar growth rate in current dollar GNP, the 4.5 per cent growth rate in average annual earnings of the Cowles-Standard and Poor industrial stock indexes since the latter part of the 19th century, and the growth rates of 5.3 per cent in current dollar GNP and 3 per cent in constant dollar GNP since the early part of this century.

As one test of the reasonableness of our method, the required average rates of return on equity which we obtain, ranging from well over $7\frac{1}{2}$ per cent at an assumed $g=.03$ to well over $9\frac{1}{2}$ per cent at an assumed $g=.05$, might be compared with an average E_0/P_0 of .069 for the three-year period. Presumably a simple E_0/P_0 ratio represents a significant understatement of the required equity yield since P_0 must exceed E_0/i_e if future investment with returns above the cost of capital is anticipated. It is not possible to say with certainty how much higher i_e is than E_0/P_0 since this depends on investors' expectations which cannot be measured with any precision. However, an i_e of .075 would seem to be at the lower end of any reasonable range while .095 might be at the upper end.⁹

As a further check on our results, we may compare them with Arditti's indirect estimates of the required rate of return for AT&T [1],¹⁰ if we assume this is not heroically different from that for the electric utilities on the hypothesis that the higher leverage of the latter is associated with and may be offset by less industry risk. Adding the change in the capitalization rate

⁸ They were also reasonably close to the actual annual growth rates in earnings and in dividends for each of the five-year periods beginning in 1954, 1956 and 1957, which averaged well over 5 per cent in earnings and somewhat over 4 per cent in dividends for the three periods. The ten-year growth rates for the period ahead were available only for 1954 where they were considerably higher than the corresponding five-year growth rates.

⁹ The few institutional and professional investors we have talked to indicate they require or expect about a 10 per cent rate of return on industrial equities, with a somewhat lower rate on electric and gas utilities. They may of course be deluding themselves but 10 per cent is quite close to (though somewhat below) the average annual rate of return (including capital gains) experienced in the Standard and Poor industrial and composite price indexes for common stock for the 1926-65 period or to the average return obtained by splicing the Standard and Poor indexes to Cowles Commission stock data back to the latter part of the 19th century. A return of 10 per cent is well below the average rate in the postwar period.

¹⁰ No electric utilities are included in this analysis.

for AT&T over this period ($-.0377$) to the realized rate of return (.1611) gives a required rate of return of .123 [1, p. 134], which of course is well above the range presented here. Another indirect estimate of the required rate of return for AT&T can be obtained from Arditti's analysis relating the required rate of return for a large cross-section of equities to a number of measures of risk, including most notably the variance and skewness of the distribution of annual returns. This analysis implies a required rate of return of .085 or somewhat above, which is about the midpoint of our range [1, pp. 98 and 124]. It is interesting to note that AT&T stock (and presumably also stock of the electric utilities) has somewhat below average variance which lowers the required rate of return but also less positive skewness which raises the required rate of return.

A final check on the reasonableness of our results may be obtained by examining their implications as to the return on book expected by investors. The 4 per cent growth rate of earnings subsumed in the 8.5 per cent figure which is the midpoint of our range reflects not only growth arising from retained earnings but also the growth (per old share) arising from external financing. Much of the latter reflects the issuance of new shares at prices substantially higher than book, thus raising the rate base per share. If only 1 per cent of the 4 per cent total represents growth from such external sources, which we suspect represents an understatement, an 8.5 per cent required yield on equity would be associated with about a 10.3 per cent rate of return expected on book equity (in view of an average payout ratio of 71 per cent for the three-year period according to Moody's 24 Utilities). Similarly, a 7.5 per cent required yield on equity would be associated with about a 6.9 per cent return expected on book equity, a result which clearly seems too low. The actual yield on book equity in this period was 9.4 per cent for the Moody's 24 Utilities (and 10.6 per cent for the FPC Class A and B Utilities which had a 73 per cent payout).

In order to arrive at an overall cost of capital, comparable with the MM figures, there is still the problem of obtaining the market weights for bonds, preferred and common. Though we do not have such data directly, we can use MM's sample book ratios of 51 per cent for bonds, 11 per cent for preferred and 38 per cent for common, and then convert these ratios to a market base by adjusting them for the ratio of market to book value of common equity, which averaged 1.59 for their sample of electric utilities in the three-year period. The resulting market weights are estimated at 42 per cent for bonds, 9 per cent for preferred and 49 per cent for common. Applying these weights to required yields of .038 for bonds (the average yield on AAA public utility bonds in that period), .045 for preferred,¹¹ and a rough estimate of .085 for common gives a before-tax overall cost of capital (prior to adjustment for underpricing) of .107.¹² This may be con-

¹¹ Since we have not been able to find a preferred stock yield index for utilities, we have used the embodied cost figures given by MM which presumably represents a small understatement of the relevant current yield. The use of a AAA bond yield presumably also results in some understatement of the relevant bond yield.

¹² The after-tax yields on common and preferred have been divided by the complement of an assumed marginal corporate tax rate of .5.

sidered the marginal before-tax overall cost of financing if the same proportions of common, preferred and bonds are used in the new financing as in the existing capital structure.

This estimated before-tax cost of financing of .107 may be compared with a figure of .083 implicit in the MM results. Even if a relatively low i_d of .075 is assumed (corresponding to a .03 growth rate), our before-tax cost of capital is still somewhat over .097. This estimate might be further reduced to .093 if an embodied past rather than a marginal current cost of senior capital is used, but this does not seem to be consistent with any useful economic concept of the cost of capital. Our admittedly crude empirical results therefore again suggest a significant understatement in MM's estimate of the cost of capital, confirming our earlier conclusions drawn from an investigation of their econometric model.

Some Estimates of the Cost of Capital to the Electric Utility Industry, 1954-57: Comment

Franco Modigliani and Merton H. Miller have been among the foremost contributors during the last decade to progress in the theory of cost of capital, security valuation, and corporation finance. The position they have earned in the field gives considerable authority to the empirical research they presented in a recent issue of this *Review* [12] on alternative theories in the area. Furthermore, the authority status of their conclusions is enhanced by the magnitude of their effort and by the categorical manner in which they stated many of their conclusions. It is therefore desirable that their findings be subject to a critical review, and since the work in which I have been involved has led to different conclusions, I felt drawn to the task.

In my analysis of their recent paper I find that the models MM employed are at best inadequate and in crucial instances are incorrect as instruments for testing their theorems. *Therefore, contrary to the conclusions they reached, MM's findings provide no empirical support for their theorems on security valuation, cost of capital, and corporation finance.*

My comments here are not concerned with arguments for or against the assumptions on which MM based their theorems; there is already a considerable literature on that subject. My concern is only with the validity of the models they employed as instruments for testing their theory, and I will describe their theory only insofar as this objective requires it.

I. The MM Model

In their classic 1958 paper [13], MM demonstrated that under certain assumptions the value of a corporation is independent of its leverage and dividend rates. That is, with S =value of its stock, D =value of its debt, V =value of its outstanding securities, \bar{X} =expected earnings before interest on its assets, and ρ =capitalization rate,

$$(1) \quad S + D \equiv V = \bar{X}/\rho.$$

The capitalization rate is a function solely of the corporation's nonfinancial risk, and for each corporation in a risk class, V will be the same multiple, $1/\rho$, of \bar{X} regardless of how the corporation is financed. The assumptions on which this theorem rests are: (1) investors are indifferent between leverage on personal and on corporate account; (2) there is no corporate income tax; (3) stockholders are indifferent as to how a corporation allocates its income between dividends and retention; and (4) corporations do not have investment opportunities with a rate of return greater than ρ .

In a subsequent note [14] that corrected the treatment of the corporate income tax in the above paper, MM showed that with corporate income taxes at the rate of τ , and with ρ on an after tax basis, equation (1) becomes

$$(2) \quad S + D \equiv V = \frac{(1 - \tau)\bar{X}}{\rho} + \tau D$$

\bar{X} now equals expected earnings before interest and taxes. Given \bar{X} , V increases with the leverage rate because interest is a tax exempt expense and because the government is certain to bear the fraction τ of any losses.

To test this theory, MM employed in [12] the following model¹ (and it is this model which is the subject of my concern):

$$(3) \quad \frac{V - \tau D}{A} = a_0 + a_1 \frac{(1 - \tau)\bar{X}}{A} + a_2 \frac{1}{A} + a_3 \frac{\Delta A}{A} + u.$$

MM explained the relation between equations (2) and (3) as follows. All

¹ See [12, eq. (14) p. 350]. The estimating equations used $\bar{X}^T - \tau R$ in place of $(1 - \tau)\bar{X}$, but as they explained [12, p. 356], $\bar{X}^T - \tau R$ is a convenient empirical approximation of $(1 - \tau)\bar{X}$.

the variables are divided by A , the book value of total assets, to avoid (in a cross section sample) correlation due to scale.² τD is transferred to the left side for convenience; this is permissible because its coefficient is equal to one under the theory. Also under the theory, the expected value of a_0 is zero and a_1 is an estimate of $1/\rho$. The variable $1/A$ is included because size may influence the value of a corporation, and $\overline{\Delta A}/A$ is included to allow withdrawal of the fourth assumption listed above, namely, corporations do not have investment opportunities with a rate of return greater than ρ .

MM were particularly interested in a_1 since $1/a_1$ is an estimate of ρ , which in their theory is a corporation's cost of equity capital. Its cost of debt capital is $(1-\tau)\rho$, and, if the corporation constrains its financing with some debt-asset ratio, q , its cost of capital is $\rho(1-\tau q)$. See [12, p. 342].

II. Objectives of the MM Paper

One objective of the MM paper was to demonstrate the advantage of two-stage least squares (2SLS) over direct least squares (DLS) as a means for estimating the parameters of equation (3). Using DLS, a_0 proved to be significantly positive, as shown in the first panel of Table 1. However, in theory a_0 should be zero, and MM reasoned that a possible explanation for its not being zero is the presence of errors in the observed values of $(1-\tau)\overline{X}$ as measurements of true expected earnings. In the event of such errors, a_0 would be biased upward and a_1 would be biased downward. One means of dealing with the problem, assuming the explanation is correct, is to constrain $a_0=0$, and the resultant parameter estimates appear in the second panel of Table 1.

However, the best way to eliminate bias in the parameter estimates is to eliminate errors in the measurement of $(1-\tau)\overline{X}$ and MM employed 2SLS to do this. With P =preferred stock and DIV =common dividends, they first ran the regression

$$(4) \quad \frac{(1-\tau)\overline{X}}{A} = b_0 + b_1 \frac{1}{A} + b_2 \frac{\overline{\Delta A}}{A} + b_3 \frac{D}{A} + b_4 \frac{P}{A} + b_5 \frac{DIV}{A} + w,$$

and then they used the values of $(1-\tau)\overline{X}/A$ provided by the regression as error-free measurements of that variable in equation (3). The resultant parameter estimates for equation (3) appear in the third and fourth panels of Table 1.

As the third panel shows, the 2SLS unconstrained estimates of a_0 are not significantly different than zero. From this MM inferred that $(1-\tau)\overline{X}$ is subject to measurement error as true expected earnings and that 2SLS improves the parameter estimates by reducing this error. My interpretation of the data presented in panel three is different: the net effect of the 2SLS

² In a curious slip MM stated that the alternative of deflating by $V-\tau D$ "which was the approach we adopted in our first paper and which was subsequently followed by Barges . . . is somewhat unesthetic . . . and will lead to biased estimates" [12, p. 349]. They were not followed by Barges [1]. The major if not sole thesis of his book was that using V or $V-\tau D$ as a deflator leads to biased estimates. He showed that the evidence MM found in support of the earlier formulation of their theory disappeared when A was substituted as the deflator.

operations was to substitute a *multiple* of the dividend for $(1-\tau)\bar{X}$, and the changes in a_0 and a_1 are due to this substitution. The basis for this interpretation will be discussed later.

Another objective of the MM paper was to test their hypotheses that the value of a firm is independent, apart from the tax effect, of its leverage rate and that its value is also independent of its dividend payout rate. *Equation (3) may be used to estimate ρ and the cost of capital if these hypotheses are true, but it does not test the hypotheses because the parameter estimates are consistent with conflicting hypotheses on leverage and dividend policy.*³ Therefore, to test their hypotheses MM introduced additional variables, and we turn to their findings on these questions next.

³ Under the MM theory a_1 is an estimate of ρ , which enters into the determination of a corporation's cost of capital. However, it follows from every alternative theory that $V-\tau D$ is positively correlated with $(1-\tau)\bar{X}$, size, and growth. Also the theories do not disagree on the numerical values of the parameters in this model.

The final objective of their paper was to develop estimates of the cost of capital on the basis of their model, and these estimates are discussed in the last section of this comment.

III. *The Leverage Theorem*

Under the reasoning that led to equation (3) the subtraction of τD from V completely accounts for the influence of leverage on the value of a corporation. Accordingly, with debt and preferred stock added to the equation's independent variables, their coefficients should not differ significantly from zero.⁴ This is what MM found with their electric utility sample. However, using a utility sample actually gave results that were against their leverage theorem, since regulatory agencies treat the income tax as an expense in determining the income a utility is allowed to earn. Only if their sample had consisted of nonregulated industrial companies would their results have been evidence in support of their theorem.⁵

To see this point, recall [14, p. 435] that the proof of MM's leverage theorem under a corporate income tax began with the statement that

$$(5) \quad X^r = (1 - \tau)(X - R) + R = (1 - \tau)X + \tau R,$$

with X = earnings before interest and taxes, $R = iD$ = interest on outstanding debt, and X^r = earnings after taxes and before interest. Their use of this expression to prove that equation (2) and not equation (1) holds in the presence of a corporate income tax presumes that X is an exogenous random variable, independent of the corporation's tax and leverage rates. As a result, since X is independent of τ and R , and since R increases with leverage X^r increases with R .

In contrast, for a regulated utility X^r is the exogenous random variable. The regulatory agency sets the rates charged consumers in order to provide the utility with an earnings after taxes and before interest rate of return that the agency considers correct.⁶ Consequently, the correct expression for \bar{X}^r in the case of a public utility should be

$$(6) \quad \bar{X}^r \equiv \bar{x}^r A,$$

where \bar{x}^r is the expected after tax and before interest rate of return the utility is allowed to earn. It follows then that a change in a utility's tax

⁴ There is one slight qualification to this conclusion. Under the traditional view (see Barges [1]) V rises with leverage up to a leverage rate considered prudent and falls sharply when the leverage rate passes this level. Hence, it would be necessary to show that few if any corporations in the sample are not prudent.

⁵ MM recognized this fact [12, fn. 12, pp. 342-43], but its implications for the model they should have used to test their leverage theorem with a utility sample went unrecognized. I have recently become involved in a public utility rate case, and in all the testimony on this and other cases I have read, the rate of return in question is earnings with taxes excluded and interest included divided by total assets. See also Bonbright [3, pp. 242-43 and 404].

⁶ The switching or arbitrage operations by which MM proved their leverage theorem assumes two firms identical in every respect but their leverage rates. In particular two firms in the same risk class have the same \bar{X} and different leverage rates. However, two otherwise identical utilities with different leverage rates must have different values for \bar{X} . Their values for \bar{X}^r will be the same, and the MM switching analysis applies to \bar{X}^r .

bill, due either to a change in the tax rate or to a change in the utility's leverage rate, may be expected to cause the agency to change consumer rates and \bar{X} so as to leave \bar{X}^r unchanged. In other words, with \bar{X}^r and not \bar{X} independent of the tax rate and financial policy, the expected pre-tax earnings on a utility's total assets is

$$(7) \quad \bar{X} = \frac{\bar{X}^r - \tau R}{1 - \tau}.$$

A change in τ or R , the interest bill, changes \bar{X} and not \bar{X}^r .

Note that with \bar{X}^r independent of a utility's tax bill, it is also independent of its leverage rate, and \bar{X}^r has exactly the same properties as \bar{X} in the absence of a corporate income tax. Consequently, the deductive argument by which MM proved their leverage theorem leads not to equation (2) but to equation (1), with \bar{X}^r substituted for \bar{X} and with ρ on an after tax basis; it follows that the equation MM should have employed to test their theorem with a public utility sample is not equation (3) but

$$(8) \quad \frac{V}{A} = a_0 + a_1 \frac{\bar{X}^r}{A} + a_2 \frac{1}{A} + a_3 \frac{\Delta A}{A} + u,$$

in which V replaces $V - \tau D$ and \bar{X}^r replaces $(1 - \tau)\bar{X}$. Since the coefficients of the debt and preferred stock variables were not statistically significant when added to equation (3), it is very likely that they would be positive and significant when added to equation (8). A plausible explanation for this is that investors, in contradiction to the MM theorem, prefer leverage on corporate account.

IV. *The Dividend Rate Theorem*

The MM position on dividend policy is that "Under ideal conditions of perfect capital markets, rational investor behavior, and no tax discrimination . . . a firm's . . . dividend policy will have no effect whatsoever on the current market value of its shares or on its cost of capital; and that despite the impressions of some writers to the contrary . . . this conclusion is equally valid whether one is considering a world of certainty or of uncertainty" [12, p. 345]. This is not the place to review the reasoning whereby numerous writers, including myself, have reached different conclusions on the subject. On that, see [6] [7] [8] [9] [10].

Assumptions that are different but appear no less plausible than MM's have led me to conclude that the rate of return investors require on a share and the corporation's cost of capital both increase with the fraction of income the corporation retains. Strictly speaking, this differs from the traditional view that high dividend payouts increase the value of a firm's shares. However, when due allowance is made for the influence of other variables on the value of a corporation's stocks, variables such as leverage and the profitability of its investment opportunities, the traditional view becomes consistent with my conclusion.

To test the traditional view MM added a dividend payout variable to

equation (3). With $DIV/(1-\tau)\bar{X}$ defined as a corporation's dividend rate and with λ the sample average of $DIV/(1-\tau)\bar{X}$, MM added the variable $DIV/A - \lambda(1-\tau)\bar{X}/A$. Ignoring the deflation by A , this variable is simply the difference between the dividend and what the dividend would have been if the dividend rate, which is based on tax-adjusted total earnings rather than on common earnings, had been the same as λ , the sample average. According to MM, their dividend policy theorem is confirmed if the coefficient of $DIV/A - \lambda(1-\tau)\bar{X}/A$ does not differ significantly from zero.

MM's parameter estimates for this dividend variable, obtained both by direct least squares (DLS) and by two-stage least squares (2SLS), and with the constant term constrained at zero, where:

| <i>Year</i> | 1957 | 1956 | 1954 |
|-------------------|------------|-------------|------------|
| DLS Value (S.E.) | .92 (2.5) | .65 (2.3) | 6.4 (2.1) |
| 2SLS Value (S.E.) | -.10 (4.3) | -1.80 (4.0) | -2.2 (3.4) |

In commenting on the DLS data, MM stated that "Findings of this kind (which are quite typical of past valuation studies) have been the main empirical support of the traditional view . . ." [12, p. 368]. Their comment surprises me, since two of their three DLS coefficients are not significantly different than zero and since past valuation studies have actually provided rather strong evidence in support of the contrary hypothesis, i.e., the dividend rate has an influence on the value of a firm's shares.⁷

In view of these other studies, I wondered why their DLS dividend coefficients were so low, and my conclusion, set forth below, was that their model is poorly designed to test their dividend rate hypothesis. In my judgment, the following model provides a straightforward test and makes clear the limitations of equation (3) for the purpose:⁸

$$(9) \quad S = \alpha_0 Y^{a_1} (1 + h)^{a_2} (1 + e)^{a_3} (1 + DIV/Y)^{a_4}.$$

S and Y are, respectively, market value of and earnings on the common stock, h is the debt equity ratio, and e is the expected rate of growth in earnings due to investment opportunities that have a rate of return in excess of the cost of capital. To avoid correlation due to scale, S , Y and DIV could be taken on a per share basis or deflated in some other way. The interpretation of equation (9) is quite simple. The expected value of $a_1 = 1$, and when h , e and DIV/Y are equal to zero, S is the multiple α_0 of Y . a_2 should be negative and a_3 should be positive. Under the MM hypothesis on the dividend rate, a_4 should not differ significantly from zero.

A comparison of equations (9) and (3), with $DIV/A - \lambda(1-\tau)\bar{X}/A$ added to the latter, reveals two major limitations of equation (3) for testing the dividend rate hypothesis. First, since the hypothesis refers to the value

⁷ Empirical studies by Benishay [2], Durand [5], and Gordon [6, Chs. 11 and 12] are among those which found that the dividend rate influences the market value of a firm's stock.

⁸ This equation still leaves something to be desired for establishing whether or not the rate of return investors require on a share and the cost of capital are independent of the dividend rate. For a model designed to test these theorems and the results obtained, see Brigham and Gordon [4].

of a firm's shares and not of all securities, the dependent variable should be S , not $V - \tau D$ as it is in equation (3), and therefore Y , not $(1 - \tau)\bar{X}$, should be the earnings variable.

The other major objection to the model MM employed is their definition of the dividend policy variable. Assuming that the dividend policy hypothesis may be tested with $V - \tau D$ and not S the dependent variable, the dividend policy variable should be the relation between the dividend and what the dividend would be if the *average fraction of common earnings* were paid in dividends. However, $\lambda(1 - \tau)\bar{X}/A$ is not the average fraction of common earnings paid in dividends. It approximates the average fraction of earnings on all assets after taxes paid in dividends.⁹ The result is not merely a poor approximation of the relevant dividend policy variable, but a biased approximation that reduces the correlation with the dependent variable. To illustrate this bias, consider two firms with the same values for $(1 - \tau)\bar{X}$ and for DIV/Y but with different leverage rates. The difference in leverage rates will make their values of Y different, and the firm with the higher leverage rate will have the smaller value for DIV . Although both firms actually have the same dividend rate, DIV/Y , the one with the higher debt and smaller Y will have a smaller value for MM's dividend variable.

In general, MM's definition of the dividend rate introduces inverse correlation between their dividend variable and a firm's leverage rate. Since the value of the firm is positively correlated with its leverage, the inverse correlation between leverage and the MM dividend rate contributes to the latter's low correlation with the firm's value.¹⁰

V. True Expected Earnings

Because the coefficients of their dividend rate variable obtained by 2SLS were all negative and not significant, MM interpreted the data as evidence in support of their dividend policy hypothesis and as a further demonstration of the advantage of 2SLS. However, my interpretation of the data is quite different. To avoid error in the reported earnings and to obtain true expected earnings, MM adopted the hypothesis that the latter are a function of the variables in equation (4), and so they used, in the second-stage regression, the computed value of $(1 - \tau)\bar{X}$ from equation (4) in equation (3). However, an inspection of Table 2 in their paper [12, p. 361] reveals that the dominant explanatory variable in equation (4) is the dividend. Hence, in the second-stage regression their error free value of $(1 - \tau)\bar{X}$ differs little from a linear function of the dividend.

Furthermore, two other explanatory variables, D/A and P/A are highly

⁹ A still unsatisfactory but more reasonable dividend rate variable given that $V - \tau D$ is their dependent variable would have been dividends on preferred and common plus interest divided by $(1 - \tau)\bar{X}$.

¹⁰ Working out the following numerical example illustrates the point. Assume two corporations both have $A = \$1,000$, $\bar{X} = \$80$, and $DIV/Y = .8$. However, let $D = \$600$ for corporation I and $\$400$ for II. With $i = .05$ and $\tau = .5$, $(1 - \tau)\bar{X} = \$40$ for both, but $DIV = \$20$ for I and $\$24$ for II. With λ equal to the average of $DIV/(1 - \tau)\bar{X}$ for the two corporations, MM's dividend variable is $-\$2$ for I and $\$2$ for II. Both corporations have the same dividend rate, and I not II has the higher payout of dividends and interest.

correlated with the interest on debt and the preferred dividends. Let TPO =total payments to all security holders, PIV =preferred dividends and R =interest on debt. $TPO = DIV + PIV + R$, and it is easily shown that the MM earnings variable

$$(10) \quad (1 - \tau)\bar{X} = TPO + RET - \tau R$$

where RET =retained earnings. We see that $(1-\tau)\bar{X}$ differs slightly from TPO , and the error free value of $(1-\tau)\bar{X}$ based on equation (4) is practically identical with a linear function of TPO .

As a result, the regression equation MM employed to test the dividend rate hypothesis by means of 2SLS was not, in fact, equation (3) with a dividend variable added. In reality, it was

$$(11) \quad \frac{V - \tau D}{A} = a_1 \left[b_0 + b_1 \frac{TPO}{A} \right] + a_2 \frac{1}{A} + a_3 \frac{\bar{\Delta A}}{A} \\ + a_4 \left[\frac{DIV}{A} - \lambda \left(b_0 + b_1 \frac{TPO}{A} \right) \right]$$

The dividend policy variable, therefore, is not based on a difference between dividends on common and some earnings figure, regardless of how biased the earnings figure is. Instead, the variable is based on the difference between the dividends on common and the "dividends" on all securities. Consequently, the variable has no relevance for the dividend policy hypothesis.¹¹

MM have rejected all evidence in support of the hypothesis that the dividend rate influences the value of a firm's stock on the grounds that the evidence is an illusion, attributable to the dividend's "informational content" with respect to true expected earnings and to the measurement error in actual earnings. Perhaps they are right, but their 2SLS use of the dividend's informational content to measure true expected earnings leads them to use the dividend as the earnings variable. This switching operation would have been perfectly transparent if S and Y had been the value and earnings variables in place of V and $(1-\tau)\bar{X}$. MM may be right, but their 2SLS procedure both cannot prove it and *does not go beyond* the informational content of the dividend in establishing the influence of earnings on share value.

VI. Growth and the Cost of Capital

As demonstrated above, MM failed to prove either (1) that investors are indifferent between leverage on personal and leverage on corporate account, or (2) that they are indifferent to a corporation's dividend rate. Under the alternative theorems, a corporation's cost of capital is not a

¹¹ The reason why a_4 , the coefficient of the so-called dividend variable is very small in relation to its standard error is easy to explain. $V - \tau D$, TPO and DIV are all correlated with each other. However, as one would expect, $V - \tau D$ has a higher correlation with TPO , the "dividends" on all securities, than with DIV , the dividends on common stock. With TPO and DIV highly correlated a_4 will be small in relation to its standard error.

constant but is a function of both the method and the level of financing, and it is a function which is difficult to estimate. It is possible that for some purposes MM's constant cost of capital might serve as a satisfactory approximation—unsatisfactory for a corporation considering a change in its financing policy or in the level of its investment—but satisfactory for representing the average cost of capital for an entire industry, using equation (3) for nonregulated industries and equation (8) for regulated ones.

However, the cost of capital approximations in the MM paper cast doubt on the usefulness of their model even for this limited purpose. Using equation (3), MM found that the average tax-adjusted cost of capital for the electric utility industry was .046, .045 and .039 in 1957, 1956 and 1954. These figures were only slightly higher than AAA bond rates for those years, and it is very hard to believe that the cost of capital for the industry was that low. It is possible, but not likely, that using equation (8) would result in higher and more reasonable averages, but it is more likely that the treatment of growth in the MM model is responsible for the substantial downward bias in their cost of capital approximations.

In deriving equations (1) and (2), MM [13] [14] postulated a corporation for which the expected earnings are the same in every future period. This is a permissible assumption if the corporation is not expected to invest at a rate of return greater than its cost of capital, and if, therefore, its earnings are only expected to grow due to retention. However, it is not a correct assumption if earnings are expected to grow additionally due to investment opportunities with a rate of return above its cost of capital. To differentiate this additional source of growth from that due merely to retention of earnings, it will be called "super growth" in the following discussion.

It is perfectly clear that most corporations—even utilities—have super growth investment opportunities and that the extent to which any corporation has such opportunities materially influences its market value. Consequently, to test the theory represented by equation (2), MM were forced to add a variable to account for super growth, and they defined this variable as follows. If a corporation is expected to make investments in operating assets which have a tax-adjusted rate of return of ρ^* , and ρ^* is greater than its cost of capital, C , this expectation will raise its market value. To represent these growth opportunities, MM suggested the quantity $\Delta AT(\rho^* - C)/C(1 + C)$. In other words, the corporation is expected to invest ΔA per period for T years at a rate of return ρ^* and obtain, thereby, a periodic rent of $\Delta A(\rho^* - C)$. Division by $C/(1 + C)$ converts the periodic rent to its present value. However, measurement problems forced MM to substitute growth in assets, $\Delta A/A$, as a proxy for the above complex of variables that determine supergrowth.

The rationale for using asset growth as a measure of super growth is the fact that a firm's investment rate should be correlated with its opportunities to invest at a rate of return greater than its cost of capital. However, this correlation may be relatively weak, particularly in the case of utilities, where investment is governed in part by the public interest. The weakness of this correlation, combined with the fact that investors may use $(1 - \tau)\bar{X}$

as well as $\overline{\Delta A}/A$ for information on a utility's super growth, causes a downward bias in MM's estimate of the cost of capital in equation (3).

To see this, note that $(1-\tau)\overline{X}/A$ is actually the rate of return a corporation is earning on its existing assets. It is also true that for corporations in general the expected return on additional assets has some correlation with the return on existing assets. For utilities, regulated as they are to earn a predetermined rate of return on assets, the expected rate of return on investment is exactly the same as the return on assets, if the regulation is perfectly efficient and if the predetermined rate is not expected to change. Hence, the correlation of $(1-\tau)\overline{X}/A$ with super growth should compare favorably with that of $\overline{\Delta A}/A$.

With the coefficient of $(1-\tau)\overline{X}/A$ reflecting the influence of super growth as well as current earnings on the value of a firm, its coefficient, a_1 , should overestimate the value of $1/\rho$, and the estimate of ρ should be too low. MM's data bear this out. It is generally accepted that when super growth opportunities are present, the earnings yield, Y/S , is below ρ , the cost of equity capital, i.e., the return investors require on a company's common stock. The striking illustrations are Xerox and IBM. However, in Table 8 of MM's paper we find that, instead their estimates of ρ are below Y/S . In 1954, for example, $Y/S = .066$ and $1/a_1 = .051$.

In conclusion, to go from either equation (1) or (2) to approximations of the average cost of capital for an industry requires a more effective means for isolating the influence of super growth opportunities on a firm's value than that used by MM in equation (3). If this is not possible, some other means than equation (3) should be used to estimate ρ . One alternative is to use the sum of the dividend yield and the expected rate of growth in the dividend. As I have shown [6, Ch. 4], under reasonable assumptions this quantity is the rate of return investors require on a share, and under MM's dividend rate theorem, it is equal to ρ , the cost of equity capital.

Some Estimates of the Cost of Capital to the Electric Utility Industry, 1954-57: Comment

In a recent article [1], Merton H. Miller and Franco Modigliani (MM) applied a variation of their well-known model in the statistical estimation of the cost of capital to the electric utility industry. While estimates obtained for the cost of capital by MM have some intuitive appeal, we conclude, on the basis of the work reported here, that these results are to be attributed more to circumstances prevailing at the time of the MM study than to the theoretical consistency of the model employed.

In this paper we report the results of an extension of the analysis used by MM to the years 1955 and 1958-64 inclusive. Although our data sources are slightly different (see Appendix A), we are convinced that the results for the three years reported by MM are not typical of those for the entire eleven-year period. Our tests indicate that after 1957 the estimates of the cost of capital derived from the MM model fall to unreasonably low levels, and the percentage of variance explained by the model decreases significantly. Further experimentation isolates the weaknesses in the MM formulation and gives strong support to the conclusion that the model is fundamentally misspecified. The results of these experiments are reported here.

Testing the MM Model in 1954-64

MM found that the value of the cost of capital (ρ) implied by their model was reasonably stable (in the area of 5 or 6 per cent) and generally increasing over the years 1954, 1956, and 1957. In applying MM's model in the years 1954-64 to the same sample of 63 companies as used by MM,¹ we used the same two-stage instrumental variables procedure described by MM to alleviate the problem of measurement error in the earnings term. The results are

¹ As given in Appendix A in [1].

TABLE 1—MM MODEL: SECOND STAGE ESTIMATES WITH COMPUTED EARNINGS

(Coefficients based on RMH Data)^aDependent Variable: $(V - \tau D)/A$

^a See Appendix A.

shown in Table 1. Even after correcting for the probable error in the growth term, as described in Appendix A, our estimates of the cost of capital closely parallel those obtained by MM for the 1954-57 period. However, the results for the 1958-64 period conflict with those of 1954-57 in several respects. First, the cost of capital (as defined by MM) implied by the coefficient of the earnings term declines from 6.1 per cent in 1957 to a level of 4.4 per cent in 1961. In 1961, the value of ρ implied by the MM model is less than the average yield on Aa-rated public utility bonds. Secondly, the percentage of the

variance explained by the model (the square of multiple R in Table 1) declines from .60 in 1954 to .26 in 1961.²

Because these results were at odds with economic logic we attempted to determine the possible causes. Toward this end, we investigated the specification of each of the basic variables in MM's structural model: the hypothesized relationship between leverage and value, the homogeneity assumption, the size factor, and the effect of growth on value. The results of this investigation are reported below.

Leverage and Value

The effect of leverage on the value of the firm is still a much debated issue. We tested a simple equity-only valuation model by subsuming an average leverage effect. The obtained regression estimates of the "cost of equity capital with leverage" for the 1954-64 period were slightly above those shown in Table 1, but not materially so. While the test was not designed to resolve the question of how leverage affects value, the results led us to conclude that MM's treatment of leverage was not the major cause for the unusual results derived from their model.

Homogeneity of the MM Equation

MM rationalize the suppression of the regression constant by stating that failure to suppress it "would imply that the book value of total assets appears . . . as one of the explanatory variables in the original equation—a specification that makes little sense from the standpoint of the theory of valuation" [1, p. 350]. To confirm this statement and to test the structural specification of their valuation equation, MM add a constant term to their structural equation with the expectation that it will not be statistically significant. In the three years tested by MM they found "considerable support for the hypothesis that the true constant term is zero" [1, p. 362].

A case can be made that because of multicollinearities among the independent variables it is not necessary to demonstrate that the regression estimates of the constant term are statistically insignificant. But, extending the estima-

²In order to ascertain that the causes for these results lay in the model and not in the use of RMH data, we replicated data for the year 1961 according to MM specifications and performed the regression analysis upon them. A comparison of data is given below. As can be seen, the results are not materially different.

MM MODEL: SECOND STAGE REGRESSION WITH COMPUTED EARNINGS—1961
Dependent Variable: $(V - \tau D)/A$

| 1957 | .052 | 15.5 (2.6) | -.240 (.13) | .743 (.31) | .66 | .065 |
| 1958 | -.223 | 22.0 (3.1) | -.258 (.15) | .944 (.36) | .71 | .046 |
| 1959 | -.500 | 27.6 (3.8) | -.361 (.19) | 1.29 (.41) | .69 | .036 |
| 1960 | -.635 | 31.0 (5.5) | -.359 (.24) | 1.04 (.47) | .60 | .032 |
| 1961 | -.930 | 38.7 (7.6) | -.600 (.34) | 1.73 (.74) | .56 | .026 |
| 1962 | -.619 | 31.1 (5.1) | -.300 (.26) | 1.13 (.64) | .63 | .032 |
| 1963 | -.430 | 29.0 (4.9) | -.458 (.31) | 1.38 (.87) | .62 | .035 |
| 1964 | -.426 | 29.2 (4.3) | -.595 (.34) | 1.19 (.94) | .68 | .034 |

tion of this coefficient to later years, we found that it becomes negative and increases in absolute magnitude (see Table 2). In 1961 the absolute value of the constant term is approximately equal to the mean of the dependent variable.

It might be argued that these results are simply the product of multicollinearity among variables and, therefore, that the nonhomogeneous test of specification is in error and should be ignored. While this reasoning has some logical appeal, it cannot be supported fully by the figures in Table 2. First, the continued stability and significance of the other explanatory variables and the measureable increase in the coefficient of determination indicate that the

constant term adds explanatory power in its own right. Second, the negative sign on the constant term from 1958 through 1964 implies that the book value of total assets appears to be negatively correlated with the market value of the firm.

We find it more reasonable to conclude that the regression estimates of the constant term may be reflecting determinants of corporate value omitted from the MM structural equation.

Size and Valuation

MM's treatment of the effect of size on value is, at best, ambiguous. The authors' motivation for including a size term is that "the results of previous valuation studies . . . suggest that the true market capitalization rate for expected earnings of large firms may possibly differ systematically from that of small firms in the same industry" [1, p. 347]. MM caution that the equation with a size term included "must be interpreted as the linear approximation . . . to the underlying nonlinear relation" [1, p. 348].

If we assume for a moment that $\Delta \bar{A} = 0$, the role of a_0 can be depicted graphically as in Figure 1.

FIGURE 1

In Figure 1, the curved line (RR') represents the assumed true relationship between earnings and value as hypothesized by MM. The slope of RR' is the inverse of the cost of capital for various levels of earnings. Since earnings are normally highly correlated with firm size, the observations of small firms would be close to the origin. Assuming that individual firm observations will lie along the curve RR' , it is clear that in estimating the cost of capital of large firms a regression estimate including a size term (MM') is superior to one which is constrained to pass through the origin. The shape of RR' in Figure 1 implies increasing returns to scale in valuation, which is consistent with the negative values of a_0 observed in Table 1.

MM contend that beyond some minimum firm size a linear approximation

to the underlying nonlinear relationship is a reasonable estimate of the marginal cost of capital to large firms. It is, therefore, important that the MM sample consist entirely of firms which are large enough (i.e., to the right of point z in Figure 1) to be in the region where the linear approximation applies. If firms of smaller size are included in the sample, the resultant cost of capital estimates will not be unbiased estimates of the cost of capital for the large firms as sought by MM.³ For example, the inclusion of several small firms in the sample may give rise to an estimate of ρ as the inverse of the slope of the line HH' in Figure 1.

We do not object to the logic of this proposition, but we do question whether MM have been a bit careless in its application. More directly, we believe that the definition of what constitutes a large as opposed to a small firm might be determined within the context of the particular sample.

If the model were otherwise correctly specified, the appropriateness of the MM sample with regard to size could be tested. However, if the model were not correctly specified, such a test might merely confirm that the model is fundamentally misspecified. We tested the following hypothesis for 1957 and 1961 using data exactly as described by MM:

Rank the firms in the sample by total assets and divide them into smaller- and larger-firm groups. Let ρ_s and ρ_L equal the regression estimates of the cost of capital for the smaller-firm and larger-firm groups respectively. If the hypothesis that $\rho_s = \rho_L$ is satisfied, then the MM sample is sufficiently uniform with respect to asset size. If $\rho_s > \rho_L$, we can infer that the sample is not sufficiently uniform. If $\rho_s < \rho_L$, the specification of the model is to be suspected.

In both years, we found $\rho_s > \rho_L$, at a confidence level of 90 per cent in 1957 and 80 per cent in 1961.⁴ Thus, the problem of the appropriate size of the sample remains unanswered.

Growth and Valuation

MM imply, quite correctly, that growth has value only if the company is expected to earn a rate of return in excess of its cost of capital on its expected future net investments. But MM's formulation of the growth term is not designed to measure correctly the effect of growth on value. The "rate of change in assets" ($\Delta\bar{A}/\bar{A}$) is used as the surrogate variable for growth, *which necessitates the assumption that ρ^* (the allowed rate of return on new investments) is constant for all firms in the sample*. This assumption is unrealistic both on a priori and on empirical grounds. The inclusion of a few companies with differing rates of return may completely distort the values not only for

³The fact that the book value of total assets was not statistically significant as an independent variable in the years tested by MM might be construed as proof that the firms in the MM sample are sufficiently large. However, as we indicated in the preceding section, this fact is not generally true in later years.

⁴If the constant term in the normalized valuation equation is not suppressed, the results are exactly the opposite, i.e., $\rho_L < \rho_s$. While these results are more in accord with our expectations, we are unwilling to place much emphasis on them due to the questionable influence of the constant term as explained in the previous section.

the "growth" coefficient but also for the other coefficients in the regression equation. As a simple test of MM's failure to take this factor into account, we formulated and tested the following hypothesis: Divide the companies in the sample into a high-return and a low-return group on the basis of the rate of return earned on assets. The coefficient of the growth variable should be greater and more significant for the high-return group if growth has an important impact on value.

The results of our test are summarized in Table 3. A number of observations appear in order based on an analysis of the data in Table 3.

TABLE 3—SECOND-STAGE REGRESSION WITH COMPUTED EARNINGS:
COEFFICIENTS AND DATA MEANS 1957 AND 1961
HIGH- AND LOW-EARNING GROUPS (CONSTANT TERM SUPPRESSED)
(Our MM Data—Correct Growth)
Dependent Variable: $(V - \tau D)/A$

| | a_0 | Size | a_1 | Computed Earnings | a_2 | Growth | ρ (per cent) |
|--------------------|----------------|------|-----------------|-------------------|----------------|--------|-------------------|
| <i>1957</i> | | | | | | | |
| Combined sample | -.21 (.13) | .068 | 16.26 (.74) | .047 | .89 (.28) | .11 | 6.15 |
| High-earning group | -.22 (.16) | .078 | 16.46 (1.04) | .051 | .78 (.43) | .11 | 6.08 |
| Low-earning group | -.16 (.25) | .056 | 15.94 (1.18) | .044 | 1.01 (.41) | .11 | 6.27 |
| <i>1961</i> | | | | | | | |
| Combined sample | -.51 (.36) | .053 | 22.65 (1.32) | .049 | 1.13 (.64) | .09 | 4.41 |
| High-earning group | -.47 (.36) | .070 | 19.50 (1.83) | .052 | 4.06 (1.17) | .07 | 5.14 |
| Low-earning group | -.92 (1.24) | .036 | 22.78 (2.18) | .046 | .71 (.85) | .10 | 4.39 |

First, and foremost, in 1961 the coefficient for the growth variable for the high-earning group is five and a half times as large as the coefficient for the low-earning group and highly significant statistically. Secondly, in 1957, the differences in the growth coefficient for the two groups are relatively small and appear to be in the wrong direction, i.e., the coefficient for the low-earning group is higher than for the high-earning group. However, these differences are not statistically significant. Thirdly, it appears that the smaller companies are the lower-earning companies on the average (see the means of the size coefficients in Table 3). But, in 1961, the smaller, lower-earning companies were experiencing a higher rate of growth in assets than the larger, higher-earning group. This factor would tend to distort further the growth coefficient values for the combined sample.

Finally, the improper specification of the "growth" variable will, in general, affect the estimates of the coefficients for the other variables in the MM model. As evidence, note the differences in the values of the various coefficients for the high- and low-earning group for 1961 in Table 3. In our opinion, this particular error in specification is so fundamental that it calls into question the value of the model itself as an estimating tool.

Conclusion

The misspecification of the growth variable combined with the effects on value of the unknown factors embodied in the regression constant emerge as the main causes of the inadequacy of the MM model. We conclude that the deficiencies in MM's model are so fundamental in nature that none of the estimates of the cost of capital reported either by MM or here can be considered reliable estimates of the true cost of capital to electric utility firms.

APPENDIX A

The Test Methodology

We had access to financial data for the companies used in the MM study as prepared by Studley, Shupert & Co., Inc. However, these data, henceforth called RMH data, were not identical in form to the data used by MM. In particular, the RMH data contained book rather than market values for the long-term debt. Therefore, to test fairly MM's model for years subsequent to 1957, we felt it necessary first to attempt to reproduce their reported results.

We selected the year 1957 as the test year. In attempting to reproduce their results, we found data sample means and standard deviations essentially equivalent to those in MM's Appendix B for all the variables except the growth variable (see columns (a) and (c) in Table A-1).

While our size (assets) means were nearly equal, we found that our mean growth term, $\Delta \bar{A}/A$, was 10.9 per cent, whereas MM's was 8.2 per cent. After careful verification of asset figures in *Moody's Utility Manual*, we conclude that a probable error exists in MM's computation of the growth variable. If $\Delta \bar{A}/A$ is calculated as the quantity $[1/5(A_t - A_{t-4})/A_{t-4}]$ rather than the correct $[1/5(A_t - A_{t-5})/A_{t-5}]$, one obtains a mean and standard deviation of the growth term identical to MM's (compare columns (a) and (b) in Table A-1).⁵

⁵ The impact of this growth term error on the earnings term regression coefficient, hence on ρ , is relatively small. In 1957, for example, the value of ρ implied by MM's two-stage computation is 6.2 per cent, whereas with a corrected growth term ρ is 6.5 per cent (see our Table 3).

However, the impact of the apparent computational error on MM's interpretation of the valuation of growth is more significant. While MM caution that their estimates of implied time horizons for growth (in their Table 11) are not to be taken seriously, they nevertheless conclude that a general expansion of time horizons was indicated. A comparison of growth time horizons for 1957 implied by MM's model before and after correction of the error in computation shows that the estimate of the horizon declines from 11 years (as estimated by MM) to below 7 years.

TABLE A-1—MEANS AND STANDARD DEVIATIONS OF PRINCIPAL VARIABLES—1957

| Variable | MM ^a | Our MM Data ^b (Adjusted Growth) | Our MM Data ^c (Correct Growth) | RMH Data ^d |
|--|-----------------|---|--|-----------------------|
| Value $\left(\frac{V-\tau D}{A}\right)$ | .851 (.12) | .855 (.12) | .855 (.12) | .897 (.12) |
| Earnings $\left(\frac{\bar{X}^* - \tau \bar{K}}{A}\right)$ | .0471 (.006) | .0475 (.005) | .0475 (.005) | .0506 (.007) |
| Size $[1/A \cdot 10^7]$ | .0670 (.091) | .0675 (.092) | .0675 (.092) | .0723 (.098) |
| Growth $[\Delta A/A]$ | .082 (.030) | .082 (.030) | .109 (.040) | .106 (.041) |
| Debt/assets | .504 (.051) | .508 (.060) | .508 (.060) | .545 (.045) |
| Preferred/assets | .100 (.047) | .100 (.048) | .100 (.048) | .113 (.054) |
| Dividends/assets | .0243 (.004) | .0245 (.004) | .0245 (.004) | .0262 (.004) |

^a Results as presented in MM's Appendix B.

TABLE A-2—MM MODEL: SINGLE STAGE REGRESSION WITH MEASURED EARNINGS—1957
Dependent Variable: $(V-\tau D)/A$

| | Coefficients of | | | | Multiple R |
|--|-----------------|-------------------|----------------|---------------|------------|
| | Constant | Measured Earnings | Size | Growth | |
| MM ^a | .164 (.06) | 15.7 (1.2) | -.278 (.08) | 1.37 (.24) | .88 |
| Our MM ^b (adjusted growth) | .025 | 15.5 (1.2) | -.207 (.08) | 1.30 (.24) | .88 |

^a Results as presented in MM paper.

^b Results using data that we gathered precisely according to MM's specifications, but with the computational difference in growth term described in text.

Table A-2 reflects the degree to which we were successful in reproducing the MM regression results. This table compares the results for the single-stage regression with measured earnings obtained by MM (their Table 1) with results using "Our MM" data with the growth term as apparently calculated by MM. At this stage we were satisfied that our numbers closely paralleled those used by MM.

We then computed sample data means and standard deviations for the RMH data shown in column (d) in Table A-1. Before using these data to extend MM's results, we wanted to test the degree to which the analyses based on RMH data would approximate results obtained using data according to MM specification. Consequently, we performed the second-stage regressions with computed earnings for 1957 with three sets of data: (1) our MM (with adjusted growth), (2) our MM (correct growth), and (3) RMH data. The results of this analysis are shown in Table A-3.

TABLE A-3—MM MODEL: SECOND STAGE REGRESSION WITH COMPUTED EARNINGS—1957
Dependent Variable: $(V - \tau D)/A$

| | Coefficients of | | | | Multiple R | ρ (1/Earnings Coefficient) |
|--|-----------------|----------------------|----------------|---------------|---------------|---------------------------------------|
| | Constant | Computed Earnings | Size | Growth | | |
| MM ^a | -.004 (.08) | 16.2 (1.7) | -.280 (.08) | 1.37 (.24) | .87 | .062 |
| Our MM ^b (adjusted growth) | .012 | 15.8 (2.4) | -.210 (.12) | 1.30 (.37) | .70 | .063 |
| Our MM ^c (correct growth) | .046 | 15.4 (2.5) | -.208 (.13) | .85 (.30) | .66 | .065 |
| RMH data ^d | .052 | 15.5 (2.6) | -.240 (.13) | .74 (.31) | .66 | .065 |

^a Results as presented in MM paper.

^b Results using data that we gathered precisely according to MM's specifications, but with the computational difference in growth term described in text.

^c Results using data as in b, with correct growth term.

^d Results using RMH data.

A comparison of the regression results based on "Our MM-correct growth" data with the "RMH data" discloses no material differences. While we could not be absolutely certain that regression analyses based on RMH data would faithfully parallel results obtained with data under MM specification in other years, we were convinced that major trends would not be obscured by use of the RMH data.

APPENDIX B: MEANS OF PRINCIPAL VARIABLES—RMH DATA
1954-1964

| Years | Variable | | | $\frac{\bar{\Delta A}}{A}$ |
|-------|--------------|----------------------------|------------------|----------------------------|
| | $V - \tau D$ | $\bar{X}^r - \tau \bar{R}$ | $1/A \cdot 10^7$ | |
| | A | A | | |
| 1954 | .898 | .049 | .091 | .129 |
| 1955 | .945 | .050 | .084 | .120 |
| 1956 | .934 | .051 | .078 | .112 |
| 1957 | .897 | .051 | .072 | .106 |
| 1958 | .964 | .050 | .067 | .105 |

1. M. H. MILLER AND F. MODIGLIANI, "Some Estimates of the Cost of Capital to the Electric Utility Industry, 1954-57," *Am. Econ. Rev.*, June 1966, 56, 333-91.

Some Estimates of the Cost of Capital to the Electric Utility Industry, 1954-1957: Reply

Ever since our paper appeared in this *Review* people have been telling us: "Very interesting. But your estimates of the cost of capital are really much too low to be believed." We suspect that, to some extent, this impression is simply a misunderstanding of our estimates, especially those presented in the critical summary Table 10. To keep the exposition simple, we stated the required rate of return in terms of a useful but unfamiliar

concept of income which we have dubbed "tax-adjusted earnings." This concept is essentially an after-tax measure which also takes into account the tax subsidy to debt, a subsidy which is very substantial indeed in this industry because of the prevailing high levels of debt. Hence, our estimates are bound to seem low if gauged against other more familiar measures of yield which are not or cannot be similarly adjusted. Examples of just this sort of improper comparison are found in the present critique by Myron Gordon (see his Section IV, 2nd par.) as well as in an earlier critique by Irwin Friend.¹

The impression that our estimates are low is perhaps also reinforced by the fact that the measure given in Table 10 as well as in other tables was not adjusted for the effect of size of firm and hence applies strictly speaking only to firms of infinite size. In our paper we did make some attempt to guard against these misunderstandings by also recasting our results in terms of the implied *before-tax* required yield for a firm of size equal to the "average" of our sample. But this was done only in a footnote (n. 54, p. 380); and to make matters worse, the numbers we actually gave in that footnote—.073, .087, and .090 respectively for 1954, 1956, and 1957—are erroneous. That there must have been something wrong with these numbers might have been apparent to the reader since, the before-tax yield should equal our tax-adjusted yield of Table 10 divided by one minus the marginal tax rate, or .48. Thus, even without correction for the size effect, the figures of footnote 54 should have been more than twice those reported in Table 10. However, since we failed to spot the error we can hardly blame anybody else for doing the same. In any event, with the additional intended adjustment for the effect of size, the correct estimates of the before-tax required yield implied by our results are .079, .094, and .098 for 1954, 1956, and 1957 respectively.²

All this is not to suggest, of course, that the widespread feeling that our estimates are unreasonably low, and that therefore something must be wrong with our approach, rest entirely on misunderstandings or on the misprint in our footnote. There are some genuine issues of substance involved. We, therefore, welcome the very detailed critique by Crockett and Friend, which presents most of the standard objections to our techniques and estimates as well as an independent estimate of the cost of capital

¹ This critique, together with our reply, is in [1, pp. 257-67].

² These figures can be obtained in a variety of ways. The simplest is to start with the cost of equity capital (as in Table 8) and make the size correction indicated in Table 9. The results for the three years are .052, .061, and .064 respectively. To obtain the size-adjusted and tax-adjusted average cost of capital, multiply these figures by $[1 - \tau(\bar{D}/A)]$ using the value of $\tau(\bar{D}/A)$ already computed in Table 7, row 2. The results are .038, .045, and .047 respectively. Finally, dividing these figures, by .48 we arrive at the before-tax required yields given above.

We should like to take this opportunity to correct a few additional misprints that we have uncovered in the meantime. In Table 1, first panel, the entry for the constant term in column 1 for 1957 should read .0164 instead of .164. In Table 2, first panel, the entry for the constant term in 1954 in column 1 should be .041 rather than .01; in the same row, next column, the parentheses should be removed from the entry (.0090); and in the second panel the debt coefficient for 1957 should read -.006 rather than -.066. Finally, the estimates of the time horizons for growth given in Table II are somewhat too long. In this connection, see footnote 15 below.

for utilities during this period. We hope that this reply will give us an opportunity to allay most of the misgivings that have been voiced.

The Supposed Biases in Our Estimating Procedures

Let us first consider Crockett and Friend's list of "substantial shortcomings in the statistical model of which [we] do not appear to be aware" and which, they claim, have led us to underestimate substantially the cost of capital. One such is that our use of dividends, along with debt, and preferred stock as instrumental variables biases the earnings coefficient upward (and hence biases downward our estimate of the cost of capital) because of a supposed "negative correlation of dividends plus contractual disbursements with risk." We fear that this criticism involves a failure to appreciate fully the properties of instrumental variables estimation. Furthermore, if it were really true that an above-average pay-out and leverage is significantly associated with below-average risk, leading to a more favorable capitalization of earnings and hence to a higher market value, then the tests of Tables 4 and 5 in which these variables were introduced explicitly in addition to our "computed earnings" should have revealed at least some significant positive effects for these variables, contrary to what we actually found. However, there is no need to argue the point along these lines. Anticipating that for any of a number of reasons some readers would be made uneasy by our choice of instrumental variables and particularly by our use of dividends we took the precaution of providing not one, but two supplementary tests. One consisted of dropping dividends entirely from the list of instrumental variables. As reported in footnote 41 the estimate of the cost of capital turned out to be almost identical. The second consisted of direct least squares estimates using what we called the "yield formulation." This formulation, we showed, can surmount the problem of bias introduced by the measurement error in earnings without recourse to instrumental variables, but it has other compensating disadvantages that we feel limit its usefulness to that of serving as a check test. The results of using this very different type of test were quite close to our original estimates (cf. our Table 6 and surrounding text discussion) suggesting once again that if our estimates of the cost of capital are indeed too low, this cannot be attributed either to our instrumental variable approach or to the particular instrumental variables we chose to use.

Another supposed shortcoming is our method of controlling for the effect of size on valuation. Crockett and Friend point out that this method could lead to an overstatement of the average earnings coefficient if ρ declined sharply with size; and they recommend the use of an explicit size variable to take this possibility into account. Actually, of course, our choice of procedure for controlling for size was not made casually or carelessly. We did look first at the scatters of V on X ; we could see no evidence of strong curvature of the kind hypothesized in their Figure 1b. Nor does there even exist in this industry a relevant group of small firms lying far below the sample range (i.e., to the left of \bar{X}_1 in their diagram). In any event, to make doubly sure that our simple method of controlling for size was not

leading to any serious distortion we also ran check tests using a continuous size variable (specifically, the log of total assets). As we reported in our paper (see footnote 51) neither the relative importance (nor direction) of the size term nor the values of the other coefficients were noticeably affected.³

Still, Crockett and Friend are correct in asserting that the measures given in our tables tend to understate the average cost of capital in that they are derived from capitalization rates which, as we acknowledged, apply only to firms of infinite size. The average cost implied by our results for any specified size of firm can be readily computed from our estimate of a_0 , the coefficient of the size variable. But since our results indicate that the effect of size is rather small and because the firms in our sample are all relatively large, correction for size cannot affect our estimates materially. In particular, the difference between the capitalization rate at infinite size and that corresponding to the mean value of the size variable in our sample in each of the three years is less than 3 per cent (cf. footnote 2 above). In terms of Crockett and Friend's Figure 1b, the difference between the slope of the line AB and that of the line OC is quite tiny within the range of sizes included in our sample.⁴

Finally, there is the question of the variable we have used to measure valuable future growth opportunities and which comes in for some criticism in each of the three comments. The problem of measuring this important, but not directly observable, quantity is a most complex and vexing one for which no one to our knowledge has yet been able to offer a completely satisfactory solution. We were the first to point out (cf. n. 17, p. 345) that our own approach suffered from shortcomings which would make its general applicability very questionable. And while we argued that these shortcomings would be at a minimum for our industry over the specific period studied, we would not assert that they are altogether absent. In particular, we would not deny that in principle our approach could produce an upward bias in the coefficient of the earning variable, as suggested by Crockett and Friend, because the ratio of earnings to assets might be conveying informa-

³ Our results using a continuous size variable are thus in conflict with some results reported by Robichek *et al.* They find, for 1957 and 1961, significantly lower earnings coefficients for firms above the sample mean in size than for those below the mean (i.e., curvature in the reverse direction from ours and from the direction that would be expected a priori). The fact that our continuous size variable shows orthodox curvature would seem to suggest that their reverse curvature from splitting the sample, far from providing a more reliable picture of the relation between value and size in the industry as a whole, probably comes from forcing the separate slopes to fit some conspicuous deviants at either extreme.

⁴ It is perhaps also worth noting that, if in fact the rate at which the market capitalizes earning rises with the size of assets, then the yield required of an incremental investment will not be the "average" cost of capital. It will be instead a "marginal" cost, which is below the average as it reflects the favorable effect that the addition to assets will have on the capitalization of earnings from the initial assets (just as, for a monopolist, the incremental revenue resulting from an increase in sales is less than the average revenue). If one is prepared to regard our formulation as a bearable approximation to the effect of size in the relevant range, then the *marginal* capitalization rate is precisely a_1 , of our equation (14), and therefore the relevant marginal cost of capital is that given in our tables, without any need to correct for size. That is why we never expressed the capitalization factor itself as a function of size, and only took size into account in the tables showing the components of valuation for the "average" firm.

tion about inter-firm differences in ρ^* , the rate of return expected from future investments.

The issue, however, is not whether our measure of growth opportunities has shortcomings—which it certainly does—but whether these shortcomings have led to a substantial underestimate of the cost of capital. Here, we would like to point out that there is at least a *prima facie* inconsistency in arguing, as do Crockett and Friend, that we both underestimate the contribution of growth to value and (largely as a consequence) also underestimate the cost of capital. For, it is conceded that the growth component arises from an excess of the rate of return on investments over the cost of capital. Hence, the presence of important growth opportunities would mean that the rates of return allowed by the regulatory authorities were significantly higher than the cost of capital. As noted in our paper (cf. Table 11 and surrounding text) an allowed rate of return after taxes on the order of the traditional 6 per cent implies a tax-adjusted return of about 5.2 per cent. Thus, if we have substantially underestimated the growth component as claimed, it is hard to see how the cost of capital could have been appreciably higher at least in 1956 and 1957 than our estimate of about 4.6 per cent.

Summing up, we feel that Crockett and Friend have not succeeded in showing any fatal flaw in our procedures which would permit our estimates to be dismissed out of hand or which would even establish *a priori* a presumption of serious bias. This is not to claim, of course, that our procedures are unexceptionable. There may well be more insidious and unsuspected mechanisms at work which have led us to underestimate substantially the cost of capital to utilities during this period. Before speculating about these, however, it is worthwhile to ask whether there is any evidence that our estimates really are so wide of the mark as to have to be explained away.

Are Our Estimates Really Far Too Low?

Both Gordon and Crockett-Friend are convinced that they have such evidence. Gordon's is that our estimates of ρ are consistently below the earning-price ratio, whereas "it is generally accepted that when super growth opportunities [valuable growth, in our terminology] are present the earning yield, Y/S , is below ρ , the cost of equity capital." But this evidence is worthless since it compares the required rate of return for a firm financed entirely by equity funds with the observed yield on stock, a comparison which is especially treacherous for a highly levered industry like electric utilities. This point is brought out in our Table 9 which was devoted precisely to clarifying the relation between the two measures. The presence of valuable growth does of course tend to depress market yields on stock—to the tune of some 20 per cent in 1957—but this effect is more than offset by the very high leverage which results in the observed average yield on stock exceeding ρ , the yield on an unlevered stock, by some 25 per cent.

A more promising and enlightening way of assessing our estimates is to compare them with the results of other "sensible" methods of estimation. This is the task undertaken by Crockett and Friend in the last half of their

paper, the method used being that suggested by Friend in his earlier critique of our paper.

We shall not here comment on the many steps involved in what they choose to call their "direct" estimates partly for reasons of space and partly because they themselves would regard their "admittedly crude empirical results" as intended to be only suggestive. Let us instead turn directly to the results of the calculation on which they base their conclusion that our estimates are significantly understated.

At this point we must call attention to one seemingly small, but actually quite important, difference between the two methods of presenting the final estimates. In constructing their overall weighted average cost of capital from the separate yields they used *market*-value weights. Our estimate, on the other hand, weights the debt component by its *book*-value. Of the two weighting schemes, we feel that the book-value weights are the more appropriate ones to use when talking about the cost of new financing (as we indicated, p. 378); but that is not the issue. The critical point is simply that the weights have to be the same in both estimates so as to permit a meaningful comparison. Adjusting their estimates to ours by using book-value weights (and using the actual tax rate of 52 per cent, as we did, rather than their 50 per cent) we find that their best estimate of the average before-tax cost of capital for the years 1954-57 now becomes 9.7 per cent (as against their original 10.7 per cent); and their lower-bound estimate becomes 8.9 per cent (as against their original 9.5 per cent). By contrast, our supposedly "low" estimates of the before-tax cost of capital were shown to be 9.8 per cent for 1957, 9.4 per cent for 1956, and 7.9 per cent for 1954.

That the Crockett-Friend rough estimates do not turn out to be significantly different from ours should not really be surprising. There were a number of clues in the numbers presented that should have forewarned them. The key element in their computation is the assumed required after-tax yield on equity capital, and if their estimates were to differ substantially from ours it could only be because of a substantial difference between us in the value assigned to this figure.

After much careful weighing of the evidence, speculation about growth rates, and soundings of professional opinion, they settle on an average yield on equity for the middle and late 1950s of between 7.5 per cent and 8.5 per cent. Consulting our Table 9, they could have seen that the average required equity yields implicit in our calculation (the sum of the average earnings yield and the growth effect, as reported in Table 9) came to 8.4 per cent for 1957, 7.8 per cent in 1956, and 6.9 per cent in 1954.⁵ Perhaps they might have wanted to quarrel with our figure for 1954, although we could also point to the fact that our 1954 figure is by no means far out of line with interest rates during the period which were also quite low by later standards. But even with this reservation, it should have been clear that our estimates could not be so far off after all.

So much then for our supposed substantial underestimate of the cost of

⁵ These figures can also be reached, up to rounding errors, by summing the cost of equity capital, the size effect, and the leverage effect as reported in the same Table 9.

capital. We turn now to Gordon whose main concern is not so much with our estimates as with our interpretation of the results of certain supplementary tests of the effects of leverage and dividend policy on market valuation.⁶

The Leverage and Dividend Tests

On the question of leverage Gordon argues that the derivation of our fundamental valuation equation is not applicable to electric utilities because it relies on the assumption that before tax earnings X "is an exogenous random variable independent of the corporation's tax and leverage rates." This assumption, he suggests, is not applicable to electric utilities because the rate of return which regulation aims at establishing is based on after-tax earnings X^r , all gains from leverage thus accruing to the customers through lower before-tax earnings. Accordingly it is " X^r and not X [which is] independent of the tax rate and financial policy." He concludes that the relevant basic valuation formula, regardless of corporate taxes, is $V = (1/\rho)/X^r$ rather than our $V = (1/\rho)/X(1-\tau) + \tau D$. If so, and if there were no other gains from leverage, then the coefficient of debt in our valuation equation should be a substantial *negative* number. Our finding of a zero coefficient would thus actually imply a considerable independent value to leverage per se, contrary to our conclusion that no gain beyond the tax subsidy was detected.⁷

This argument is interesting though its formulation may be a bit

⁶ Crockett and Friend are also critical of these tests, but they present no bill of particulars beyond some references to the role of nonlinearities. We did not go into the question of curvature in our paper mainly because the paper was already quite long and because any detailed consideration of such second-order refinements would have carried us too far afield from our main task of providing estimates of the cost of capital. For what it may be worth, however, we can at least report that in the few tests of curvature we did carry out in anticipation of an eventual follow-up paper we found no compelling evidence of strong nonlinearities of a kind that would require any modification of our conclusions about the gains from leverage or from alternative dividend policies.

⁷ Some idea of the quantitative magnitudes involved can be obtained by observing first that, if there were neither tax nor nontax advantages to leverage, the fundamental valuation equation (neglecting growth or other control variables) would be

$$(1) \quad V = \frac{1}{\rho} X^r$$

where X^r = after-tax earnings. To get an equation comparable to the one we fitted, first subtract τD from both sides and then add and subtract $\tau R/\rho$ on the right obtaining:

$$(2) \quad V - \tau D = \frac{1}{\rho} (X^r - \tau R) + \tau \frac{R}{\rho} - \tau D = \frac{1}{\rho} X(1 - \tau) + \tau \left(\frac{R}{\rho} - D \right)$$

If we can approximate R as τD (i.e., some average rate of interest times the debt) we can rewrite (2) in terms of tax-adjusted income and debt as

$$(3) \quad V - \tau D \cong \frac{1}{\rho} (X^r - \tau R) - \tau \left(\frac{\rho - \tau}{\rho} \right) D.$$

Taking ρ as approximately .06, τ as approximately .04, and τ as .52, equation (3) implies that the coefficient of D in our test equation should be something on the order of $-.15$ to $-.20$.

misleading. Actually the arbitrage argument from which we derived our basic valuation equation for the case of a corporate income tax American-style does not make explicit reference to just what determines \bar{X} . What we do need to assume is that the random variable $Z = X/\bar{X}$ is the same for all firms in a risk class and hence in particular that it is independent of leverage (though not necessarily of tax rates). Under this assumption, as shown in [2] the distribution of X^r/\bar{X}^r will depend on leverage and tax rates and in particular its variance will be reduced by leverage. Thus our treatment of electric utilities as a risk class implicitly assumes that the random variable X/\bar{X} is independent of leverage, and this assumption may appear somewhat questionable in the light of Gordon's observations about the nature of regulation. On the other hand, Gordon's valuation formula is at least as doubtful. Indeed, for his reasoning to be valid it is required not only that before-tax earnings \bar{X} should be a linearly decreasing function of leverage, as indicated by his formula (7); it would also have to be true that the distribution of the random variable $G \equiv X^r/\bar{X}^r$ is independent of leverage. This property cannot readily be deduced from the nature of regulation. In fact, it has some peculiar implications about the *modus operandi* of regulation, e.g., that it would make the uncertainty of *before-tax earnings* an increasing function of leverage.⁸

On the whole one might be inclined to conclude that a reasonable approximation to the applicable valuation formula might lie somewhere between ours and Gordon's. But there are several pieces of evidence suggesting that in fact the relevant approximation is much closer to ours than to his. In the first place, if regulation actually aimed at, and succeeded in, enforcing his equation (6) then $\bar{X}^r - \tau R/A$ would have a strong and stable negative correlation with D/A . Yet the correlation varies widely from year to year being noticeably negative only in 1957 and actually being positive, though small, in 1954. (See our appendix Table B2, p. 389.) Gordon's interpretation would also imply that leverage obtained via non-tax-deductible preferred stock would be equivalent from the stockholders' point of view with that obtained from debt. Hence if, as Gordon argues, stockholders really do prefer leverage per se, over and above any of its tax effects, we should expect to see that preference demonstrated in the case of preferred stock as well as debt. Yet, as we noted in connection with our Table 4, the coefficients of preferred stock in our test equation were neither significantly different from zero nor even consistently of the same sign. All things con-

⁸ If $X^r/\bar{X}^r = G$ independent of leverage and tax rates then

$$X = \frac{X^r - \tau R}{1 - \tau} = \frac{G\bar{X}^r - \tau R}{1 - \tau} \quad \text{and} \quad Z = \frac{X}{\bar{X}} = \frac{G\bar{X}^r - \tau R}{(1 - \tau)\bar{X}}.$$

It follows in particular that

$$\sigma_Z = \frac{\bar{X}^r}{(1 - \tau)\bar{X}} \sigma_G = \sigma_G \left[1 + \frac{\bar{X}}{(1 - \tau)\bar{X}} \right]$$

would be an increasing function of leverage. That leverage fails to increase the market value of the firm in Gordon's model may be thought of as reflecting the fact that the tax benefits of leverage would thus be offset by an increased variance of before-tax earnings.

sidered, then, it would seem safe to characterize Gordon's interpretation of our leverage tests as ingenious, but of little practical consequence in the present context.

On the issue of the effects of dividend policy, Gordon objects strongly to the form of our tests which he regards both as a poor approximation to the dividend hypothesis being tested and one which is biased against the traditional view.⁹ His position boils down to the following: the hypothesis that a high payout increases the market value of shares implies that total value should be favorably affected by the relation of dividends to *profits*, not to tax-adjusted earnings. If there were no debt or if leverage were roughly the same for all firms, then a high level of dividends relative to earnings would also imply a high payout. But leverage is not constant and since we fail to control for it (except implicitly via the τD component of the dependent variable) our test will tend to attenuate the coefficient of dividends, biasing it towards zero and understating its significance.

In principle, we would accept this argument, but it clearly cannot account for our results. For one thing, it could not explain the consistently *negative* signs of the coefficients in the more relevant two-stage test since this type of bias can push an estimated coefficient toward zero, but not change its sign. Moreover we too were concerned about possible downward bias in the dividend coefficient for related but somewhat different reasons (see our footnote 46). Accordingly, we ran a check test in which we extended the two-stage approach to the dividend variable as well as to the earnings variable. The result was that in all 3 years the dividend coefficients were less negative than those of Table 5, and in 1957 the coefficient was actually positive though only of the same small order of magnitude as in the direct least squares test. Although these results tend to confirm the existence of bias in the coefficients of Table 5 they also show that the bias is not large enough to force any modification of our main conclusion, namely that the data show no sign of a strong, positive effect of dividends of the kind hypothesized by Gordon.¹⁰

The RMH Paper

We now turn briefly to the paper of Robichek, McDonald, and Higgins (hereafter RMH). This is basically a replication of some of our tests to

⁹ Another and quite different line of attack on our dividend results is contained in Section V of the Gordon paper. That argument, however, despite the very positive tone with which it is presented and the frequent use of such terms as "hence" and "consequently," is just hand-waving and will not stand up to any serious scrutiny.

¹⁰ The reader may wonder why we did not simply present a test in terms of the value of the shares, profits, and dividends that would have met Gordon's objection directly. The answer, as we pointed out (see our footnote 48), is that it was not possible to construct such a test given the necessity of using a two-stage instrumental variable approach and given the limited set of instrumental variables we had at hand. For, in an equation with the value of shares as dependent variable it is essential to include both debt and preferred stock as independent variables in the structural equation. To include dividends as well would mean that the only thing keeping the second-stage computed profits variable from being an exact linear combination of the other independent variables would be the constant term (included in the first stage and suppressed in the second). A glance at Table 2, second panel, makes it clear, however, why this was not enough to permit identification of the second-stage equation.

another sample of public utility data running from 1954 to 1964, in which great pains were taken to follow slavishly the details of our definitions and procedures.

For the period where the RMH data overlap ours (1954, 1956, and 1957), it turns out that their results are quite close to ours, and much closer still for their special MM test sample in 1957, a sample based on precisely the same firms and definitions we used.¹¹ Naturally, we are grateful for this independent audit and gratified by the closeness of the agreement during our sample period. This does at least remove one possible suspicion about the source of our "peculiar" results! However, as they extend the tests beyond our sample period, their results change quite substantially. In particular, the coefficient of the earnings variable keeps rising, implying a drop in the cost of capital between 1957 and 1964 by some 25 per cent, to an implausibly low value.¹² Unable to offer any explanation for this striking difference in performance before and after 1957, they call a plague on both houses and conclude that "none of the estimates of the cost of capital reported either by MM or here can be considered reliable estimates of the cost of capital to electric utility firms."

Actually these results hold little surprise to anyone who takes the pain to inspect the behavior of the sample means reported in their Appendix B. The puzzle is right in these basic data and not in the results one obtains by applying our specific approach to them. For the fact of the matter is that between 1957 and 1964 their measure of market value relative to the book value of assets rises by a hefty 43 per cent (from .80 to 1.28) while at the same time the measure of the rate of earnings on assets rises a modest 14 per cent (from .051 to .058).¹³ And, to top it off, the average rate of growth of assets computed over a five year period—which for all its shortcomings is still a relevant measure of growth, without which valuable growth cannot

¹¹ Readers should not be misled by the seeming large differences in the standard errors and multiple correlation coefficient in the second stage regression for 1957 reported in their Table A-3. Apparently RMH neglected to make the necessary correction for the standard errors explained in our footnote 39. If so, all the standard errors and values of R reported in their Tables 1 and 2 are also erroneous and conclusions based on them, e.g., in their first section, are unreliable.

¹² RMH also find that, when they estimate the equation in nonhomogeneous form, the constant term which was zeroish to slightly positive for our sample period becomes negative and very sizably so. The only suggestion they offer for the absurdly large negative intercepts is that they "may be reflecting determinants of corporate value omitted from the MM structural equation." As far as we can see, however, the major difference between our structural equation and anyone else's would be in our omission of leverage and dividends. It seems hard to believe that those omissions could produce anomalies of the order of magnitude found—for despite all the controversy, the various theories are not *that* different or the issues would have been settled long ago. But RMH didn't even try to eliminate some of these more obvious candidates.

We suspect that these anomalies might be traced to inadequacies of the instrumental variables in later years, a suspicion reinforced by the fact that the constant term takes on its largest negative values just when the value of R reported by them for Table 1 is lowest. But since RMH present neither standard errors for the constant term, nor first stage regressions, nor direct least square results we have no way of checking out this hunch.

¹³ These figures relate to market value and earnings adjusted for leverage. But since leverage is unlikely to have changed drastically in the period it seems safe to infer that most of the change is in the relation of the market value of the stock to net profits.

exist—declines by 55 per cent (from .106 to .050). It is hard to see how, confronted with these data, any model—as long as it incorporated the view, by now widely accepted, that the cost of capital is closely related to the way the market capitalizes earnings, with some adjustment for growth—could fail to yield the conclusion that the cost of capital must have fallen dramatically over this interval. Indeed, when the authors discarded our model and tried to estimate directly a capitalization rate for returns to equity capital they found a drop in this rate between 1957 and 1964 of some 36 per cent!¹⁴ This conclusion seems rather unavoidable—unless there is something wrong with the basic data.

At least two possible sources of bias come readily to mind. In our study in computing V we endeavored to estimate debt at market value. Because this procedure is very time consuming RHM used the book value of the debt. Since long-term interest rates rose between 1957 and 1964 one might expect some tendency for the market value of debt to fall relative to the book value, imparting an upward bias to their estimates of V . But we doubt that this bias could be very significant (especially since the increase in the long rate was largely over by 1959).

A potentially far more serious source of trouble is in the treatment of “charges for deferred taxes” in the measurement of earnings. These charges essentially represent the discrepancy between taxes actually paid and the higher taxes that would have been paid in the absence of various incentive tax measures permitting a faster depreciation of physical assets. There are strong reasons for holding that these charges should be added back to reported net of tax earnings in measuring the earnings the market capitalizes. As indicated, we experimented with this concept of earnings in our own analysis (see p. 356). But we ended by using the reported profits which gave a somewhat better fit, on the consideration that the relevant tax provisions were relatively new, and quite possibly, even by 1957, investors had not seen through this accounting complexity. But we would rather expect that in later years the market would have learned to make the needed adjustment, especially as the size of the adjustment became more important with the revised depreciation guidelines and the investment credit. Thus the measure of earnings which we found adequate for our sample period and which was presumably used also by RMH may well have become increasingly downward biased.

These remarks about the measurement of earnings serve also to point up what in our view is the fatal shortcoming of the RMH tests, robbing them of their potential usefulness. The authors fail to appreciate that the concepts of the model—especially such concepts as the market’s evaluation of future earnings and growth potential—do not have exact observable counterparts. The best that can be done is to approximate them somehow from the data at hand. A particularly glaring illustration of this failure is provided by the

¹⁴ These estimates which are alluded to in their section “Leverage and Value” were reported in a preliminary version of their comment circulated as *Research Report #118R*, Graduate School of Business, Stanford University, Table 6. The fall in the estimated capitalization rate for profits is from .078 in 1957 to .050 in 1964.

measurement of future investment opportunities, which we suggested proxying by the observed past growth of total assets. We chose to measure past growth by the growth in assets over the previous 4 years or the ratio $(A_t - A_{t-4})/(A_{t-4})$, because, as we candidly stated, this particular measure "happens to yield consistently higher gross and net correlations with total value than other simple smoothings we have tried" (p. 345). However, we wrongly stated that the measure used was $(A_t - A_{t-5})/A_{t-5}$.¹⁵ RMH discovered our error, and confirmed that the four-year measure actually used did perform a good deal better than the five-year measure. But they then proceeded merrily to use the latter, less effective, measure we erroneously said we had used, labelling it "correct growth," as though this particular approximation was an essential logical implication of our model. The fact of the matter is that we settled on our various approximations only after facing a large number of empirical questions. The RMH results suggest that, if we had looked at their data and period rather than ours, then our answers to some of these questions would have been different. But we fail to see how this entitles them to reject the answers we did find for our sample and the approximations based on those answers—unless, of course, they are also prepared to argue that approximations not valid *everywhere* are not valid *anywhere*.¹⁶

It might be useful in closing to attempt to summarize where we think matters now stand. In critical exchanges of this kind, in which so much of the emphasis is inevitably on technical details, it is easy to lose perspective and to overlook such progress toward agreement as has been made. In terms of substantive findings, for example, we feel there should now be agreement, at least, that our estimates of the cost of capital have been constructed with due care; that the more obvious sources of bias have been checked out; and that the numbers themselves, properly interpreted, are neither manifestly inconsistent with a priori expectations nor with the results obtained by other estimating techniques.

On the matter of the leverage and dividend tests, we would certainly agree with our critics that our results do not close the issue. The problems here are far too difficult to be settled by any one empirical study. We trust they will equally agree that our results show at least that the issue is still open.

¹⁵ In the tests actually presented we restated the growth ratio in annual terms; and, misled by our notational error we multiplied the four-year growth by $\frac{1}{4}$ instead of $\frac{1}{5}$. This scaling error, of course, is of no great consequence and leaves all the other coefficients, as well as the t -ratio of the growth coefficient itself, unaffected. It does, however, affect the attempted "unscrambling" of the growth term presented in our Table 11 by leading to an overstatement of the implied horizons.

¹⁶ That they may very well have some such principle in mind is suggested also by their discussion of their "experiment" with the growth variable in their Table 3. They find that splitting the sample on the basis of growth makes for no significant difference in any of the coefficients for 1957, which is one of our sample years. It does, however, make a considerable difference in 1961. From this they conclude not that our approximation works better in 1957 than 1961, or even that it doesn't work at all in 1961; but rather that "this particular error in specification is so fundamental that it calls into question the value of the model itself as an estimating tool."

As to methodological matters, we would hope that Crockett and Friend would concede that what they call our "indirect" method is at least as valid and valuable an approach to estimating the cost of capital as their "direct" method. Theirs may perhaps have the advantage of not requiring a prior confrontation of the leverage and dividend issues; but, if this is an advantage, it is obtained only at the cost of having a less useful estimate—a single average point estimate rather than the cost of capital function derivable by our procedure. In any event, there is no necessity for researchers in this area to restrict themselves to any one method. The two approaches are complementary and anyone undertaking a study along our lines would be well advised to check his results by alternative approaches, including possibly that suggested by Crockett-Friend.

As for the problem of controlling for the measurement errors in earnings, the instrumental variable approach would appear to be a useful tool in valuation studies, though, as the RMH results indicate, there is nothing automatic about it. Those planning to take up where we left off would be wise to devote considerable thought to the selection of the instrumental variables and especially to expanding the set of such variables considerably beyond the basic few we used so that adequate tests of specifications can be made (particularly tests involving the value of shares rather than the value of the firm).

Finally there is the vexing question of growth. Here there would certainly be agreement that the particular approximation to growth potential that we used is likely to be of only very limited usefulness as we conceded in our original paper. But this is no reason to despair; our variable, after all, was about the simplest possible approximation one might make; and it is at least encouraging that nature does not seem to be so hostile as to rule out simple methods even in easy cases such as ours. There are a large number of promising possibilities and approaches still to be tried; the next step is to try them.

The Possibility of a Social Welfare Function: Comment

In his recent article, James S. Coleman seems to assert that there is ordinarily a stable equilibrium outcome to a vote trading situation with

many decisions and many voters.¹ The assertion is based largely on analogy to a market with many goods and many traders.

Ordinarily, I claim, no such stable outcome exists. Furthermore, if there is a stable outcome with vote trading, it must be exactly the same as the outcome without vote trading! These statements are made more precise in what follows.

Consider the following situation. There are n voters, X_j , $j=1, \dots, n$, and m measures up for consideration, A_i , $i=1, \dots, m$. Each measure is completely described by a vector of utility payoffs to each individual,

$$|a_{ij}| = [a_{i1}a_{i2} \dots a_{in}].$$

Payoffs are additions to or subtractions from an individual's utility, depending on whether a_{ij} is positive or negative. Ordinarily a measure will benefit some individuals at the expense of others; that is, for a given i , at least one a_{ij} is positive and one a_{ij} negative. However, other measures are not excluded from consideration.

Without vote trading, decisions are taken as follows. Each voter X_j is given a description of all measures A_i , that is, a matrix

$$\|a_{ij}\|$$

composed of the payoff vectors for all measures. Without being allowed to communicate with any of the others, each voter records his vote for or against each measure. The votes are then counted. Each measure that receives at least $(n+1)/2$ (if n is odd) or $n/2+1$ (if n is even) "for" votes is adopted, and all other measures are rejected.

With vote trading, decisions are taken in exactly the same way except that a bargaining period follows distribution of descriptions of the measures. During the bargaining period, each voter can enter binding agreements with others as to how they all will vote on particular measures. At the close of the bargaining period, votes are cast and counted to determine which measures are adopted, and which rejected, just as before.

Definition 1: A majority set is any set of voters X_j with at least $(n+1)/2$ members (if n is odd), or at least $n/2+1$ members (if n is even).

Definition 2: An outcome is a set of measures adopted. Denote the k^{th} outcome by T_k .

Assumption 1: The payoff vector of an outcome T_k ,

$$|a_{kj}|, = \sum_{i \in T_k} |a_{ij}|.$$

That is, utility payoffs are additive for each individual.

One can therefore form the payoff matrix for all outcomes,

$$\|a_{ki}\|,$$

from the payoff matrix for all measures,

¹ [2, pp. 1117-18; also note 9, p. 1114]. Tullock makes the same assertion: "If logrolling is the norm (and it will be no secret to the reader that we think it is), then the problem of the cyclical majority vanishes" [1, p. 330].

$$||a_{ij}||,$$

by adding payoff vectors for each possible combination of measures, from none of the A_i , through any one, any combination of two or more, on up to all m .

Assumption 2: For each voter X_j ,

$$a_{kj} \neq a_{k'j},$$

for all k and k' such that $k \neq k'$. That is, no individual is indifferent as between any two outcomes.

Assumption 3: Each voter X_j acts as if he wanted only to maximize the expectation of his own utility payoff.

Assumption 4: There are no tie measures, that is A_i that benefit exactly $n/2$ and harm exactly $n/2$ voters. This assumption is automatically satisfied if n is odd. For n even, allowing tie measures would weaken the results slightly and complicate the exposition a great deal.

Theorem 1: Without vote trading, there is a unique outcome which includes all A_i that benefit any majority set and excludes all A_i that harm any majority set. I denote that outcome by T_b .

Lemma 1: Without vote trading, each voter X_j votes for any measures A_i for which $a_{ij} > 0$, and against any A_i for which $a_{ij} < 0$.

Proof: X_j acts as though he were attempting to maximize his expectation of a_{kj} (Assumption 3). Since utility payoffs for each individual are additive by Assumption 1, the way for him to do this is to maximize his subjective probability for adoption of all A_i for which $a_{ij} > 0$, and minimize the probability of adoption of all A_i for which $a_{ij} < 0$. If X_j is at all uncertain about how others might vote on A_i , his vote for A_i will maximize the probability of adoption, and his vote against A_i will minimize the probability of adoption. If, however, X_j is subjectively certain as to how others will vote on A_i , he will see his own vote as being either decisive or immaterial. If he sees his vote as decisive, he will vote for A_i if $a_{ij} > 0$ and against it if $a_{ij} < 0$. If he sees his own vote as immaterial, he may cast it randomly for or against A_i . But he cannot rationally cast his own vote randomly without admitting the possibility that others might also do so. And that brings him back to the case in which he is uncertain as to how others may vote, and votes for A_i if $a_{ij} > 0$ and against it if $a_{ij} < 0$.

Lemma 2: For each voter X_j , all a_{ij} are either $>$ or < 0 .

Proof: Included in $||a_{kj}||$ is a payoff vector for rejection of all A_i . Rejection of all A_i leaves the status quo unchanged, so these payoffs are all zeros. Lemma 2 is thus just a statement of Assumption 2 for the special case in which T_k' is the rejection of all A_i , and T_k is the adoption of each A_i individually in turn.

Lemma 1 and Lemma 2 together imply that each X_j casts a vote either for or against each A_i .

Now there are three things to prove in Theorem 1: (a) T_b is unique, (b) T_b includes all A_i that benefit any majority set, and (c) T_b excludes all A_i that harm any majority set.

To prove (a), note that by Lemma 1 the number of votes for A_i is uniquely $N(a_{ij} > 0)$, that is, the number of positive payoffs in $|a_{ij}|$. And whether or not A_i is adopted is uniquely determined by whether or not $N(a_{ij} > 0) \geq (n+1)/2$ (if n odd) or $n/2+1$ (if n even). Thus T_b is uniquely determined given $||a_{ij}||$.

The proof of (b) is trivial: If A_i benefits any majority set, $N(a_{ij} > 0) \geq (n+1)/2$ (if n odd) or $n/2+1$ (if n even) by Definition 1, and so it is adopted.

To prove (c): If A_i harms any majority set, $N(a_{ij} < 0) \geq (n+1)/2$ (if n odd) or $n/2+1$ (if n even). Since all a_{ij} are either < 0 or > 0 (Lemma 2), $N(a_{ij} > 0) \leq n - (n+1)/2 = (n-1)/2$ (if n odd) and $n - (n/2+1) = n/2-1$ (if n even) and so A_i is rejected.

I note in passing that T_b may be such that $|a_{bj}| < 0$, that is the outcome without vote trading may hurt all voters.²

Definition 3: An outcome is unstable if there exists any group of voters that individually prefer another outcome, and collectively are able to act so as to assure the preferred outcome. All outcomes are either stable or unstable, but not both.

Theorem 2: A necessary condition for an outcome T_c to be stable with vote trading is that it be identical with the outcome without vote trading, T_b .

Proof: Assume that $T_c \neq T_b$, and show that T_c is unstable.

If $T_c \neq T_b$, then at least one of the following two statements is true: (a) T_c excludes at least one A_i that is included in T_b , (b) T_c includes at least one A_i that is excluded from T_b .

Consider (a) first. The A_i that is excluded from T_c but included in T_b benefits some majority set S , by Theorem 1. Therefore, all members of S prefer $T_d = T_c \cup A_i$ to T_c , because utility payoffs are additive for each individual by Assumption 1. Further, S is able to assure T_d by voting en masse for all measures in T_d and against all measures not in T_d . Therefore T_c is an unstable outcome, by Definition 3.

The argument if (b) is true is similar. The A_i that is included in T_c but excluded from T_b harms some majority set S , by Theorem 1 and Assumption 4. Therefore all members of S prefer $T_d = T_c - A_i$ to T_c , by Assumption 1. Further, S is able to assure T_d by voting en masse for all measures in

² An $||a_{ij}||$ that would result in such a T_b is

$$\begin{bmatrix} -2n & 1 & 1 & \cdots & 1 \\ 1 & -2n & 1 & \cdots & 1 \\ 1 & 1 & -2n & \cdots & 1 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & 1 & \cdots & -2n \end{bmatrix}$$

Clearly, it makes a big difference what measures come to a vote. It might be useful to regard political decision-making as a two-step process: (1) picking, from among the infinity of multi-dimensional continua of possible measures, a finite set to present for vote, and (2) deciding whether to adopt or reject each measure presented. The second step seems to have received a good deal more analytic attention than the first.

T_d and against all measures not in T_d . Therefore T_e is an unstable outcome, by Definition 3.

Theorem 3: If the introduction of vote trading is "beneficial" in the sense that some majority set can, with vote trading, improve the payoffs to all of its members over those without vote trading, there is no stable outcome with vote trading.

Proof: The "if" clause is just a statement that the outcome without vote trading, T_b , is not stable with vote trading (Definition 3). But by Theorem 2, if T_b is not stable with vote trading, there is *no* stable outcome with vote trading.

Note: Since T_b includes (excludes) all individual measures that benefit (harm) any majority set, the "if" clause is true if and only if T_b excludes (includes) some combination of two or more measures than benefits (harms) some majority set.

To what extent have I substantiated my opening remarks? I claimed first that no stable outcome ordinarily exists with vote trading. This is a statement with empirical content that can be refuted only by examination of $\|a_{ij}\|$'s that "ordinarily" characterize vote trading situations. Theorem 3 states a condition under which no stable outcome exists, and my claim is based upon the feeling that this condition is often fulfilled.

My second opening statement, that if there is a stable outcome with vote trading, it must be exactly the same as the outcome without vote trading, is just Theorem 2. The proof of Theorem 2 substantiates the statement, given the assumptions.

The Possibility of a Social Welfare Function: Comment

It has been possible for some time to demonstrate that under certain conditions competitive forces will achieve a socially optimal allocation of private goods in an exchange economy through the operation of the price system. What has remained an insurmountable problem, however, has been to select a socially optimal allocation of resources once public goods are introduced into the model. The field of selection usually is limited to Pareto optimal points. By definition any shift from one Pareto optimal point to another involves a loss for some members of the community and a gain for others. The chief

problem in selecting *the* socially optimal allocation of goods has been to determine what these gains and losses are, and then devise a way by which the gainers can compensate the losers. The characteristics of the public good preclude the use of the price system for making these exchanges, since it is to the advantage of every individual to conceal his true preferences for this type of good.¹ The basic problem which must be solved when dealing with public goods, therefore, is to devise a method for determining individual preferences for these goods and then on the basis of these revealed preferences select the set of public goods which is socially optimal [4, pp. 131-132].

Professor Coleman has presented a model which argues that this problem can be solved by means of a voting process, if voters are allowed to enter into vote trading agreements [2]. Unfortunately, these vote trading agreements cannot be relied upon to reveal the true preferences of individuals. This will be demonstrated in Section I. The objections to Coleman's model will be removed with a simple extension of this model, which is presented in Section II. In Section III some additional conclusions are drawn regarding both models.

I. Coleman's Social Welfare Function

The demonstration that competition will bring about a socially optimal allocation of private goods rests on a rather restrictive set of assumptions. For our purposes the two most interesting necessary conditions are: first, that all agreed-upon transactions do in fact take place. It is because goods actually must be exchanged that individuals are forced to reveal their preferences for each commodity. A consumer can only obtain additional units of one commodity by actually giving up units of some other good. Second, the number of buyers and sellers must be large enough, and the initial distributions of goods and wants wide enough, so that no individual or group of individuals is capable of colluding and achieving monopoly or monopsony power over a good. Competition among buyers and sellers will produce an allocation of private goods which is socially optimal in the sense that the marginal social benefit received from any good equals the marginal social cost of supplying it. The equilibrium set of prices will produce an allocation of goods which is uniquely determined by the initial distribution of goods and consumer tastes.²

In Coleman's model, each decision to supply a public good (along with a tax scheme to finance it) is called an *event* [2, p. 1120]. Individuals are partially able to *control* these events by voting for or against them [2, p. 1119]. They may increase their control over certain public goods by entering into agreements to swap votes. The voter agrees to give up his votes on some issues (by voting against his wishes) for the pledges of other individuals to vote as he does on an issue he considers important. These agreements should increase the expected utility gain of the voter by increasing his control over the issues

¹This follows directly from its definition as a good which *must* be supplied in equal quantities to all the members of a community regardless of their contributions to its financing. For definitions of private and public goods, see Samuelson [6]. Also, note Head's refinements on these definitions [3].

²For a complete proof of the theorem stating all the necessary conditions, see [1, Ch. 3].

which are of the greatest interest to him. Given large numbers of issues and voters, one can picture the voter entering into a set of vote exchange agreements such that the last amount of expected utility sacrificed by giving up control over his vote on some issue equals the gain in expected utility from securing control over additional votes on other issues. If all voters enter trade agreements until this condition is met, a set of decisions on public goods is obtained which may be termed socially optimal owing to its similarity to the result for the private good market.³ Voter preferences are revealed by means of the vote trading agreements into which the votes enter.

Our criticism of Coleman's model is that these trading agreements cannot be relied upon to reveal individual preferences: first, because they do not remove the incentives each voter has to conceal his true preferences—which is the basic problem with which we began; second, because no one can be expected to keep these agreements once the number of voters is very large.

The difficulty with getting individuals to reveal their preferences for public goods arises because each individual must consume equal quantities of the good once the decision is made to supply it. If an individual is then approached by the tax collector and asked to assess the value of the public good to him, he naturally will tend to understate this value. The same incentives exist when voters enter trading agreements. If voter *B* approaches *A* and asks him whether he intends to vote for issue *X*, an issue *B* strongly favors, it is to *A*'s advantage to say no even if he too is for the issue. *B* may then offer to vote with *A* on some other issues *A* favors, if *A* will agree to vote for issue *X*. Of course, *A* too will have no way of knowing whether or not *B* really is "giving up" his votes or just claiming to sacrifice them on these issues. Hence, there can be no assurance that the vote trading agreements will reveal the true preferences of the voters. They will continue to have incentives to misstate their preferences when the agreements are being struck, in order that they obtain greater bargaining power.

In demonstrating the second point, it must be noted that it is a necessary condition for achieving a socially optimal set of decisions on public goods, that the number of voters be large. Otherwise, a voter is in a monopsonist's position on any issue of great importance to him. He will be able to gain complete control (a majority of votes over the issue) without sacrificing an equivalent loss in expected utility through trading his votes on other issues [2, p. 1118]. Unfortunately, the existence of a large number of voters precludes the formation of the coalitions and agreements which are also necessary for the vote trading activities of Coleman's model.

When voting decisions are made sequentially, the temptation to violate voting agreements is large. If two voters agree to swap votes on a pair of issues, as soon as the first issue is decided one of the voters will have fulfilled his part of the bargain. The second voter then has a greatly reduced incentive to live up to his part of the agreement and vote against his own wishes. If he does de-

³ This will be demonstrated in greater detail in Section II. Although this conclusion is never actually drawn in Coleman's paper, it is implicit in his statements at the end of Section III [2, p. 1120].

cide to violate the agreement, the only way the first voter can retaliate is by refusing to enter into further agreements with him or by voting against some issue the violator favors.

With a large number of voters, no single individual's vote will be considered decisive for the outcome of a vote on an issue. It also will be nearly impossible to single out a violator of an agreement for punishment without similarly punishing other members of the coalition (who have not broken the agreement) by voting against an issue they favor.⁴ The total loss in welfare for the members of the coalition from carrying out punishment is likely to be much greater than the expected gain from disciplining a single violator. Hence, the member of a large coalition must view the probability as rather small that the other members will retaliate against any vote he takes which is against the coalition's agreements. If, under these circumstances, voters are not willing to enter into and keep vote trading agreements we are left with the problem with which we started, the problem of trying to get individuals to reveal their true preferences towards bundles of public goods by means of a voting process.

We conclude that coalitions among large numbers of voters can be expected to be unstable for the same reason that collusive agreements among large numbers of sellers are thought to be unstable. Each individual does not expect his decision to alter the decisions of the rest of the group. If they abide by the agreement and he breaks it, he stands to gain. If they do not maintain the agreement and he does, he loses. If no one maintains the agreement, he is worse off than in the first situation, and better off than in the second. Since all other participants are thought to view the situation similarly, the likelihood is that most individuals will choose to break the agreement.

Indeed, it would be embarrassing if this were not the case. The demonstration that competition will produce a socially optimal allocation of private goods rests upon the assumption that large numbers of buyers and sellers *are not capable* of maintaining collusive agreements when it is to the advantage of each individual to break such agreements. The demonstration that voting will produce a socially optimal set of decisions regarding public goods cannot be left to rest on the premise that large numbers of voters *are capable* of reaching agreements when individuals stand to gain from violating such agreements.

Fortunately, this premise is not essential for the latter demonstration as now will be shown.

II. *Exchanging Votes in a Vote-Market*

The difficulty with Coleman's model is that voters do not actually exchange votes, but only agree to trade votes and hence have an incentive for concealing their true preferences at the time these agreements are formed. Furthermore, with a large number of voters the incentives to violate these agreements will

⁴The "nearly" may be dropped if voting is by secret ballot, since it then would be impossible to identify a violator. While Coleman's model is thus obviously limited to groups which vote by roll call, this is not the case for the model presented below in Section II.

be so large that few voters can be expected to abide by them. The solution is obviously to replace the set of agreements with a system in which votes literally are exchanged. That is, assume every voter has the right to cast one vote for each issue. He may either exercise his right to vote on a given issue or trade it to someone for the latter's right to vote on one or more issues. These transactions could be conducted in vote-markets in which proxies were exchanged. One might envisage that at first the votes on each pair of issues would be traded in a separate market. In time, the votes on one issue undoubtedly would become a medium of exchange and all purchases and sales of votes would be made for votes on this issue. Conceivably this even might be a token vote-money (e.g., a vote on whether or not the marigold is designated as the national flower). A set of vote-prices would be established for each issue, probably in terms of units of vote-money.

More formally, let

U_{ij} = the absolute value of the change in utility for individual j attached to the i^{th} issue,

c_{ij} = the number of votes j holds on issue i ,

$p_{ij} = f_{ij}(c_{ij})$ = j 's subjective probability that the outcome of the vote on issue i will be as he wishes, and

P_i = the vote-price on issue i in units of vote-money.

The U_{ij} are absolute values of the utilities because it is assumed that the voter is indifferent between voting for an issue which increases his welfare and voting against an issue which decreases it to the same degree. The probability of success (p_{ij}) is assumed to be a monotonically increasing function of the c_{ij} up to the point where j possesses 50 per cent of the votes on issue i (where it becomes 1.0). It is also essential that, within the increasing stretch of the curve, the second derivatives of these functions be negative. This is the analogue of the diminishing marginal utility assumption in consumer theory. It implies that successive increases in an individual's stock of votes on a given issue make smaller and smaller additions to his subjective probability of success. The assumption is plausible for a stretch of the probability schedule which just precedes the point at which the voter owns 50 per cent of the votes on an issue. Whether it also is true for the beginning portions of the curve is more debatable.⁵ We shall not take time to settle the question of increasing marginal probability here, however, but will simply assume that the f'' are everywhere negative.

If we further assume that each individual maximizes his expected net utility gain from public goods subject to the constraint imposed by the initial egalitarian distribution of votes, then (1) becomes the equilibrium condition for every voter j and every pair of issues i and k . The vote-market equivalent of the marginal rate of substitution is the ratio of the change in the subjective probability of success on issue i to the change in the subjective probability of success on issue k , each multiplied by the utilities attached to their respective issues.

⁵ For example, the assumption implies that at no other point on the curve will the voter's subjective probability of success be increased by the acquisition of another vote by an amount as great as his original probability of success when he has only one vote.

$$(1) \quad \frac{U_{ij} f'_{ij}(c_{ij})}{U_{kj} f'_{kj}(c_{kj})} = \frac{P_i}{P_k}$$

This will be called the marginal rate of probability substitution (MRPS). In equilibrium the MRPS for issues i and k will equal the ratio of the vote-prices for these two issues. A fall in the vote-price of issue i relative to the vote-price of k will induce the voter to increase the number of his votes on issue i (thereby reducing the marginal increase in the probability of success of an additional vote on i) and decrease his votes on k (thereby increasing f'_{ij}). This exchange of votes on k for votes on i will continue until the MRPS has been brought into equality with the lower vote-price ratio for i and k .

The similarities between this result for the vote-market for public goods and the traditional solution for the private good market should be obvious. First, the number of voters and issues must be large enough so that no individual or small group of individuals can obtain monopoly or monopsony power. Second, it is necessary that votes *actually are exchanged* if the true preferences of each voter are to be revealed. Third, among the set of all possible combinations of public goods the equilibrium set of vote-prices will determine a combination which is Pareto optimal.⁶ Finally, the exact combination of public goods chosen out of the set of all possible Pareto optimal combinations will be uniquely determined by: (1) the initial distribution of votes, (2) the voter preferences toward the public goods (U_{ij}), (3) the subjective probability schedules of the voters regarding each issue (f_{ij}), and (4) the voting rule employed.⁷

Before further comparing Coleman's model with this one, a brief look must be taken at the enigmatic question of income distribution. When discussing the proper mix of public and private goods, most analysts have followed Wicksell and assumed an equitable distribution of income is given at the start.⁸ Since few students of public finance are now willing to allow the initial income distribution to be determined by market forces alone, the proper redistribution of income also will have to be decided by voting. In terms of our model this means decisions on income distribution must be included as a subset of the set of all voting issues. An individual would be able to swap his votes on various aid-to-education programs for votes on redistributive tax schemes. He could increase his power to select a favorable distribution of in-

⁶ If all voters benefit from a given public good-tax combination, it already is included in the subset of chosen public goods. The addition of any public good not already in this subset, therefore, must involve a loss of welfare for at least one voter. For the initial subset not to be Pareto optimal this voter must be compensated for his loss with votes on some other issue. But if it is possible for a group of voters to exchange votes and have no voter worse off and at least one voter increase his welfare, then the original set of vote-prices could not have been the equilibrium set.

⁷ A switch from simple majority voting to a $\frac{2}{3}$ majority rule would change the voter subjective probability schedules and most likely would require a new set of vote prices for equilibrium.

⁸ This is the approach R. A. Musgrave favors [4, pp. 84-86].

come, but only by giving up his right to affect the decision on the level of government supported education *and the method by which it is financed*. Hence, in our model allocation and redistribution decisions would have to be made jointly. In this sense, the approach resembles that of Samuelson [6].⁹

III. *Some Further Thoughts on the Two Models*

On the basis of Coleman's analysis and the criticisms lodged against it here, one can conclude that, when voters are able to make and keep vote trading agreements, their welfare will be greater than if no agreements were made. On the other hand, the resulting set of policy decisions will fall far short of being in any sense socially optimal. If the number of voters is not so large as to preclude the formation of partially stable coalitions, it is too small to remove completely the monopsony power a voter will be able to enjoy over any issue of vital importance to him. Hence, logrolling agreements among legislators probably are the socially suboptimal set of decisions they long have been thought to be.

One must even qualify a conclusion, that the welfare of all voters is increased when the voters enter trading agreements. First, it is impossible to judge the extent to which the set of voting decisions is driven away from the Pareto optimal set, because the voters mis-state their preferences in order to increase their bargaining strength. A further element of uncertainty is present because of the instability of coalitions. This will result in an unpredictable number of violations of the trading agreements with an unmeasurable impact on the welfare of all the voters.¹⁰

For voter preferences to be revealed by means of vote-markets, voters would have to be able to trade votes on all important issues decided by the government, i.e., all of the issues currently decided in both the legislative and executive branches. This would place an impossible burden on the voter who attempted to undertake the amount of research which would be required for him to make rational vote trading decisions. Nor is the problem for him reduced greatly if a representative form of government is assumed. Even if the representatives are able to carry out their vote trading activities in an informed manner, the voter would have the difficult task of evaluating the alternative candidates for Congress on the basis of the sales and purchases of votes

⁹ Musgrave's separation of a Stabilization Branch of the government also would have to be abandoned in the context of this model [4]. Some people benefit from inflation, others lose. Decisions regarding stabilization policy would have to be decided by voting, and votes on this issue would be traded like votes on any other issue in the vote-markets.

When compared with the "ideal" procedure for selecting government policies as depicted here, Musgrave's Distribution, Allocation and Stabilization Branches appear to be, rather ironically, of greater practical value for evaluating actual government policies, than of theoretical interest as a schema which provides the format under which government decisions "should" be made.

¹⁰ For example, it is possible that a public good which would benefit all voters would not be approved, if a majority of them decided to vote against it as a means of punishing violators of previous agreements.

M. Olson compares the decision-making process of groups of coalitions to the price-making models of oligopoly theory and therefore regards the nature of the final decisions as a priori indeterminate [5, p. 43, n.].

they promised to make (or had in the past made) in the legislative vote-markets.

Viewed in this perspective, some of the criticisms of Coleman's model may appear unjust, for it has been formulated with the actual operations of the legislative process in mind and is certainly more attuned to the method by which government policies are in fact selected [2, p. 1116]. On the other hand, Coleman does stress the theoretical contribution of his model [2, p. 1121-22], and does draw the conclusion that a socially optimal set of public goods would be selected by means of the voting process, if voters were free to enter into trading agreements and the numbers of issues and voters were very large [2, pp. 1118-20]. This conclusion we have had to reject for the reasons given above, and hence must prefer, when judged on theoretical grounds alone, the vote-market model to Coleman's vote trading agreement model.

In developing the vote-market model we have chosen not only to abandon the real-world context in which Coleman's model was formulated, but also to employ a slightly different set of concepts and symbols from those Coleman introduced [2, p. 1119-20]. This was done so that the model could be developed as analogously as is possible to the competitive model of consumer theory. In doing this, we feel we have remained true to the major point Coleman wanted to make, "that, just as a free market with pure competition can be conceived in economic change, and used as a theoretical model from which actual systems can be examined, a similar model of pure competition can be conceived in collective decisions. Although actual social systems deviate from this model, it can nevertheless serve as a basis from which the deviations can be studied" [2, p. 1118].

The Possibility of a Social Welfare Function: Reply

R. E. Park argues that no stable outcome exists in a vote trading situation unless it is the outcome that would occur without trading, and purports to prove this argument in his Theorem 2.

The central point in his argument can be shown by a simple example. Consider two issues and three voters, with utilities a_{ij} given by the table below:

| Voter | Decision | |
|-------|----------|------|
| | I | II |
| 1 | -1.0 | -1.0 |
| 2 | +1.9 | -0.1 |
| 3 | -0.1 | +1.9 |

A direct vote on the two issues without exchange will lead to rejection of both actions. Thus, Park argues that, if there is a stable outcome, it must be this outcome, which we will label $--$. But now we let vote trading take place, and assume that voters 2 and 3 make an exchange, agreeing to vote positively on both decisions. Park's argument can best be shown by evaluating all four possible outcomes, or each of the three voters.

| Voter | Outcome | | | |
|-------|---------|------|------|------|
| | $++$ | $+-$ | $-+$ | $--$ |
| 1 | -2.0 | -1.0 | -1.0 | 0.0 |
| 2 | +1.8 | +1.9 | -0.1 | 0.0 |
| 3 | +1.8 | -0.1 | +1.9 | 0.0 |

His proof of Theorem 2 is carried out through assuming the stability of an outcome other than $--$, arising through vote trading (in this case $++$), and then showing that it is in fact unstable. He shows, in effect, that a majority can be found who prefer a different outcome that is one decision closer to the no-trading outcome. In this case, that is illustrated by the $+-$ outcome, in comparison to the $++$ outcome. (The $-+$ outcome could be just as well used.) Voters 1 and 2 prefer the $+-$ outcome to the $++$ outcome, so that, according to the argument, they, acting as a majority, will reject the $++$ outcome, and take instead the $+-$ outcome. But then the process is iterative, so long as the outcome is not $--$: voters 1 and 3 prefer the $--$ outcome to the $+-$ outcome, and therefore as a majority, reject the $+-$ outcome.

However, it is the very instability of the new outcome, once the first agreement is broken, that raises questions. Consider the situation from the point of view of voter 2, once an agreement has been made with 3. By breaking this agreement, and making a new agreement with 1 (to vote $+-$), he stands to have a utility of 1.9, rather than 1.8, but only with that probability equal to his belief that 1 will not break this agreement to agree with 3 to vote $--$, in which case 2 would have 0.0 utility.

In short, he must assess the expected utility of two exchanges, the one he has, and the one he might make instead. If his belief that 3 will hold to the $++$ agreement is slightly higher than his belief that 1 will hold to the new agreement, then he will find the expected utility of the $++$ agreement greater. And there is reason to expect such a difference in subjective probabilities on 2's part: 1 has more to gain by breaking the $+-$ agreement than does 3 by breaking the $++$ agreement. The complete calculation of expected utilities would involve an infinite regress of subjective probabilities of others' actions, perceptions of the subjective probabilities they hold, and

so on, including estimates of his own probabilities of breaking an agreement. However, a truncation of this calculation would show that under plausible assumptions (i.e., that 1 has considerably more to gain than either himself or 3 by breaking the agreement in question), then 2 (and 3 as well) has higher expected utilities under the + + agreement than under any other.¹

If, then, stability of a given outcome is defined not in terms of a determinate utility calculation of voters, acting under the assumption that a given agreement will be implemented, but in terms of expected utilities of voters estimating the probabilities of broken agreements, Park's Theorem 2 does not hold. Furthermore, since Park's theorem depends upon first making and then breaking agreements, it is inconsistent with a utility calculation that evaluates the outcome under an agreement as if it had zero probability of being broken (which is equivalent to the utility-under-certainty calculation implied in his statement that "all members in S prefer T_d to T_c ", and the unstated assumption that they will therefore not vote T_c).

Park's theorem follows from his assumption about voters, and his consequent definition of stability. However, it is these assumptions, and the stability definition that follows from them, that I suggest constitute an inappropriate definition of rationality in the complex situation raised by the making and breaking of vote agreements. His theorem shows that a different definition of stability is necessary for voting situations involving vote exchanges. The definition of stability must instead be something like this: An outcome in a voting situation that allows vote exchanges is unstable if there exists a majority, each of whose expected utility calculations for a different outcome is greater than that for the outcome in question, taking into account the probability of agreements being broken.

But this is not a very satisfactory result, for I have given no general procedures for calculating these expected utilities that take into account the probability of broken agreements. It appears clear that such calculations, however crudely made, are the basis for the stability that often (but not always) occurs in voting situations involving vote trading; but it is not clear just how to develop a model that appropriately generates these subjective probabilities isomorphic with the way a rational voter would arrive at them.

It is useful to note that by an argument almost identical to that of Park, one could show that the only equilibrium in a private goods market is the one in which all individuals left the market with exactly those goods they entered it with. Excluding individual 1 from the above example, we arrive at the usual exchange situation in a private market. Suppose decision I is "individual 3 giving up his good to individual 2," and decision II is "individual 2 giving up his good to individual 3." Utilities appropriate to an exchange situation would be those given earlier:

¹ It is useful to note that in a 3-person game in which the division of 1 unit is to be determined by a majority vote, the Von Neumann-Morgenstern solution set for the game consists of the three permutations of the outcome $(0, \frac{1}{2}, \frac{1}{2})$. As J. M. Buchanan has reminded me, the rationale for this is precisely the rationale for 2 and 3 maintaining their trade in the example given in the text. The dominance of this outcome over a division $(\frac{1}{3}, \frac{2}{3}, 0)$ lies in the fact that this illusory temptation of 2 by 1 would likely be followed by a defecting agreement of 1 with 3 to give $(\frac{1}{2}, 0, \frac{1}{2})$. See [1, Sec. 22.1].

| Trader | Decision | |
|--------|----------|------|
| | I | II |
| 2 | 1.9 | -0.1 |
| 3 | -0.1 | 1.9 |

Assume that either individual can reject any positive action (i.e., a unanimity rule is required for an action). If we consider again the four outcomes $++$, $+ -$, $- +$, and $--$, then the utilities are:

| Trader | Outcome | | | |
|--------|---------|-------|-------|------|
| | $++$ | $+ -$ | $- +$ | $--$ |
| 2 | 1.8 | 1.9 | -0.1 | 0.0 |
| 3 | 1.8 | -0.1 | 1.9 | 0.0 |

As before, individual 2 prefers outcome $+ -$ to $++$, so that he can reject the $++$ outcome in favor of $+ -$, but then 3 can reject that in favor of $--$. Thus no exchange would occur.²

In this case of two-party exchange of private goods, the absence of equilibrium occurs because each party has the power to break an exchange agreement. He cannot ordinarily (though he can in cases of delayed physical transfers) realize the outcome he most prefers (gaining without giving up anything), because the other party has veto power. But equally, in the voting case, he has no assurance of being able to realize the outcome he most desires, because it is in the interest of others to break the new agreement. Park's Theorem 2, although it does not prove the instability it purports to prove, for the reasons given above, does show that stability of exchange in voting systems may be more difficult to reach. The theorem says, in effect, that there is always a set of voters interested in offering to a member or members of one side of an effective exchange (an exchange which can control the vote outcome) all that he has, or they have, under the present exchange without the cost it involves.

In private markets as well as in voting systems, there must be security measures to insure the equilibrium that would otherwise be unstable. Perhaps the most important in both cases is the continued existence of the collectivity, which allows persons who have suffered from broken agreements to punish offenders by refusing further trades. In private markets, the institution of escrow is another safeguard, and laws regarding contracts are a third. In legislatures, a system of standing political credit, with a party leader or floor officer

²The exchange of private goods is in fact a special case of the prisoner's dilemma, where the two alternatives for each party are to keep the good or give it up. The matrix in this example would be:

| | Keep | Give up |
|---------|------------|------------|
| Keep | 0 / 0 | -0.1 / 1.9 |
| Give up | 1.9 / -0.1 | 1.8 / 1.8 |

Without some mechanism of trust or enforcement of the agreement, the only rational action for each individual is to keep his good.

acting as the central intermediary, often exists. Another possible institution, which does not exist in most voting systems, is that of physical exchange of vote proxies, proposed by Dennis C. Mueller.

Mueller in his comment raises problems, all of which stem from the fact that a collective action is a public good. Thus if a vote is conceived as a resource that can be exchanged, it too is a public good, since it constitutes some fraction of control over the collective action which is a public good.

Mueller suggests that this fact leads a voter A to misrepresent voting intentions, so as to trade off a vote to a voter B who will use it as A would have done (thus providing no benefit to B, and no cost to A). He suggests also that the absence of physical exchange (and not the public-good nature of the vote) will lead to wholesale breaking of agreements.

The latter point is not difficult, I believe, to dispose of. In a collectivity with a sequence of collective actions or events extending indefinitely into the future, any violation of an agreement need not be punished, as Mueller supposes, by a coalition's voting against an outcome favored by the offender. It can instead be punished merely by the refusal to engage in further agreements. It becomes greatly to the interest of others also to learn of such defections so as to avoid agreements with unreliable people, thus extending the punishment. Just as in private-goods markets where goods are not physically transferred simultaneously, some means of insuring payment is necessary. Because the collectivity extends into the future, such potential punishment can serve just as well in vote markets as in private-goods markets.

However, the misrepresentation of a voting intention is a serious difficulty, no different in nature than the understatement of benefits that would invalidate Wicksell's taxation voting scheme. There is no reason, however, to suppose that the physical exchange of a vote proposed by Mueller would itself prevent that. What would prevent it is physical exchange plus negotiability of the exchanged vote. Thus it is not enough for A to be able to sell his proxy to B for B's proxies on other issues; what is necessary is for B to be able to trade off that proxy in turn. If this negotiability existed, then when A sells his vote, he has no knowledge of how it will be used, and must assume a cost to him proportional to his interest in the collective action (i.e., proportional to U_{ij} , the absolute value of the utility difference between outcomes). With this amendment then A is no longer able to profit by misrepresenting his intentions. This I see as a major step forward in the removal of "public-goods effects" from collective actions. The resulting system of vote markets is, as Mueller indicates, wholly in accord with my major aim, that of developing a theory of pure competition in collective decisions comparable to that of the perfect market for private goods. (I would also expect such full negotiability of votes to constitute a practical advance toward achieving social optimality in actions of real legislatures.)

However, this is unfortunately not the only way the public-good property of a collective action affects vote markets. There is a second problem. This arises from the fact that a vote exchange is made on the basis of the preferences of the two parties to the exchange; but because the votes are public goods, the exchange has consequences for the other voters as well. This is

made evident by using Mueller's equation (1), which gives the marginal rate of probability substitution. Assume first that an individualistic equilibrium is reached, so that this marginal rate of substitution is for all individuals equal to the ratio of vote prices as indicated in equation (1). But now two voters, j and h , who are on the same side on actions i and k communicate, so that for each the probability that the outcome of the vote will favor his interests becomes $f(c_{ij} + c_{ih})$ and $f(c_{kj} + c_{kh})$. This changes the marginal rate of probability substitution for each, and leads each to seek out more votes on one or the other issue. If a number of persons communicate, this upsets the equilibrium of vote prices. Thus any description of the perfect system of vote exchanges, with Mueller's modification of it, is valid only in the case where individuals act wholly individualistically, and have no knowledge of vote commitments obtained by others. Even in this case, it is not perfectly clear that the externalities involved in every vote exchange are eliminated by the assumption of a perfect (individualistic) market.

Still another problem exists. The use of a marginal rate of probability substitution in markets for private goods implies, as Mueller indicates, that the marginal probability of success due to a vote commitment decreases with the number of votes controlled. However, I have investigated the shape of this marginal curve under very plausible assumptions, and it is clear that under most conditions it does not decrease. The shape of the curve depends upon the votes controlled by opponents and allies, and it is only in the case where the votes controlled by opponents is zero that the marginal probability everywhere decreases. Indeed, when the number of votes controlled by the opposition increases at the same rate as one's own, the marginal probability of a vote commitment *increases* as the number of votes controlled increases.

This can lead to behavior quite different from that which occurs in private markets. Rather than buying a "market basket" of votes for different decisions, an individual may use all his resources for the decision which interests him most. And the normal functioning of the price mechanism to establish a new equilibrium would not work in the same way.

For such analysis as this, a useful decision rule to examine at the outset is the probabilistic rule I discussed in my paper. In this decision rule, the probability of success is proportional to the number of votes for and against the action. This is the only decision rule in which a voter can reasonably assess the marginal probability of success due to a vote commitment, independently of the distribution of vote commitments pro and con held by others. With this decision rule, the marginal probability is always $1/n$. This means that the marginal rate of substitution for a voter between actions i and k is always U_{ij}/U_{kj} , and he will always buy i rather than k if this ratio exceeds the ratio of prices, never reaching an equilibrium. But the effect of this behavior upon the establishment of a set of prices is itself unclear. It may be that a set of equilibrium prices could not become established under such conditions of nondecreasing marginal utility curves.

An added complication arises when markets are mixed, that is, when some of the resources that are used to buy votes are private goods, and some are public goods in the form of votes. In a legislature with committee structures

and privileges of various sorts that can be dispensed by one person for the private use of another, and personal favors, such a mixture exists. When private goods, such as personal favors or money, can be exchanged for a vote commitment, then the problem of paying the cost of a public good arises. For if a vote commitment is purchased, to be cast in favor of a collective action, then all who favor the action gain, but only the individual who purchases the commitment pays the cost. As Olson's work implies, this can lead to failure to purchase vote commitments which are too costly for one individual to purchase, but which would provide a benefit to each if costs were appropriately allocated.

If all the goods used in exchange are votes in actions of collectivity, the problem of paying the cost of obtaining a vote commitment is less serious, though it still exists. If A gives up a vote on one action for a vote on a second, he incurs a utility loss in loss of control of the first votes. He is paying the cost of the public good, but it is a public cost, since the vote he gives up is a public good. It is a cost experienced by all those who agree with him on the action whose vote he gave up, just as there is a gain experienced by all those who agree with him on the action whose vote he gained. Thus there is a sharing of costs just as there is a sharing of benefits of the exchange. But those who oppose him on the first action but agree with him on the second action experience a gain in both actions, and those who agree with him on the first and oppose him on the second experience a loss on both. Thus we cannot say that there is a sharing of costs and benefits, as is necessary in the rational provision of a public good.

Altogether, I have no quarrel with Mueller, and fully accept his modification of the theory I proposed in my paper (with the amendment about full negotiability of vote proxies). However, there remain a number of difficult problems that neither he in his comments nor I in my paper have addressed, as I have indicated in my comments above. I believe these are not insoluble, so that we will in time have a precise theory of perfect vote markets.

The Economic Status of American Economists, 1966: A Preliminary Report

Thanks to the cooperation of the members of the profession in responding to the last two National Register questionnaires it is now possible to summarize certain trends in the structure of economists' salaries and employment between 1964 and 1966.¹ For example, preliminary comparison of the data

¹ Economists were included by the National Science Foundation as part of the biennial

gathered during these two years reveals at least ten features of general interest:

1. The average (median) salary of economists rose by 9 per cent, from \$12,000 in 1964 to \$13,000 in 1966.

2. The \$13,100 median salary of the economists was the highest reported for any profession, the most nearly similar medians being those for statisticians (\$12,800) and for physicists (\$12,500).²

3. The largest percentage increases in salary were obtained by those economists at the higher salary levels, with the result that the range of salaries became even wider in 1966 than it had been in 1964.

4. Graduate degrees are becoming increasingly numerous among economists and those with a Ph.D. degree obtained a larger increase in median salary (11.6 per cent) than those with lesser academic degrees.

5. The economics profession is experiencing a rapid influx of new members, as is indicated by the high rates of increase in the numbers of economists with less than ten years of professional experience.

6. While levels of salary continue to be strongly related to length of professional experience, the largest *increases* in median salary were generally obtained by those with relatively short periods of previous experience.

7. Educational institutions and the state and local governments were the two types of employer that showed the greatest rates of increase in the numbers of registered economists as well as the largest increases in median salaries.

8. Research activity (including industrial as well as academic research) engaged an 18 per cent larger number of registered economists in 1966 than in 1964, as compared with an increase of only about 7 per cent in the number of economists engaged in teaching and in the total of all activities.

9. In spite of the influx of new personnel, the median salary of those engaged in research rose by 9.7 per cent, or by slightly more than the average for economists as a whole.

10. The relatively low median salary of economists engaged in teaching and the relatively high median salary of those engaged in management both rose at the slightly less-than-average rate of about 8 per cent between 1964 and 1966.

This brief note on the highlights of the 1966 data is to be followed by a more detailed report in a forthcoming *Supplement* to the *American Economic Review*, which will contain a series of analyses of external and internal relationships of both salaries and incomes of economists in 1964 and 1966.³ To provide the data necessary to update changes in the employment and salary structure of economists, members are urged to respond to the forthcoming 1968 National Register questionnaire which will be circulated, as before, through the American

compiled National Register of Scientific and Technical Personnel for the first time in 1964, and the first detailed report on the data relating to economists was prepared by the Committee on the NSF Report on the Profession, N. Arnold Tolles (chairman), Ewan Clague, and Alice Hanson Jones, and published by the American Economic Association [2].

² Cf. [1, p. 2]

³ Acknowledgements to those guiding and assisting the author in these analyses will be found in the forthcoming *Supplement*. Meanwhile, the author will endeavor to respond to inquiries regarding the National Register data on economics.

TABLE 1—DISTRIBUTION OF ECONOMISTS' SALARIES, 1964 AND 1966

| | Salary (\$000's) | | Per cent Change 1964-1966 |
|----------------------|------------------|------|------------------------------|
| | 1966 | 1964 | |
| Median | 13.1 | 12.0 | 9.2 |
| Lowest decile | 8.5 | 7.8 | 9.0 |
| Lower quartile | 10.1 | 9.3 | 8.6 |
| Upper quartile | 17.6 | 16.0 | 10.0 |
| Highest decile | 23.0 | 20.0 | 15.0 |
| Inter-quartile range | 7.5 | 6.7 | 11.9 |
| Inter-decile range | 14.5 | 12.2 | 18.9 |

Economic Association and other cooperating associations.

Summary of Salary Distributions. The summary in Table 1 shows how the range of economists' salaries became even wider in 1966 than in 1964.

Salaries of the lowest paid one-tenth of the economists advanced, between 1964 and 1966, at about the same rate as did the median salary (9.0 per cent), but the lower paid quarter showed a less-than-average advance (8.6 per cent), and in 1966 the lowest decile and lower quartile salaries of the economists were actually lower than the corresponding salaries of the statisticians (\$8,700 and \$10,200, respectively).⁴ In contrast, even in percentage terms, the increases in the higher salaries were greater than the percentage increase in the median salary. Particularly striking was the rise in the salary of the highest paid one-tenth of the economists who had salaries of \$23,000 or more in 1966, which was 15 per cent greater than the \$20,000 or more received by the corresponding group in 1964. Thus the lowest salary of the highest paid one-tenth of the economists in 1966 was \$14,500 above the highest salary of the lowest paid one-tenth of them. This inter-decile range of \$14,500 in 1966 contrasted with the corresponding range of \$12,200 in 1964.⁵

Academic Degree. The increasing importance of graduate degrees in the economics profession and the superior salary increase for those with the Ph.D. degree are shown in Table 2.

In two years, 1964-66, the number of Ph.D.'s in the profession increased by 10 per cent and the number of master's decreased by 11 per cent, whereas there was practically no change in the numbers of economists with bachelor's degrees. Thus 85 per cent of the registered economists in 1966 had earned a graduate degree (11,000 of 13,000). The reasons for the relatively low level of salaries of those with master's degrees (\$12,000 in 1966) and the relatively high salary levels of those with bachelor's degrees or less (\$14,700 and \$16,500 respectively in 1966) have been described in an earlier report [2, pp. 34-38, 46]. Between 1964 and 1966, the relatively low median salary of those with master's de-

⁴ Cf. [1].

⁵ In 1966 the inter-decile range was 1.11 times the median, whereas in 1964, it was only 1.02 times the median.

TABLE 2—ACADEMIC DEGREE AND SALARY INCREASES OF ECONOMISTS, 1964-1966

| Academic Degree | 1966 Register | | Per Cent Changes 1964-1966 | |
|------------------------|---------------------------------|--|-------------------------------|-------------------------------|
| | Number Registered (000's) | Median Salary ^a (\$000's) | Number Registered | Median Salary ^a |
| Total reporting degree | 13.0 | 13.1 | 9.0 ^b | 9.2 |
| Ph.D. | 5.6 | 13.5 | 9.9 | 11.6 |
| Master's | 4.6 | 12.0 | 10.8 | 9.1 |
| Bachelor's | 2.7 | 14.7 | 1.8 | 8.9 |
| Less than Bachelor's | 0.1 | 16.5 | -13.3 | -1.2 |

^a Among employed respondents reporting salary and degree (11,079 in 1966 and 9,883 in 1964).

^b Derived from exact, rather than rounded, numbers (12,989 in 1966 and 11,998 in 1964).

degrees rose by 9.1 per cent or about the average per cent increase for all economists, while the relatively high median of those with a bachelor's degree showed a below-average rise (8.9 per cent) and the median salary of the small group without a college degree actually fell (-1.2 per cent). Economists with Ph.D. degrees, on the other hand, enjoyed an 11.6 per cent increase in average (median) salary over the two years, 1964-66.

Professional Experience. The variance of economists' salaries in 1964 has been shown to be more closely associated with length of professional experience than with any of the other six characteristics of economists thus far analyzed [2, pp. 64-70, 43-51]. While detailed analysis of the 1966 data is not complete, Table 3 does show the regular upward progression of economists' median salaries with lengthening professional experience up to 29 years of such experience (col. 2).

In 1966 economists with less than two years' experience had a median salary of \$9,000 whereas those with 20 or more years of experience had a \$17,400 salary median. The fuller detail available for 1966, but not for 1964, shows that average salaries contrived to rise with increased experience up to a median of \$18,200 for those with 25-29 years in the profession. However, economists with 30 or more years of experience earned somewhat smaller average salaries than did the 25-29 year group (\$18,000 and \$17,500 respectively).

The high rates of increase in the numbers of economists with less than ten years of experience between 1964 and 1966 appear to show that the profession has been receiving a considerable influx of new members (cf. col. 3, Table 3).^c Indeed, a considerable turnover among economists seems to be taking place. Thus there appears to have been an actual decline of 11.5 per cent between 1964 and 1966 in the number of economists with 10 to 14 years' previous ex-

^c This and all other conclusions which are based on relative numbers of registered economists in 1964 and 1966 may be subject to variations in the rate of response to questionnaires in the two years—a potential influence which has not yet been tested.

TABLE 3—PROFESSIONAL EXPERIENCE AND SALARY INCREASES OF ECONOMISTS, 1964–1966

| Years of Professional Experience | 1966 Register | | Per Cent Changes 1964–1966 | |
|----------------------------------|---------------------------|--------------------------------------|----------------------------|----------------------------|
| | Number Registered (000's) | Median Salary ^a (\$000's) | Number Registered | Median Salary ^a |
| Total reporting experience | 12.5 | 13.1 | 11.0 ^b | 9.2 |
| Under two years | 0.6 | 9.0 | 54.3 | 15.4 |
| 2–4 years | 1.7 | 9.3 | 21.0 | 10.7 |
| 5–9 years | 2.2 | 11.0 | 12.9 | 10.0 |
| 10–14 years | 1.8 | 13.0 | –11.5 | 8.3 |
| 15–19 years | 2.1 | 15.0 | 24.4 | 11.1 |
| 20 years and over | 4.1 | 17.4 ^c | 8.3 | 8.8 |

| 35–39 years | 0.5 | 17.5 | — | — |
| 40 years and over | 0.5 | 17.5 | — | — |

^a Among employed respondents reporting salary and years of experience (10,806 in 1966 and 9,688 in 1964).

^b Derived from exact, rather than rounded, numbers (12,509 in 1966 and 11,269 in 1964).

^c Medians of separate experience in groups shown on the following lines, weighted by corresponding numbers shown in column 1.

perience and the rates of increase of those with 20 or more years' experience were below the average increase in the numbers in the profession. The more experienced economists evidently were not being replaced as they died, retired or left the profession. On the other hand, the rates of increase in the net numbers of the least experienced members were very high, ranging downward from a 54 per cent increase of (the small number) of those with less than two years of professional experience to a 13 per cent increase in the net number of those with five to nine years of experience.

Taken by itself, the fact that the economics profession was less experienced in 1966 than in 1964 would have tended to reduce the average rise in economists' salaries. However, it was the least experienced members of the profession who received the larger salary increases between 1964 and 1966. As compared with the 9 per cent overall rise in economists' salaries, the entering group with less than two years experience had a 15 per cent higher median salary in 1966 than did the same experience group in 1964, while those with from two to four years' experience received an 11 per cent higher median salary in 1966 than did those with similar length of experience in 1964. While it is still true that salaries are strongly related to length of experience, this positive relationship was somewhat weakened between 1964 and 1966 by the above-average salary increases provided to the relatively new recruits to the economics profession.

TABLE 4—TYPE OF EMPLOYER AND SALARY INCREASES OF ECONOMISTS, 1964-1966

| Type of Employer | 1966 Register | | Per Cent Changes, 1964-1966 | |
|------------------------------------|---------------------------------|--|--------------------------------|-------------------------------|
| | Number Registered (000's) | Median Salary ^a (\$000's) | Number Registered | Median Salary ^a |
| Total registered | 13.1 | — | 8.3 | — |
| Total report specified employer | 12.0 | 13.1 | 7.2 ^b | 9.2 |
| Educational institutions | 5.6 | 11.1 ^c | 11.2 | 7.8 ^d |
| State and local governments | 0.5 | 13.0 | 78.1 | 11.1 |
| Federal government | 1.3 | 14.7 | 6.8 | 7.3 |
| Industry and business | 4.1 | 15.3 | 3.6 | 6.3 |
| Non-profit organizations | 0.5 | 16.2 | 0.4 | 8.0 |

^a Among employed respondents reporting salary and type of employer (11,145 in 1966 and 9,941 in 1964).

^b 11,976 in 1966 and 10,922 in 1964.

^c Estimated from a weighted average of the \$10,500 median salary received by 2,953 who reported 9-10 month salaries, and the \$13,000 median salary received by 1,609 who reported 11-12 month salaries (excluding 1,037 respondents who did not report salary or did not report whether salary was for 9-10 or for 11-12 months).

^d Derived from estimate in column 2 and recorded median of \$10,300 in 1964.

Type of Employer. The greatest rates of growth in the employment of economists and the largest increases in median salaries, between 1964 and 1966, occurred in educational institutions and in state and local governments, as is shown in Table 4.

The employment of economists by educational institutions increased by 564 or 11.2 per cent while the relatively low median salary of this group rose at the below-average rate of about 8 per cent. State and local governments, although small employers of economists, increased their employment of members of this profession by 215, which represented a 78 per cent increase, while raising the median salary of their economists by 11 per cent between 1964 and 1966. The Federal government, private industry and non-profit organizations each paid the higher median salary, both in 1964 and 1966, but over the two-year period, these better paying types of employment all experienced below-average rates of growth of economists' employment and below-average rates of income in the median salaries of economists.

Work Activity. The outstanding increase in economists' employment between 1964 and 1966 consisted of employment on research, as is shown by Table 5.

The employment of economists on research increased by 18.3 per cent over the two years, 1964-1966. The salary inducements to engage in research are suggested by the slightly higher-than-average (9.7 per cent) increase in the median research salary which occurred in spite of the dampening effect on salary of

TABLE 5—WORK ACTIVITY AND SALARY INCREASES OF ECONOMISTS, 1964-1966

| Work Activity | 1966 Register | | Per Cent Changes, 1964-1966 | |
|----------------------------------|---------------------------------|--|--------------------------------|-------------------------------|
| | Number Registered (000's) | Median Salary ^a (\$000's) | Number Registered | Median Salary ^a |
| Total registered | 13.2 | — | 8.3 | — |
| Total reporting work activity | 12.0 | 13.1 | 6.5 | 9.2 |
| Teaching | 3.7 | 10.5 ^b | 7.2 | 8.2 ^c |
| Research | 2.3 | 12.5 | 18.3 | 9.7 |
| Production | 1.1 | 13.0 | -8.0 | 11.1 |
| Other work activity | 1.1 | 14.0 | 0.6 | 9.2 |
| Management | 3.8 | 17.4 | 6.2 | 8.1 |

^a Among employed respondents reporting salary and class of work activity (10,572 in 1966 and 9,744 in 1964).

^b Estimated from a weighted average of \$10,000 median salary received by 2,508 who reported 9-10 month salaries and the \$12,100 median salary received by 621 who reported 11-12 month salaries (excluding 591 who did not report salary or did not report whether salary was for 9-10 or 11-12 months).

^c Derived from estimate in column 2 and recorded median of \$9,700 in 1964.

the new entrants into this activity. Teaching employment increased by 7.2 per cent, slightly greater than the 6.5 per cent increase in employment of economists generally but slightly smaller than the increase in the total registration of economists. Due to a change in classification, the exact rise in the teachers' median salary is not known at this time, but the estimated rise of 8.2 per cent was smaller than that average 9.2 per cent rise for economists as a whole. The relatively high salaried activity of management also showed a less-than-average 8.1 per cent rise in median salary between 1964 and 1966 and a less than average 6.2 per cent increase in the numbers of economists employed on management work.

BOOK REVIEWS

General Economics; Methodology

Our Free Enterprise Economy. By MORRIS A. COPELAND. New York: The Macmillan Company, 1965. Pp. vii, 302. \$5.95.

In the preface to this medium-length book Professor Copeland says that it "was written from an institutionalist viewpoint"; and, "Hitherto, there has been no adequate systematic statement of the way institutions organize economic activity in an industrialized free enterprise economy that has no general economic manager." In brief, the book is a partly orthodox, partly unorthodox, introductory discussion of the United States free enterprise economy. Exactly to whom the book is addressed is not clear from the preface but Copeland is presumably thinking chiefly of introductory students and intelligent laymen, and hoping, perhaps, to persuade a wider group of economists of the value of the institutionalist approach. Some of the technical terms such as open-market operations receive a briefer exposition than is customary but a glossary at the end of the book partially justifies this procedure.

The book covers most of the topics one would expect in a work of this sort though the general approach and the set of subjects discussed reflect the institutional point of view. It casts a rather wide net. Thus, Copeland gives brief attention to such wide-ranging topics as the effect of the FBI and CIA on personal freedom, and the desirability of some sort of federal financing of election campaigns. He gives some attention to what sometimes seems to be almost innumerable matters but emphasizes two "major problem areas": maintaining adequate aggregate demand, and developing better labor-management institutions. A prominent feature of the book (which, however, does not dominate the entire exposition) is its emphasis on ten "central management functions" which are performed mainly by nineteen "social, legal, and economic institutions." A brief listing of these using Copeland's summary titles will not satisfactorily convey the full nature of the discussion and analysis, but will suggest its flavor. The three basic central management functions are: the main programming function, the personnel function, and the distribution function; the four ancillary functions are: the resource-use-regulating function, the progress-promoting function, the capital-accumulation function, and the level-of-output-determining function; three supplementary functions of relatively recent origin made necessary by the way in which the basic functions are performed are: the account-keeping function, the terms-of-trade-regulating function, and the authority-and-discipline function. The nineteen institutions are: freedom of calling, trade, the market, the price system, the profit system, the free enterprise system, the business corporation, property, contract, the debtor-creditor relation, money, the income and money circuit, competition, the wage system, the business accountancy, capitalism, business mores, private wrongs, and bankruptcy.

My criticisms fall into two major classes. First, Copeland discusses many

matters in a rather cursory manner and/or a manner which gives little sense of other, often more penetrating, discussions in the literature. Thus, the analysis of problems relating to property rights appears at several different points and is not carried very far. The brief explanation and evaluation of the Pigou effect (p. 84) is not felicitous. The rather lengthy discussion—at least in a book of this type—of the theory of economic replacement of durable goods (pp. 183-91) seems rather elementary and inadequate to this reviewer (who has spent considerable time in that literature). The only literature cited at all extensively is J. M. Clark's writings on overhead costs and workable competition.

Second, although Copeland's discussion of institutions is often interesting and relevant, the logical structure of the argument is left unclear. Is Copeland's list reasonably complete and free of overlapping? Are there relationships among the institutions and their roles? The reader must supply his own answers.

It would be uncharitable and intellectually dishonest not to point out the book's desirable attributes. Copeland wants to throw light on the role institutions play in economic life and wants to acquaint the reader with a wider range of subjects than is found in the usual economic treatise. He shows good sense at many points in the exposition. He emphasizes the virtues and problems of a free enterprise economy in a way that this reader approves.

There are undoubtedly economists who will have no reservations about making this book the central core reading in an introductory course. Some will probably use it with the idea that they can tighten up some of the reasoning. It will be of interest to many others only as an example of what one author can achieve in an introductory analysis of our economy from an institutionalist point of view.

H. LAURENCE MILLER, JR.

Carleton College

Income Theory and Related Empirical Studies

Economic Activity. By G. C. HARCOURT, P. H. KARMEL AND R. H. WALLACE.
Cambridge: Cambridge University Press, 1967. Pp. 323. \$9.50; paper, \$3.25.

Economic Activity provides an elementary treatment of macroeconomic theory with particular emphasis on the Australian economy. The text has not been designed for use beyond the introductory level—either in content or presentation—and would be unsuitable for such.

The book opens with a description of the Australian National Income Accounts and proceeds through the usual two-sector model of real income determination. In later chapters, the authors discuss consumption and investment behavior, the multiplier, the role of the government sector, inflation, trade and employment.

With few exceptions, the text is standard fare. The authors distinguish carefully between *ex ante* and *ex post* concepts and the section on consumption is

pleasantly broad for an elementary study and encompasses discussion of normal, relative and permanent income. Unfortunately, these hypotheses are disregarded in the discussion of the multiplier and their implications are never explored.

STEVEN M. GOLDMAN

University of California, Berkeley

Economic History; Economic Development; National Economies

Modern Economic Growth: Rate, Structure and Spread. By SIMON KUZNETS.
New Haven and London: Yale University Press, 1966. Pp. xvii, 529.
\$12.50; paper, \$2.95.

This book, the culmination of one phase of a lifetime study of growth by a distinguished scholar, discusses so many subjects, often in quite a fresh fashion, that it is difficult to visualize an economist who will not find something to interest, challenge, and stimulate him. As seen by Kuznets, modern economic growth began in the 1780's in Great Britain, not before the late 1830's anywhere else, reached 15 or 16 countries early enough (50 years ago) to permit study of long term trends, and has now penetrated countries containing one-fifth to one-fourth of the world's population. Its dominant and distinctive feature is application of science to problems of economic production. Scientific advance and exploitation of its potential for growth made possible most of the rise observed in per capita product, and required new attitudes and changes in social institutions. In Kuznets' view, causes, characteristics, and consequences of modern growth are in large degree common to all countries experiencing it; this book is devoted to discovering common patterns, examining why they appear and the process by which they took place, and exploring their consequences and interrelationships.

The author ranges too widely over subject matter, time, and space to permit even a listing of the many interesting and often novel questions discussed, but some indication of scope must be attempted. The first six chapters deal with the past growth of developed countries, although the underdeveloped world is often brought in for contrast or to draw inferences about the past. Kuznets finds that modern growth has been characterized by a much faster population rise than in previous times, an increase of per capita product at unprecedented rates of from nearly 15 to 30 per cent per decade, and a rise in total product of from 20 to nearly 50 per cent per decade. Rapid population growth resulted from and, on balance, probably also contributed to higher per capita product—several ways in addition to scale economies are noted—although it may have adversely affected the saving rate. The per capita rise in man-hours worked and capital was small and can account for less than one-fifth of the rise in per capita product; the rest is due to new knowledge, changes in the quality of inputs, and scale economies. The share of agriculture in total product has declined, that of industry has risen, and that of services has not changed much or consistently. Output per man in the three sectors rose by av-

erage, above-average, and below-average amounts, respectively, but a high growth rate of efficiency has characterized all major producing sectors. Changes in the industrial distribution of employment, including the effect on urbanization, had great social and economic consequences which are discussed. The size of enterprises has increased. The share of labor in income has risen and that of capital and land declined. Income inequality has been reduced, though only since World War I or II, and the turnover among size classes has increased. Shares of government consumption and gross capital formation in total product have increased at the expense of private consumption and there have been important shifts within these aggregates. Major changes in international aspects of growth, including interruption of the rise in the ratio of foreign trade to national product, occurred around 1913 but these were not so great as to require distinguishing the pre-1913 and post-1913 periods as distinct for analysis of growth.

Kuznets next turns to the underdeveloped countries. He classifies the areas of the world by income in 1958 and considers the significance and appropriate modification of income comparisons when differences are great. Underdeveloped and developed countries are compared with respect to much the same aspects of economic and social structure as were considered in examining changes in developed countries. Many differences seem similar in direction to those observed in the process of growth but some are not, and Kuznets stresses that technological innovation and changes in consumer tastes greatly qualify the possibility of inferring past or future temporal changes from cross-sectional comparisons. The question of whether 175 years should be considered a long or short period for growth to spread from 1 to 20 or 25 per cent of world population is asked; after consideration of the necessary time lags and difficulties, the period seems to Kuznets a short one. A final chapter provides a summary and discusses three general qualifications that could profitably be read immediately after Chapter 1.

If the reader is more intrigued than convinced by Kuznets' conclusions on controversial points, it is likely to be for two reasons. First, interpretations of historical developments rest to an unusual extent on the author's personal research, especially his articles in *Economic Development and Cultural Change*; economic historians, especially, may feel discussion of some topics pays insufficient attention to other investigations. Second, marshaling of statistical evidence to establish patterns is exceptionally informal. For each topic the sample consists of those countries in a loosely specified category for which relevant statistics are available; it varies from topic to topic. For intertemporal comparisons, the same is true of time periods except that they must usually be long or changes pronounced. In the analysis of modern growth, periods before it began in each country seem usually to be excluded when income changes, but not population changes, are examined. Findings are sometimes based on inspection of data for several individual countries. More often, especially in cross-sectional comparisons, they are based on unweighted averages of data (usually percentage distributions) for available countries. Sometimes aggregates implying a weighted average of countries, with shifting country weights,

are used instead. Where only averages or aggregates are presented, the reader has no opportunity to observe dispersion. Countries are usually compared or combined at the same dates, irrespective of the elapsed period of modern growth. Kuznets suggests the date of entering modern growth probably affects the speed of growth and, by implication, of associated changes, but this point does not enter the analysis systematically, nor are these dates indicated for more than a few countries.

Kuznets' procedures might be quite satisfactory for growth analysis if all changes were uniform and continuous, once short fluctuations are ironed out. Uniformity is often sufficient to permit a clear statement with respect to usual direction of change or difference. Confidence in findings with respect to typical *magnitudes* must rest heavily on faith not only in the skill and artistry of the investigator—here the reviewer's confidence is high—but also in the *existence* of typical magnitudes.

Where data are utterly lacking, Kuznets frequently uses illustrative calculations, based on reasonable or extreme assumptions, to establish what the historical record must have been. These are ingenious and usually persuasive; when they raise a doubt it is usually because they use values (e.g., a 15 per cent per decade growth rate of per capita product) that are regarded as representative but are hard to identify with any particular place or period.

One such calculation (p. 394) raises an interesting point of emphasis. It yields the result that the ratio of per capita product in presently developed countries to that in countries with 1958 per capita product under \$100 was 7 to 1 a hundred years ago and 18.5 to 1 now. "Thus almost six-tenths of the present differential is due to . . . growth . . . over the last century." The same ratios imply per capita product in the low income countries was already 86 per cent below the advanced countries a century ago and is 95 per cent below now; would it not be equally valid to say that nine-tenths of the present relative differential had already emerged a century ago?

Finally, three short observations. A calculation on page 78 erroneously assumes that a 25 per cent drop in the capital-product ratio over a long period means the growth rate of capital was 25 per cent lower than that of product; with a product growth rate of 3.05 per cent annually over 70 years (for example) the difference in growth rates would actually be only 14 per cent. In analyzing income shares, Kuznets states (p. 184) that gains in "residual efficiency" are explicitly or implicitly so assigned as to raise the labor share; this appears to derive from confusion between current and constant price data. The comparisons between advanced and underdeveloped countries of productivity by sector in Chapter 8 are extremely precarious because the method does not allow for differences in relative prices.

Kuznets has now carried the study of long term growth on an international basis about as far as the extensive approach used in this book can take it. With his active participation the appropriate next phase, comparison of detailed country studies conducted along uniform lines, is well under way under the aegis of the Social Science Research Council.

Estimating Foreign Resource Needs for Economic Development: Theory, Method and a Case Study of Colombia. By JAROSLAV VANEK WITH RICHARD BILSBORROW. New York: McGraw-Hill, 1967. Pp. x, 180. \$8.95.

This valuable book is mainly an exercise in the two-gap method introduced by Chenery, containing theoretical as well as applied contributions for the case of Colombia, which is studied in great detail. It consists of three parts: Part 1 providing what is called the "Groundwork"; Part 2, the Estimation Structure and Projections for Colombia"; and Part 3 an "Analysis of Results." The "two gaps" referred to are known as the savings gap and the trade gap; the former constituting the gap between investment desired and savings the nation is supposed to be able to make, and the latter the gap between imports needed and exports supposed to be attainable. If defined sufficiently widely, the two gaps must be identical "ex post." They are estimated in advance (or "ex ante") in order to determine the country's need for foreign finance. The equations on which these estimates are based need not contain the variables which in reality take care of the adjustment of one gap to the other. In the Chenery approach they indeed do not contain them. This then leads to two different figures for the two gaps. Chenery calls the bigger one among them the dominant gap. He has presented arguments for believing that in many developing countries at first the savings gap is dominant and later on the trade gap.

Vanek's book first of all sets out (in Part 1) the method and the initial situation in Colombia, by which phrase he indicates the figures available for the period 1954-1963. Next, in Part 2, the estimation of the various relations needed to determine the two gaps is given. This is followed by a number of "key estimates" for 1965 and 1970. Key estimate group A is based on work done by the Committee of Nine of the Alliance for Progress. It is a group, since for various parameters different estimates are used. Group B is based on the recent performance of the Colombian economy. As group C a set of estimates representing a low alternative for growth is shown. Finally, group D is based on Colombia's national development plan sectoral rates of growth. Comparisons of the key estimates with some estimates by the International Bank for Reconstruction and Development are made. Finally, in the same Part 2 one chapter is devoted to what is known as sensitivity analysis: how much are the gap figures influenced by variations in a number of the parameters used? Since the influence of no less than 50 parameters is studied, a tremendous number of alternatives have been calculated for which the author must be given credit.

Part 3, the "Analysis of Results" supplies some further theory in Chapter 6, to which we will return later. It also contains three more chapters; one about the use of the gross capital-output coefficient; one about savings and the terms of trade; and, to end, Chapter 9, summarizing the evidence for Colombia.

Clearly the book makes contributions of two types. On the one hand it contains an enormous amount of figures, observed as well as estimated (for future periods), for Colombia, which constitute very valuable information about the

past and the expectations for the future of Colombia. The various groups of key estimates with all their alternatives are carefully described and argued and represent, with the final choices made, a precious documentation about Colombia.

The other type of contribution the book makes are contributions to the two-gap theory. Since this is a young branch of economic thinking, it can hardly be expected to have reached already a stage of established doctrine. In the reviewer's opinion the author has not yet provided us with what a textbook on this theory three years from now should contain; but the book does have some useful new concepts and vistas. Compared with classical theories or models on the subject, the basic new element brought by Chenery, namely the possibility of the inequality of two gaps which "should" be equal (and will be equal) derives from similar possibilities in a linear programming model. It is equivalent to the non-existence, in the short run, of equilibrium, where it was assumed to exist in classical theories. One recognizes elements of various other theoretical structures; for instance, dynamic theories or theories in which non-fulfilled expectations play a part (as also in the theory of imperfect competition). As so often, the innovating author himself is not always clear in his formulations. Vanek has added several concepts which will contribute to more clarity. Thus, he distinguishes between two adaptation processes, one which leads to the equality *ex post* of the two gaps and another which adapts either of the gaps to what he calls the minimum requirements. The author also contributes by making a distinction between autonomous and policy-induced adaptation processes. In essence this is equivalent, the reviewer feels, to distinguishing between various types of additional variables which must be added to the estimating model in order to make it complete. Among these variables there may be policy instruments and there may be "free variables" whose values are the result of market forces (or of private decisions, which is more or less the same).

Yet the text is not yet quite satisfactory to this reviewer. It remains desirable that a still more systematic treatment emerge, in which the various types of variables are explicitly listed and in which, in addition, the types of problems are listed which are treated. Thus, in the end, it will become possible to answer all questions which the new theory (or method) evokes. One such question is whether the *ex post* gap need necessarily show a value inside the interval of the two *ex ante* gaps. I see a possibility for the *ex post* gap to be outside that interval. Another question is how many categories of estimates it is useful to distinguish: is it at all useful to distinguish between minimum and non-minimum requirements and by variations in the type of assumptions used? With the large number of variables and assumptions at stake we may finally end in confusion. These are a few questions one hopes will be answered in the ideal textbook three years from now about the subject. Even so Professor Vanek produced a most valuable book.

It was also a good idea to add Chapter 9, which is easy to understand for the practitioner in development aid. One question that came to the reviewer's mind is whether we can be content with the rates of growth of the Colombian

economy considered in this volume. Even the official plan is not very ambitious with its 6.1 per cent per annum.

J. TINBERGEN

Netherlands Economic Institute

Europe's Postwar Growth—The Role of Labor Supply. By CHARLES P. KINDLEBERGER. Cambridge, Mass.: Harvard University Press, 1967. Pp. xi, 270. \$6.50.

Charles Kindleberger, with this work, has given us another interesting, useful, and in some ways rather different book.

The task Kindleberger set himself was to "explain," so far as organized statistics and educated insights permit, the rates of growth of most Western European economies, rapid, normal, and slow, in terms of the availability of extra labor on favorable terms. This is the theme that prevents the book from becoming a hodgepodge of statistics, facts, and observations, arranged by country, but with little other sense or order. If this theme seems overworked at times, the reader should be tolerant.

At the outset the author necessarily presents Arthur Lewis' thesis of growth through unlimited supplies of labor as outlined in two well-known articles in *The Manchester School*. Lewis there holds that developing economies go through two distinct stages. During the first, when labor is available in infinitely elastic supply to a capitalizing sector (probably industry but possibly modern agriculture), additional investment (from domestic or foreign sources) results in more workers being employed at unchanging capital to labor ratios. Later, as extra labor from backward, subsistence, rural sectors becomes available only at higher real wages, capital *deepening* substitutes for capital *widening*. In effect, as Lewis stresses, the old classical labor cost theory of value tends to prevail in Stage I, during which period development heavily depends on extra capital, financed from profits. In Stage 2, profits and wages depend on marginal productivity, and savings and investment can flow from wages as well as profits.

With this theme in mind, namely, that rapid growth requires available extra labor at little if any extra real cost, Kindleberger examines the postwar record, to 1964 approximately, of (1) fast growing developed economies with expanding labor supply, namely Germany, Italy, Switzerland, and the Netherlands; (2) fast growers with limited labor, Austria and France; (3) slow growers with limited supplies of labor, Scandinavia, Belgium, and the United Kingdom; (4) undeveloped countries of emigration, Portugal, Spain, Greece, and Turkey. What he has to say about these economies is invariably interesting, and he pieces a great number of varied facts together in a skillful and usually persuasive way. Whether this has anything to do really with the Lewis schematic, is not apparent, but also is perhaps unimportant.

The main complaint this reviewer has concerns Kindleberger's indiscriminate use of incremental capital to output ratios (ICORs). Practically, an aggregate ICOR is obtained by taking some period such as a decade for a national economy, and dividing any extra output into any extra capital stock

(i.e. investment). The resultant quotient has of course no operational meaning. For instance, if this ratio is 3, it does *not* mean that \$3 million of new investment will *cause* \$1 million of extra output. Extra output also comes from extra labor force and productive innovations. It would be no more meaningless, and perhaps less, to attribute all extra output to extra labor employed over time. However, if Kindleberger is analytically careless in this one regard, he is in numerous company.

In some respects, as the author disarmingly admits, this book is several works between one pair of covers. Thus the main contribution is the treatment of the various Western European countries (Chs. II through VII), but there are also some very illuminating if general chapters on labor migration in Europe (Chs. VIII through XI), while the last two chapters are a sort of afterthought on some economic aspects of the United States. Some chapters (e.g. Ch. X on the Costs and Benefits of Labor Migration) could well stand alone as journal articles.

Neglecting these caveats, *Europe's Postwar Growth* with its special reference to differences in extra labor supply from country to country, rewards careful reading. It is brimful of selected data. It is hard to suggest any other single work of late, except Denison's *Why Growth Rates Differ* (Brookings, 1967), that gives a superficially informed reader so much to absorb and ponder.

Lastly, Kindleberger offers throughout an honest balancing of arguments and a modest scepticism, uncommon virtues among many economic development writers.

STEPHEN ENKE

General Electric-TEMPO

The Challenge of Development: Theory and Practice. Edited by RICHARD J. WARD. Chicago: Aldine Publishing Co., 1967. Pp. viii, 500. \$6.95.

The forty-five articles making up this volume were selected from a much larger number of papers delivered in 1963 at a United Nations conference on "The Application of Science and Technology for the Benefit of the Less Developed Areas." This collection is distinguished by the unusually wide range of subjects covered and the heavy emphasis on descriptive technology and case studies of new enterprises and social overhead projects. A third of the book is devoted to general planning models and to human resources as factors in development. The remaining two-thirds of the book covers less familiar material ranging from the role of plant genetics in food production to highly specific essays on how to build a railroad, how to organize a textile industry, etc. Finally, in the last fifty pages there is a return to general models but with the emphasis on social and cultural variables. The clear intent of the editor was to provide a kind of miniature encyclopedia of concepts and case problems in applied development work suited to the needs of the pragmatic minded administrator. My comments, though limited to a sample of the articles, will keep this purpose in view.

Hollis Chenery's deftly executed "Model of Development Alternatives" demonstrates with equations and graphics the consistent sets of alternatives

open to development planners given the constraints of the expected inflow of foreign capital, the rate of domestic saving, the composition of internal and external demand, etc. However, in the process of empirical implementation, the initial equations are necessarily simplified and one begins to wonder whether the limits to growth derived from the model are as much a result of the constraints imposed through such simplifications as they are attributable to the resource limits of the country discussed. The administrator reading the Chenery article gets a picture of the development process in terms of an aggregate production function with one independent variable (capital stock) which increases through additions from domestic saving or foreign capital inflow (p. 42). Of course an elaboration of the model proceeds from this base but there is little recognition of the problem of underutilization of the existing capital stock or of effective utilization of additions to the capital stock. This omission is remedied in part by P. N. Rosenstein-Rodin ("Planning the Use of External Resources") who discusses the "absorptive capacity" of a country, i.e., its ability to use capital productively. The emphasis given to the problem of utilizing foreign capital and the measuring of absorptive capacity is a needed corrective to much of the thinking about development in terms of simplified schema. Of the remaining articles in the section, two seemed of general theoretical interest: E. P. Holland, "Principles of Simulation" describes the application of this technique to development problems. While the article starts out with some promising statements of purpose, it leads through a rambling discussion to the results of "simulation runs" which at least as presented here seem to offer little of value to the development planner. Howard S. Ellis in a brief theoretical discussion of the effects of regional economic integration succinctly evaluates the possible gains from integration, and shows the relation of national development planning to the kind of gains that can be achieved.

Part two on "Developing Human Resources" is the most disappointing section of the volume in that it shows little recognition of the theoretical work being done on the economics of investment in public health, education, etc. There are brief reports on the setting up of an occupational health unit in Peru, a manpower training program in Africa, and a fragment on "Improving Public Management." Bert Hoselitz contributes a readable essay on the "Entrepreneurial Element in Economic Development" using psychological factors stressed by McClelland along with an explanation in terms of socio-economic structure. The main article by P. M. Hauser on "Population and Labor Force Resources" competently reviews familiar material on the high cost of population growth to an underdeveloped country. But the analysis of the effect of high birth rates on age structure, and the consequent dependency burden of less developed countries, is much too limited. It is true that the population "under 15 years" may be proportionately greater in the underdeveloped countries but the labor force participation rate of children in subsistence agriculture is very high while children in industrialized countries produce little and require a costly education. We cannot measure dependency burdens simply by looking at age composition tables from the *Demographic Yearbook*!

The case studies in parts three and four are written by specialists who are knowledgeable about the industry or project discussed, but engineering or in-

dustry data must be related to broader economic concepts if maximum benefits are to result. A comparison of two articles will illustrate the point. J. Wickersham's article on food processing seems to reason as follows: milk is a very important food; the underdeveloped countries have low per capita consumption of milk; hence it is clearly desirable to set up milk processing plants, details of which are then presented. No consideration is given to the alternative possibilities of supplying needed proteins at lower cost through say the production of fish meal or other high protein flour additives. By contrast, John Gallagher's "Markets as a Basis for Industrial Development," which describes the operations of Sears Roebuck in Latin America, shows an awareness of the strategic economic elements: Sears used its buying power to develop local sources of consumer goods, increasing domestic employment and capital formation, and allowing more foreign exchange to be used for capital imports. Small manufacturers were assisted through a careful projection of future demand schedules and by prompt payment for goods which reduced the need for borrowed capital. The article offers much useful and detailed information along these lines.

The many articles on aspects of agricultural development are too numerous to even list, but I can report that they are generally well done and informative. The three articles by Todd, Greenman, and Hagan on hydrology, reclamation, and irrigation along with the Sherman Johnson and R. P. Christensen essay on the efficient use of agricultural resources merit particular attention.

Despite the limitations noted, this volume is worth having on one's shelf, if only as a reminder of the staggering range of specialized knowledge and skills which must be brought to bear on the problem of development. A reading of the book is a good antidote to the common preoccupation with general models and simple policy formulas.

MORTON PAGLIN

Portland State College

Numerical Models of Economic Development. By A. QAYUM. Rotterdam: Rotterdam University Press, 1966. Pp. ix, 106. \$21.50.

A reviewer may serve a useful purpose by drawing attention to a significant new contribution to the literature. Or he may serve an equally useful purpose by pointing out a book that the reader can well afford to pass up. Professor Qayum's book can easily be passed up.

The book contains 10 essays dealing with various aspects of economic growth, with particular reference to developing countries. The issues raised by the author are central to the study of economic growth. However, much of the book is characterized by a relatively sterile and unoriginal application of mathematics to economic problems; and where the author attempts an original contribution, his analysis is frequently muddled.

For example, consider the second essay, "Theory of Income Generation and Economic Growth." Here we have what looks like a straightforward multiplier-accelerator model. Income in period t , (Y_t) , is written as the sum

of outlays on investment in period t , (O_t), and effective demand in period $t-1$, (X_{t-1}),

$$(1) \quad Y_t = O_t + X_{t-1}.$$

Then we have

$$(2) \quad X_t = \delta Y_{t-1}$$

$$(3) \quad O_t = \beta(X_t - X_{t-1})$$

where β (despite the author's assurances to the contrary) looks suspiciously like an accelerator. The reader is then told that " O_t is open, and it can be raised or lowered, and Y_t will correspondingly change." The author does not try to reconcile this with equation (3). Qayum also denies that (1) is a Keynesian identity. Indeed, the Keynesian identity "is not relevant." Equation (1) represents "a major shift of emphasis from a static identity to a dynamic equation."

Or consider the last essay, "Life of Capital and Economic Growth." Here the author examines the effect of factor substitution on the level of output. He uses a notion of capital (after Johansen [1]) where "there are substitution possibilities *ex ante* but not *ex post*." New capital goods are combined with uncommitted labor according to a chosen factor ratio. But the factor ratio, once selected, remains constant for the life of the capital. According to Johansen, capital is built to employ a technique that will achieve continuous full employment of capital and labor. Qayum, however, has a better idea. Instead of building capital in period t to take account of labor availability in period t , the capital should reflect labor availabilities in periods $t, t+1, \dots, t+h$ where h is the lifetime of the capital. This may sound good, but it ignores the fact that capital built in periods $t+1, t+2, \dots, t+h$ absorbs labor becoming available in those periods, so that building unemployment into the model involves pure waste. The author presents a numerical example and a "proof" to support his contention. However, he has furnished us with a proof of the wrong theorem. His analysis is appropriate for the contemporaneous allocation of labor among firms: given the same production function in all firms, and given each firm's capital stock, it pays to allocate labor so as to equate the capital-labor ratio everywhere. The problem of allocation over time has an important difference. If labor is set aside in period 1 to be used in period 2, there is a loss that is never regained. Indeed, using Qayum's example, and any plausible parameter values, full employment of labor in both periods is the best alternative. Qayum reaches contrary conclusions only because he has formulated the problem incorrectly. (There is also a computational error in his numerical example.) Qayum's treatment of this problem reveals an underlying misunderstanding about the notion of relative factor scarcities in a growing economy. If capital and labor are growing exponentially, then the labor intensity built into each new unit of capital should reflect the incremental factor ratio obtaining at the time the capital is built. It is irrelevant how the factor ratio changes over time, given that new investment is continuously taking place.

The other essays are less muddled than the two discussed here. However, the reader may be puzzled to find such statements as: "Labor-intensive meth-

ods are all right, if the increase in effective demand can be met by goods produced by *fresh* investment outlays in successive periods" (*italics his*). Or "A trifling but stubborn fact of the present day world is that the countries which are in short supply of capital goods are also in short supply of consumption goods. This shows that there is a large degree of interdependence and substitution between the two." One more: "The usual models, which are sensitive to changes in consumption only, cannot account for developments that are initiated by changes in the demand for capital goods (to start with)."

This reviewer feels that the reader is unlikely to learn much or to gain many new insights from reading this book.

REFERENCE

1. LEIF JOHANSEN, "Substitution versus Fixed Production Coefficients in the Theory of Economic Growth: A Synthesis," *Econometrica*, April 1959, 27, 157-76.

Peasant Agriculture, Government, and Economic Growth in Nigeria. By GERALD K. HELLEINER. Homewood: Richard D. Irwin, 1966. Pp. xx, 600. \$9.25.

Agriculture and Nigerian Economic Development. By H. A. OLUWASANMI. New York and London: Oxford University Press for the University of Ibadan, 1966. Pp. vi, 240. \$7.20.

While these two studies seemingly cover the same topic, in actuality both the content and approach are dissimilar. Helleiner's book, a volume in the Yale University Economic Growth Center series, is research oriented and heavily quantitative; that of Oluwasanmi is an expanded and very readable, largely qualitative essay. In content, Helleiner incorporates an exhaustive examination of the role of the government in economic growth and, although data in Oluwasanmi do not go beyond 1961, Helleiner includes material as late as 1965. Both emphasize, however, that the impetus in Nigerian economic growth from the turn of the century and until recently has come from the export of "peasant" agricultural products. In development literature, industrialization and the so-called enclave economies have received widespread attention. It is refreshing and surprisingly provocative to see serious attempts to evaluate the oft overlooked place of traditional agriculture in accelerating and maintaining economic growth.

In the areas of agriculture and government upon which Helleiner concentrates, his findings and analysis offer the most detailed and complete data since those of the IBRD's report on its Mission to Nigeria published in 1955. The 350 pages of text are accompanied by 31 pages of useful bibliography and some 204 pages of statistical appendix. The first two chapters of *Peasant Agriculture, Government, and Economic Growth in Nigeria* are devoted to the economic history of growth since 1900, pointing out that until World War II governmental attempts at stabilization were negligible. This characteristic was reversed during the war years and last two decades.

The following three chapters should be of particular interest to the agricultural and land economists as they investigate peasant agriculture, its nature, principal exports and its position in the economic development of Nigeria. These sections give, in essence, a case study of Nigerian agriculture which dovetails well with the recent outstanding two volume *Experiences with Agricultural Development in Tropical Africa* (by John C. DeWilde *et al.* Baltimore 1967) which concentrated upon Kenya, Mali, Uganda, Tanzania, Upper Volta, Chad, and the Ivory Coast. Helleiner points out that the basis of Nigerian agriculture was free from the frequently found enclave-plantation feature and rested firmly among the peasants. It was traditional in form, technologically underdeveloped, and functioned with a communal form of land tenure which had the social advantage of no tenant-landlord relationships or a landed aristocracy. However, this tenure system has been breaking down in favor of individual peasant ownership.

The author successfully argues against the commonly held position of many development economists that the African peasant either fails to respond or responds perversely to economic incentives. An additional characteristic is the regional overspecialization of the farmer, i.e., cocoa in the West, oil palm in the South, groundnut and cotton in the North, rubber in the Midwest. Although Helleiner estimates that from 1900 to 1962 the export sector's volume increased more than sixteen-fold and accordingly provided the fuel for economic growth, present economic indicators reflect some limitations for agricultural export expansion as income elasticity of demand for all Nigerian agricultural exports is relatively low and specifically that price elasticity for cocoa is among the lowest but still higher than unity. Yet real prices are influenced by a combination of world market forces and government fiscal policy.

Chapters 6 through 14 will hold the attention of development and public finance economists. Helleiner's analysis of the Marketing Boards, their evolution and use as a tool of government fiscal policy, is the best available. Since the outbreak of World War II, such Boards as statutory monopolies have controlled the purchase of agricultural products domestically and sale on world markets while establishing prices paid to Nigerian producers on a basis of nonmarket criteria. In the mid-1940's Nigerian Marketing boards existed for specific crops (cocoa, groundnuts, oil palm produce, cotton) and later were broken into Regional Boards on a cross-commodity basis. Helleiner notes that economic interest has been directed toward the stabilizing role of these boards but "Growth should always have carried greater weight in Nigerian policy formation than stability, and there exists no conclusive evidence that the two are correlated" (page 159). The Boards' surpluses have been designated for stabilization and for research and development with the latter progressively expanded only recently. In the balance, the Boards were more effective in acting as earners of tax revenues than in their stabilization objectives which included producer incomes and prices, with the latter more attainable than the former.

While peasant agriculture spurred growth in the first half of the century, apparently the public sector will be, at least for the time being, the prime mover toward development. It is noted in discussing revenues that, even by African standards, the government sector in Nigeria is small relative to the

GDP. However, government expenditures in the 1960's reached 15 per cent of the GDP resulting in recurrent deficits rather than the former surpluses. Public borrowing both domestic and foreign is increasing. The foreign trade sector remains a dominant contributor to revenues through import and export duties. There is some blurring on the share of direct taxes in public revenues in the last decade or so which could use clarification (page 219, text and page 210, Table 50). One might have found beneficial a fuller breakdown so that the growing impact of oil royalties and income taxes on this industry could be assessed. (The same omission regarding oil is also noticed in Oluwasanmi's work.)

Helleiner concludes with a largely descriptive chapter on the National Development Plan, 1962-1968. Among other targets, 15 per cent of the national output is earmarked for investment to achieve the required 4 per cent growth rate with half the cost of public investment and the private investment to be financed from abroad. Yet at the halfway point, the obstacles to successful implementation are growing serious as the external debt servicing commitments are approaching over 10 per cent of the projected exports. Short of extreme austerity measures, the key may be held in the exploitation of oil.

The first five chapters in *Agriculture and Nigerian Economic Development* cover agriculture and the national economy, Nigerian agriculture in historical perspective, land use and population. These chapters require careful reading because of their brevity unless one is well versed in the socio-economic conditions of that country. The author dramatizes his subject by closely relating Nigerian development to its most primitive and backward sector, peasant agriculture. Commercialization of agriculture became the most essential characteristic, explaining early Nigerian economic growth as synonymous with this process. Commercialization was stimulated by a dual policy of taxation assisting the monetization of the economy and the introduction of new crops. Oluwasanmi concludes that, in the past, investment of scarce capital resources in agriculture to generate growth in other sectors was the most profitable decision considering the limitation of social conditions and institutions.

On the subject of land tenure, this work differs from Helleiner's in that the treatment is extended to include the sociological and regional implications as well as the strictly economic, which points up Oluwasanmi's intimate knowledge of indigenous conditions. While the overall Nigerian agricultural picture is not unlike that of other developing countries, nonetheless, it is not the scarcity of land but the low level of technical know-how and implements which restricts the acreage of peasant farms to that workable by the family unit. The author maintains that Nigeria as a whole is not overpopulated but that social barriers present a very real problem to rational land resource allocation.

In subsequent chapters Oluwasanmi deals with patterns of production, marketing, and finally agricultural development and industrialization. Emphasis is centered upon avoiding so-called pure research and concentrating on pragmatic aspects à la Theodore Schultz. This view is reinforced by the limitations on available funds and the redundancy in federal and regional agencies. Throughout this work the awareness of the complexities of change makes for a sobering outlook. The author gives the impression that he is under no illusion

of magically moving the Nigerian economy to an industrialized status. The closing position which Oluwasanmi advances challenges the belief that industrialization *per se* is the panacea for underdevelopment in Nigeria. His book provides the development economist with the stimulating and still fresh view of the key role of modern agriculture in the development process and, indeed, the essential support the agricultural sector can offer industrialization.

For those in African studies, development, and agricultural economics the decision is not which of these two studies should be read, but rather in what order. This reviewer would suggest first the broader, more interpretive volume by Oluwasanmi followed by Helleiner's book which contains a wealth of economic data and analysis.

RAGAEI EL MALLAKH

University of Colorado

The Economics of African Development. By ANDREW M. KAMARCK. New York and London: Frederick A. Praeger, 1967. Pp. xiv, 294. \$7.50; paper, \$2.50.

In his preface of somewhat dubious value, Pierre Moussa correctly observes that very few syntheses have been written on the economic development of Africa as a whole, covering all sectors: "This is because it is difficult to know all fifty countries . . . of Africa; very often comparable information is lacking from one country to another and it is therefore very difficult to make meaningful generalizations" (p. vii). The inherent difficulty of this task stems from the continent's vast size and its large absolute number of political and economic units, from the present paucity but rapidly proliferating availability of "facts" (including but not solely statistical data), and from the tremendous variety that is Africa, a diversity manifest in the geographical, political, and cultural as well as economic realms. In undertaking this survey of economic characteristics and development problems of sub-Saharan Africa, Dr. Kamarck has drawn upon his broad experience of over a decade of economic work on Africa for the World Bank Group. Specialists will find here many particulars to fault, but the whole succeeds better than its parts. This is a comprehensive and well-structured introduction to the subject.

The book is addressed to a broad audience of general readers and social science students (hence the textbook format and paperback edition), and requires of its readers very little background in economics. Kamarck's approach is largely descriptive and derivative. There is no underlying or unifying theoretical model or theme, and the analyses are eclectic. A few simple analytic tools are employed (e.g., the backward-bending supply curve), and these are generally efficiently and adequately explained. By and large, the text is well written in uncluttered prose and noneconomists will find it relatively free of academic jargon. Readers may learn much here about African development, but little about economics *per se*. What is original is not the analysis but rather the summarizing and synthesizing of a wide range of sources bearing on the whole scope of African development problems.

The text consists of twelve chapters including four useful maps, a thirty page statistical appendix, and an adequate index. The first chapter briefly

touches on Africa's economic history, and the next three chapters describe the structural characteristics of African economies. Each of the four following chapters focuses on a particular sector: agriculture, mining, industry, and infrastructure. Other chapters are concerned with foreign investment and aid, plans and planning, internal and external political considerations, and prospects for the next generation. As may be inferred from this organization, references to individual countries are scattered throughout. The book is not intended to be and it is not a suitable vehicle for learning about any particular country. Unfortunately, it also cannot be regarded as the reliable source of facts and data which one might have hoped for; more on this point below.

Kamarck is generally more concerned with describing things as they are now than with tracing the course of how they came to be that way. His focus is on the emergence of African economies into "the mainstream of world commerce and life." Consequently, both his historical perspective and his opening chapter on that topic are very short. One paragraph passes over the economic history of the entire period from ancient Egypt to the European entry into the slave trade. The history of the slave trade and its impact receives three pages, while the role of chartered companies is also passed over lightly. More background on developments in the first half of the 20th century is provided in various chapters, and some attention is given to both costs and benefits of the colonial heritage, but the reader will acquire only little appreciation of the significant variations in legacies arising from the installations, institutions, and influences passed on to Africans by their colonizers. In Kamarck's view, World War II represented a turning point in African development, and his main focus is on the causes and effects of the generally respectable growth rates achieved in the postwar period.

The three chapters on structural characteristics of African economies are the most useful part of the book. Here are collected the most important comparisons and generalizations on the composition of output and trade, the distribution of income, the balance of payments, money and banking arrangements, and common denominators of African economic experience and attitudes. Kamarck shows clearly that there is as yet no such thing as "the African economy" in the sense of an economically integrated continent. "Economically and financially, African nations are more like a series of islands lying off the coast of Western Europe than like parts of a single continent" (p. 21). In his view, "the propulsive and dominant sectors are external: exports, foreign investment, and other expenditures financed from abroad. These essentially still determine the size and growth pace of African economies" (p. 27). These conclusions are well supported in an excellent chapter on Africa's position on the world scene. In addition to documenting the continent's great dependence on foreign trade and on non-African capital and personnel, this chapter includes an attempt to construct an over-all balance of payments account. This account for 1963 and 1964 interestingly reveals, for example, that sub-Saharan African countries together appear to balance out in their commodity trade account; the deficit on services and invisibles is just matched by long-term capital inflows.

Notwithstanding the great diversity among the various national economies, Kamarck observes several common denominators which distinguish the problems, processes, and prospects of African development from other continents. These include "a greater sense among Africans of belonging to a single entity," a high rate of migration by workers across national boundaries, the relative absence of population pressure on the land, the "openness" of the economies, the historical importance of the government sector, the egalitarianism and the openness to innovation of most African societies, and various legacies of colonialism, including the large number of "micro-states." The statement that the total population is "probably . . . between 200 million and 250 million in 1966" brings to mind Stolper's observation that the "two major aspects that appear to distinguish the problems of development in Africa . . . from the problems found elsewhere [are]: the lack of hard facts in crucial fields and the absence of a population problem" (*Planning without Facts*, Cambridge 1966, p. 4). The very great wealth of information collected and summarized by Kamarck might itself seem to belie Stolper's point about the lack of facts, but Kamarck himself stresses how sketchy and tenuous our information is on many critical aspects of African development. In fact, this theme dominates his chapter on agriculture; here he laments both our technical ignorance (e.g., about soils and diseases) and our even greater lack of knowledge of the economics of the African farm (including social and cultural factors). Such considerations underlie his warnings against both large-scale transformation projects in agriculture and overly aggregative economic plans. While his long chapter on agriculture is full of information and examples, however, the chapter on planning is itself too aggregative. Here one might have hoped for more on the planning experiences of particular countries such as Ghana and Guinea rather than for so many broad homilies on the possible pitfalls in the making of economic plans in general.

It has been noted that this book's strength is in its scope rather than in its suitability as a source. This is a summary, not a sequel to W. M. Hailey's *An African Survey*. It is not a controversial book, but it is inevitable in a work of this type that specialists will find the generalizations too general. Some errors are simply egregious, as, for example, in Table 8 in the Statistical Appendix, which is not accurately reproduced from Department of Commerce sources. More significantly, economic historians may well dispute the view that "the economic history of the years since World War II has demonstrated that there were no economic reasons for the continuation of European colonial empires" (p. 68); some observers may question whether "emphasis on the importance of economic development . . . coincides with the African *Weltanschauung*" (p. 49); economic anthropologists may fault the lack of consideration for ethnographical factors; economists may criticize the spurious accuracy in the calculation of rates of return on investment. Everyone may regret that there are no footnotes and that the selected bibliographies at the end of each chapter are short and unannotated.

Whatever its shortcomings, however, this sympathetic but realistic appraisal of African development is a significant contribution. It is clearly the

best available introduction to this field and it can be recommended enthusiastically.

ROBERT P. ARMSTRONG

Center for Development Economics
Williams College

Economics of Development—With Special Reference to India. By D. BRIGHT SINGH. New York: Asia Publishing House, distributed by Taplinger, 1966. Pp. xiii, 611. \$9.75.

Economic development is an area where textbook writing is still extremely difficult. The discipline is in an unusual state of flux, the literature is predominantly descriptive but vast, and many contributions are not easily accessible because they are made in foreign languages. Even so, we have been exposed in recent years to many economic development textbooks by economists residing in developed countries. One of the new dimensions introduced by the present text is that it comes from a university professor from India.

Both the approach and the selection of topics is orthodox. In eighteen long chapters are covered the most important and popular topics of the development literature up to 1963. The author starts out with two general chapters on the meaning of underdevelopment and theories of growth. The first chapter, with its detailed and systematic examination of the nature of underdevelopment, provides insights that make it one of the best in the book and the literature.

The next three chapters examine in detail and in a lucid way three sets of factors affecting development: institutional and sociological elements, population, and capital formation. By synthesizing the literature, and making extensive use of statistics, Singh is successful in providing, both here and in subsequent chapters, a panorama of the development process rather than a panorama of personal views of development economists as found in Benjamin Higgins' book.

The author assigns a key role to capital formation and demonstrates its importance by an extensive treatment of the factors or aspects of economic development related to investment and capital formation. In the following eight chapters, Singh deals with investment financing (Ch. 6), investment criteria (Ch. 7), monetary (Ch. 8) and tax policy (Ch. 9), deficit financing (Ch. 10), and the external sector (Chs. 11-13). The treatment of the external sector is one of the most detailed available. The last five chapters deal with agriculture, stability, the role of government, planning and the book concludes with a chapter exclusively dedicated to planning in India.

The area of development textbooks is one of differentiated oligopoly. Different types of textbooks can and are being written. One type aims to provide the student with the "basic tools of the trade." Such a textbook is hardly possible in economic development, since the tools are only partly known. Singh recognizes this limitation and makes no attempt to deal exclusively with development theory. Another type of textbook combines the existing body of theory with extensive references to the literature and statistical material. The book by Singh, which systematically summarizes the literature and incorpo-

rates a vast amount of statistical material, falls clearly into this category. Another type of textbook classification, or textbook variation, is important in understanding and evaluating the Singh book. Some texts are written on the supposition that supplementary reading material is both abundantly available and required of the students. Most U.S. texts belong to this category. Other texts, however, are written explicitly with the aim of saving the student the laborious efforts of exploring the literature by himself. Language barriers, inadequate library facilities, and a different approach to education create the need for such texts. The present book aims to do just that and this accounts for its formidable size of 600 pages.

The Singh book, as a consequence, will be most valuable for intermediate courses in economic development in English-speaking countries where supplementary reading is kept at a minimum. In the United States adoption *in toto* would not be efficient. Some of the nontechnical chapters, however, could serve as useful supplements to the Bruton book.

This textbook is impressive in the sense that it comes from a person who has lived in less developed countries, has a good feel of the problems facing them, has carefully read and incorporated the literature, avoids generalizations, is more interested in substance (key issues) than form (the presentation of elegant models with limited validity is kept in bounds), and has a minimal propensity to impose on the student the slogans and the word mongering so popular in economic development literature.

The textbook has some fundamental limitations. It does not incorporate the literature since 1963 (writing was terminated in 1963 and publishing in 1966); it presents a view that is based on the writings about developed and developing nations by economists residing mainly in the United States and India; makes few suggestions about the gaps existing in our knowledge of the field; is not sufficiently theoretical for a graduate economic development course; and incorporates practically no "foreign-language" literature. Furthermore, the tremendous degree of mosaic diversity within the underdeveloped world is not brought out strongly enough. Like many other economists, Singh has a tendency to view the growth process in terms of the narrow agriculture-industry framework. The fact that some less developed continents, such as Latin America, have at least 50 per cent of value added in services, which is neglected in the above framework, also goes unnoticed in the book.

Overall, it should be mentioned that the book, with its special emphasis on India, will serve as a useful example of how basic economic training can become more "intercultural."

MARKOS J. MAMALAKIS

Yale University

Economic Growth and Development. By BRUCE R. MORRIS WITH C. WENDELL KING. New York and London: Pitman, 1967. Pp. xi, 429. \$7.50.

In contrast to some other areas of applied economics, there is not yet a surfeit of texts in economic development. This reviewer is familiar with a half dozen good intermediate texts which differ significantly in conception and coverage. However, since many instructors prefer to use books of readings which,

although they introduce the student to some of the important literature, lack the kind of unifying thread intrinsic to a good text, it is likely that there is a market for a new text with its own unique orientation. Bruce R. Morris has attempted to meet the demand.

The author tells us that three points of view underlie his approach to the economic development of poor countries: (1) that "the combination of development measures applicable to each country is unique," (2) that "a wide variety of more or less interrelated measures is necessary for development and that the all too scarce resources of the country must be allocated in a manner calculated to achieve the best results," and (3) that "the primary problem in economic development is the improvement of the human element, and it is this that should have priority in the investment program" (p. x). The dust jacket refers to these points as "three vital theses," but it is more accurate to say that they represent the author's beliefs about economic development which, as statements of belief, probably command rather wide acceptance. The second point amounts to little more than a statement that poor countries should allocate their resources efficiently, and is so central to the concern of professional economists that it should be unnecessary to state it as a basic proposition undergirding an economics text.

The organization of the book follows from the first point of view. Since the author believes that the combination of development measures applicable to each country is unique, he does not attempt to present any theory of economic development which he believes to be generally applicable, but instead tries to touch upon all the problems and possible solutions which might be relevant in understanding the economic position of any poor country. Although this does not prevent the author from taking rather definite positions on certain topics (e.g., inflation, population), his general view is that the investigator must take a close look at the individual country before he can give useful advice. Each chapter then becomes a catalog of the many things that might be relevant in a given country to the aspect of development covered in that chapter.

The first two chapters contain some quantitative data on poor countries, a description of their significant characteristics, and a brief survey of theories of economic growth from the Mercantilists through the Classical school, and up to and including the modern-day contributions of Leibenstein, Nurkse, Hirschman, Rostow, Lewis, Hagen, Hoselitz, Myrdal, and Rosenstein-Rodan. Chapters three through thirteen cover those aspects of economic life which the author believes are important to understanding the economic problems and prospects of poor countries. These aspects include social and cultural factors, agriculture, population, labor, industry, technology and entrepreneurship, sources of finance, international trade, institutional arrangements, and the control of economic decisions. Chapters fourteen and fifteen cover investment criteria and programming and some typical policy decisions.

The author eschews the use of "mathematics and complex diagrams" (p. ix). He believes the beginning student must first "acquire a working knowledge of what is happening in the underdeveloped countries." The only mathematical symbols used are included in a brief discussion of Harrod-Domar

.

growth models (pp. 49-51). The paragraphs pointing out the implications of these models are particularly unsatisfactory. Only three diagrams are used, the first of which (p. 125) is adapted from an article by Mellor and Stevens (*Journal of Farm Economics*, August, 1956) and is not carefully drawn. Also the textual explanation of what this diagram is meant to convey is inadequate.

The editorial work on the volume is poor. The table of contents is a simple list of chapter headings, and there is no list of tables and charts. There are sentences ending with phrases such as "and the like" (p. 367), "and so on" (pp. 438, 476, 496), "four hours of time" (p. 445), and paragraphs where a good editing job could have substantially improved the clarity of the material. The index was carelessly done, and because a detailed table of contents is omitted, it is very difficult to locate many topics. For example, the following topics, all of which are covered in the text, cannot be located by referring to the index: "big push" (erroneously attributed to Hirschman rather than to Rosenstein-Rodan), "critical minimum effort," "multiple exchange rates," and "blueprint planning." A random check of the index uncovered several errors and omissions. There are also errors in the footnote references.

Space allows only a few substantive criticisms of the book.

1. The chapter on theories of economic growth lacks an adequate synthesis of the various ideas on growth and development which are surveyed. In addition, the treatment in parts of this chapter and elsewhere in the book is so synoptic that it is often difficult to get at the main linkages in the argument.

2. Familiarity with the work of F. H. Harbison and C. A. Myers might have led the author to temper his suggestion that poor countries "lay greater emphasis at early stages of development on establishing technical schools at various levels to train people in such skills as building trades and machine operators . . ." (p. 188). Harbison and Myers, in *Education, Manpower, & Economic Growth* (p. 56), have taken a divergent position: "Our observations . . . lead us to believe . . . that most of the Level I countries [most underdeveloped by their index] have not reached a stage of development where pre-employment vocational schools at the secondary level are really practical."

3. In discussing migratory labor in Africa, Morris writes that one of the disadvantages is that "agriculture is disrupted by variations in the labor force." Morris ignores the work of men such as W. J. Barber in *Economic Development and Cultural Change* (April, 1960) who has argued that the periodic migration of at least some African tribesmen represents a rational adaptation to the periodic labor requirements for male labor in a context of slash and burn agriculture. It seems more reasonable to say that migration may in some instances relieve the pressure upon peasant agriculturists to change agricultural methods which are no longer appropriate because of an increased population-land ratio.

To close on a more favorable note, the chapter on social and cultural factors contributed by C. Wendell King, a sociologist, is a welcome innovation. The treatment of the sociological dimensions of the change process is especially interesting. Finally, the book does impress upon the reader the complexity of

the problems facing poor countries, and the necessarily tentative nature of much of the analysis and of many of the policy recommendations in the field. It also will serve to acquaint the student with a fairly wide body of literature.

FRANCIS M. McLAUGHLIN

Boston College

Impact of Western Man: A Study of Europe's Role in the World Economy 1750-1960. By WILLIAM WOODRUFF. New York: St. Martin's Press, 1967. Pp. xvii, 375. \$8.50.

Throughout its history—at least until the mid-twentieth century—European civilization has been expansionist and evangelical. In the Middle Ages it spread south to the Italian and Iberian peninsulas, west to the British Isles, north to Scandinavia, and eastward across the German and Polish plains to Russia and even, for a time, to the Near East. In the fifteenth, sixteenth, and seventeenth centuries it spread across the oceans to the Americas and set up outposts on the shores of Africa, Asia, and the islands off East Asia. In the last two centuries the carriers of European, or Western, civilization extended and intensified their pressures on other cultures and civilizations. In keeping with their evangelical tradition Westerners tried to impose by persuasion or force—frequently with considerable success—their culture, their religion, their technology, and their economy on the alien peoples with whom they came in contact. Only the discords and fissures within Western civilization itself prevented complete domination of the world by the West.

This is a story of epic proportions. Few other than authors of textbooks have dared attempt to tell it. Even segments of the story have their pitfalls. Professor Woodruff tells us in his preface that he was aware of them, but even he has not been able to avoid them. It is to his credit, in any case, that he has made the attempt. Perhaps his trial will stimulate other, more successful attempts. His plan is straight forward enough. Following a brief introductory chapter, he traces the course of European expansion and imperialism from the voyages of Columbus and Vasco da Gama to the mid-twentieth century. Then follow chapters devoted to European emigration, foreign investment, the diffusion of technology, the "conquest of distance" (which overlaps in part the two previous chapters), and international commerce. Each of these chapters is accompanied by a tabular appendix which presents in summary form the principal statistical and some other factual information relevant to its subject. In a short "epilogue" he presents his ideas on the philosophical implications of the story.

The principal contribution of the book is that it brings together in one place a great deal of the factual information relevant to the subject of European expansion in the last two centuries. Unfortunately, since the author relied almost exclusively on secondary sources, some of the information is incorrect, contradictory, outdated, or otherwise misleading. For example, he exaggerates "the destruction of Spanish sea power . . . in 1588" (p. 19); he incorrectly states that "real wages rose relatively less in the United States in the period 1860-1913" than in the principal European countries (p. 67); he repeats the discredited myth of the security-conscious French investor (p. 117); he im-

plies that European technology was in a state of "relative retardation" with respect to the rest of the world as late as the beginning of the eighteenth century (pp. 165-66); and he appears to believe in the long-outmoded theory of geographical determinism (pp. 166-67). On page 226 one reads that "railways crossed the great mountain ranges of the Andes . . . and opened up the remotest part of every continent," but on page 231 we are told (correctly) that "in 1960 three quarters of Latin American territory had no railway communications at all." And what is one to make of the statement (p. 192) that in the U.S. iron industry "modern techniques followed closely, if tardily, upon European developments"?

The tabular appendices, on which much effort was apparently expended, and which might have constituted the most important contribution of the book, are quite disappointing. Much of the information is derived from easily accessible standard reference works. Table V/6, "Electrical Energy, 1960" for example, is reprinted directly from the United Nations *Statistical Yearbook, 1962*. (The relevance of this information to the "impact of Western man" is not entirely obvious.) The tables relating to foreign investment are especially misleading. Table IV/1, the key table, lists gross but not net investments; this results in showing Sweden, Canada, and the United States as creditor nations before World War I, when in fact they were net debtors (Canada still is). On the other hand, some important creditor nations, such as Belgium and Switzerland, are omitted altogether. Moreover, the estimates of investment (and of foreign commerce in Chapter VII) are garnered uncritically from a variety of sources with little attempt to systematize or reconcile their differences. The internal contradictions in the tables of foreign commerce are especially glaring. The appendix to Chapter VI, on the diffusion of technology, simply lists the dates and a few particulars of notable inventions, discoveries, and applications in the fields of agriculture, mining, industry, etc.

Professor Woodruff has not succeeded in reconciling in his own mind the precise outlines and limitations of his subject. The very title of the book reveals its ambivalent character, linking "Western man" with European influence; at many points it is difficult to know whether the inhabitants of the United States, the British dominions, and Latin America are regarded as agents or as objects of Western influence. Part scientific popularization, part textbook, and part scholarly treatise, the volume is not notably successful in any of these genres. There is also a confusion with respect to the geographical and cultural scope of the volume; although apparently devoted to the consequences of European expansion for the rest of the world, much of the text in fact deals with purely internal European development. A similar confusion exists with respect to its contents, partly a catalogue of facts and figures, partly a philosophical essay on the theme, "whither civilization?" The latter ambivalence carries over into the author's prose style as well. Three examples will suffice to illustrate (and will illustrate as well the author's—probably unconscious—ethnocentrism): "More recently techniques have been developed for the recovery and utilization of uranium, titanium, beryllium, zirconium, and vanadium, used in nuclear reactors, etc." (p. 181); "The great metal birds that wing their way across the sky, or the voices that splutter and

hiss through the ether, remain part of the white man's magic" (p. 250); "It is a world of growing enlightenment. The European often brought light where prior to his intrusion there was darkness. . . . It is easy to be dazzled by the marvels of modern communications, but at least the white man's conquest of distance has made the world more fully aware of its collective dilemma" (pp. 336-37).

RONDO E. CAMERON

University of Wisconsin

The Dynamics of Growth in New England's Economy, 1870-1964. By ROBERT W. EISENMENGER. New England Research Series No. 2. Middletown, Conn.: Wesleyan University Press, 1967. Pp. xv, 201. \$9.00.

The New England region is poorly endowed with raw materials; it is distant from most consumer markets in the United States; and it has an unaccommodating climate. How then does it experience continuing growth, and what factors may account for its per capita income being higher than the national average. The documentation of this puzzle, and its solution, constitute the subject of Dr. Eisenmenger's book.

One of the main factors offsetting the disadvantages of the region, according to the author, is lower wages (or, more highly-skilled employees at the same wage rates). Lower labor costs can lead to more labor-intensive production processes or to a more labor-intensive industry mix. Eisenmenger's calculations suggest that two-thirds of the labor intensity differential between the United States and New England is simply due to differing output composition. The additional important elements in the region's growth are the fondness of business executives for living in the area, and the presence of agglomeration economies accruing from the high degree of urbanization in the region.

Although the author weaves supporting evidence into his presentation, this reader does not feel that all aspects of the thesis have been rigorously proved. Consider the alleged disadvantage of being distant from consumer markets on which the author elaborates in Chapter II. As Eisenmenger recognizes in Chapter VII, New England manufacturers are well situated with respect to the northeastern population belt. Besides, how important *quantitatively* is the transportation disadvantage, and how, if at all, has it been affected by the postwar trucking revolution?

Neglect of the quantitative dimension of locational factors is also exhibited in Eisenmenger's discussion of the residential preferences of executives and their role in the region's growth. He says: "Most manufacturing firms in New England are managed by men who were born or raised in the region where their manufacturing facilities are located. Unless their firms are failing, these men do not consider relocating to improve their profit position" (p. 99). Regardless of whether the statement is factually correct, and no evidence for such a sweeping generalization is found in the book, readers would have liked to know whether these firms are not, typically, the very small ones, and, if so, whether their contribution to New England's growth is quantitatively significant.

One important locational factor which receives only perfunctory treatment by the author is agglomeration economies. Perhaps one could not expect a full treatment of this subject in a volume devoted to general consideration of the economy of the region. However, the four paragraphs devoted to this question fall far short of this reader's expectation in the light of the importance of the subject.

On the positive side, Eisenmenger has succeeded in presenting a generally interesting study of the New England economy. In doing so, he relied heavily on traditional price theory and incorporated a great deal of current and relevant data into his analysis. This approach has produced a book which will be helpful to students of regional economics.

MATITYAHU MARCUS

Rutgers-The State University

Statistical Methods; Econometrics; Social Accounting

Mathematics in the Social Sciences and Other Essays. By RICHARD STONE. Cambridge, Mass.: M.I.T. Press, 1966. Pp. xiii, 291. \$12.00.

This is an excellent collection of essays reflecting the usual high standard of work from Mr. Stone. Anyone seriously interested in the application of econometric methods, model building, and theoretical reasoning to problems of national planning will benefit from reading these essays.

The title of the collection is misleading. A better synopsis of the contents might be: Econometric and other Mathematical Methods for Economic Planning. Seventeen essays are presented. The first (and possibly easiest to read) is entitled "Mathematics in the Social Sciences"; the remainder have titles such as: "Three Models of Economic Growth"; "Models of the National Economy for Planning Purposes"; "Transitional Planning"; "A Dynamic Model of Demand"; "The Changing Pattern of Consumption"; "Multiple Classifications in Social Accounting"; and so forth.

Except for the first and possibly the next two essays the collection comes so close to being a book that in this reviewer's opinion it is a pity that Stone did not see fit to do the rewriting that would have added the extra coherence.

The first essay appeared in *Scientific American* and has the strengths and weakness of an article at that level of exposition. It is an excellent summary and reminder for those who already know a great deal. It only pays the usual economist's lip-service to other social sciences (which is probably all that can be expected in seventeen and a half pages).

The second essay on "The *A Priori* and the Empirical and Economics" makes an eloquent case for the importance of mixing both an empirical and theoretical approach to economic problems. It is excellent reading for the fledgling model builder.

Undoubtedly economists should be (and once were?) men of broad education, but given their lack of linguistic ability, footnotes translating the French and Greek quotations might help οἱ Πολλοί.

In his essay on "The Housekeeper and the Steersman" Stone touches on cy-

bernetics and the problems of control and feedback. I found the treatment somewhat slight. Hardly any discussion of simulation was given. Furthermore here and in the subsequent essays little if any consideration is given to the co-ordination of planning models with planning processes. Economic theorists, econometricians, administrators, data gatherers, and policy makers must all harmonize in an overall systems approach if the type of work envisioned and pioneered by Stone is to succeed. He is undoubtedly acutely aware of this, yet this message is at best only tangentially implicit in these essays.

"Misery and Bliss," an article on population savings and consumption, provides a fine example of Stone's ability to combine his powers as an applied economist and a theoretician in building models to contrast positive and normative theory. The Modigliani and Brumberg saving function is used and policy implications are derived from a simple differential equation model.

In the ninth essay, "A Model of the Educational System," a dynamic program is formulated. It is obvious that for long-range planning socio-economic factors such as education must be taken into account; however, as is pointed out, one of the most difficult problems to be tackled is how we wish to define the educational process. (For example, should an educational cost be imputed to being brought up in a stable and literate home?)

Several subsequent essays deal with regional accounting and the multiple classification of social accounts. An excellent exposition of the problems involved and a plea for a unified system of social accounting are both given.

The collection ends with "British Economic Balances in 1970," calculated from the model of British economic growth developed by the Department of Applied Economics at Cambridge.

The collection of essays serves a useful function: the elegance and apparent ease with which Stone is able to model economic or socio-economic processes serves to whet our appetites. It is to be hoped that this is followed by a more unified book on planning models and planning processes.

M. SHUBIK

Yale University

The Meaning and Measurement of the National Income and of Other Social Accounting Aggregates. By EDGAR Z. PALMER. Lincoln: University of Nebraska Press, 1966. Pp. xiii, 417. \$10.95.

The field of social accounting is not oversupplied with good, up-to-date texts that satisfactorily provide—among other things—review of past developments and present trends in the field; detailed discussion of technical points and controversies, including reference to the relevant literature; sharply focussed comparison of social accounting practices in different countries; and a generalized approach to the subject that puts its various subelements into perspective and facilitates the exposition and understanding of specific points. To anyone who attempts to teach a social accounting course that goes beyond the barest rudiments, there is considerable interest in the appearance of a book that, according to its preface, "attempts to condense [the] discussions" in the literature, to bring "into focus many of the controversial questions in the field," to emphasize "the development of the concepts and measurement of so-

cial accounting," to look critically at many of the concepts and practices, and to provide a "vision [of] a complete and interlocking system of social accounts. . . ." There is a real need for a book that could deliver this package. It is, therefore, disappointing to find that Professor Palmer's book does not adequately fill the need. Although there are several sections that should be of considerable interest both to the student and to the expert, the book as a whole has certain deficiencies that keep it from being the long-sought-for, modern, comprehensive textbook in this field.

One problem is that the exposition is not always up to date; and to a greater extent than one would normally expect from a 1966 publication date. One gets an impression of a book basically written or thought through at various earlier periods in the past, with discussion of subsequent developments not really well integrated into the body of the book. For example, at several points, past developments and controversies seem to be discussed to a great extent as they were lived through, that is, without the benefit of the insight and explanatory power that might be provided by putting them in the perspective of subsequent developments in the various issues. Similarly, little advantage is taken of the power and discipline of the use of a comprehensive and articulated sector accounting structure in facilitating the explanation, clarification, and comparison of concepts. Indeed, despite frequent references to the matter, the book does not, in general, adequately expose the reader to the approach, which plays such an important role in recent work in the field, of dealing with social accounting concepts within such a schematic framework. The title of the book, with its emphasis on specific aggregates rather than on structure, is indicative of its tone in this respect.

Even in the sections dealing with the various social accounting systems currently put out in the United States—income and product, input-output, flow-of-funds, balance of payments, the descriptions are not always up to date. The basic discussions are in terms of versions of the systems other than the current ones. While mention is made of some of the changes that have occurred since the version described, in no case is it done systematically or completely. To some extent, of course, this may be due to the time lag between submission of final copy and publication date, but this is not the whole explanation since the book does contain certain references to publications of even later date than some of the slighted developments. As an extreme example of this, in the case of the flow-of-funds accounts, the description is in terms of the 1954 version and the author mentions only a few minor aspects of the considerable changes made in 1959, and to much lesser extent in 1962 and other years, when the current system was established.

There are other instances of inadequate discussion of recent developments and literature. For example, although the author expresses great interest in closer structural integration among the existing published sets of accounts, he neither makes adequate reference to relevant discussions that have appeared in the literature, nor mentions the extent to which changes in the published sets of U.S. accounts have been in the direction of closer integration. In this connection, as in several others, there is no mention of the Conference of Eu-

ropean Statisticians, which has been a major forum for developments in social accounting in recent years.

Despite the broad coverage set forth in the preface and attempted in the body of the book, one gets the impression that the author's real interest in social accounting (as indicated also by the book's title) is in one particular aspect—the definition of income. A large part of the book is devoted to a discussion of various problems in the concept of income, both in national and private accounting. Some of his suggestions for changing the boundaries of income concepts (as well as similar suggestions on the boundaries of production and capital formation) are of interest, although the presentation and terminology sometimes make it difficult to be sure of the exact consequences of his suggestions for all aspects of the structure of accounts. The discussion is occasionally marred by a tendency to mix together points and quotations relating to the definition of income for a variety of purposes—e.g., taxes, corporate management, measurement of national productive activity, income distribution, consumption functions—often with no hint to the reader that what is relevant for one purpose may not necessarily be so for another.

Because of these and other problems in the presentation, the book is probably not completely suitable as the general textbook for specialized courses in social accounting or as a supplementary text on the subject in more general courses. Similarly, it is hard to see it, as the author hopes, as helpful to the average layman. On the other hand, specialists and advanced students in the field, who should not be thrown off by the omissions and lapses and the occasional unusual terminology, should find much to interest and stimulate them in various parts of the book—e.g., in the author's individual approach to many questions, in the attempt to present the historical development of various measures and concepts, and in the valuable insights on many particular points.

STANLEY J. SIGEL

Board of Governors of the Federal Reserve System

Economic Systems; Planning and Reform; Cooperation

Central Planning; Evaluation of Variants. By KRZYSZTOF PORWIT. Translated from the Polish by Józef Stadler and edited by Helen Infeld. New York and Oxford: Pergamon Press, 1967. Pp. vi, 200. \$3.50.

We learn from the preface that this book, published in Polish in 1964, had previously been circulated under a preliminary version and discussed at the Planning Commission, at the University of Warsaw, at the Polish Economic Association, and at the Academy of Sciences. Most of the prominent figures of the economic profession in Poland are said to have contributed by their advice to the final form of the text, while the author is a member of the research department of the planning commission. For all these features the book *a priori* attracts our attention.

Its purpose is to advocate a new methodology for the preparation of long-term plans. The author strictly confines himself to this important but narrowly defined subject. He does not suggest that, simultaneously to the new meth-

od proposed for planning, reforms should be introduced in the actual operation of the Polish economy. Neither does he devote any space to detailed informative facts on the present process of planning.

The main theme of the book is very well explained in the introduction; it runs about as follows. In making a long term plan, one implicitly or explicitly chooses among the various possible combinations of the available productive techniques. The present method of planning is not satisfactory from this point of view because it studies hardly more than one variant. The choice among various organizations of the productive sector should receive much more attention. This requires a complete rethinking of the planning methodology, all the more so because the development of modern calculation methods and equipment makes possible a much more rigorous approach than was possible before.

In principle the problem amounts to the solution of a large mathematical program. But the dimension of the latter and the wealth of information that it should incorporate are so gigantic that one cannot hope to solve the problem directly or even to pose it completely. To get around the difficulty, one should combine "complex calculations," a rather unfortunate expression to designate computations made at the central level on the basis of a simplified model of the whole economy, with a number of "sector calculations," each one dealing in more detail with the organization of one particular industry. Complex calculations will use relatively little information on the various industries, but they can embrace the whole set of mutual relationships in the economy. Sector calculations must take as externally given the information concerning the elements outside of the particular sector, but they make possible a more detailed analysis of the data within the sector.

The idea that information must be exchanged between the central planning commission and the industries or smaller units is certainly not new in the literature of Eastern Europe. But Porwit has a particular notion as to how it should be organized. The complex calculations should involve an aggregate linear program and permit the determination of dual prices for groups of commodities. Such dual prices would then enter as given parameters in the sector calculations.

Conveying these propositions is the main object of the book. In order to make them clear, the author thinks it necessary to explain how the choice of a plan amounts to the solution of a mathematical program and what are the significance and exact nature of dual prices. Moreover he considers his proposal as being so substantial as to imply a complete reorganization of planning procedures and therefore as to require intermediate measures during a transition period. This explains the organization of the book: chapter 1 carefully formalizes the problem of long-term planning as an activity analysis linear program; chapter 2 deals with dual prices—it considers particularly those referring to the constraints on investment and on foreign balances; chapters 3 and 4 examine respectively the complex and sector calculations; chapter 5 discusses the problem posed by the progressive introduction of the proposed method.

As an exposition of its main proposals, the book is excellent. Porwit knows

perfectly both the theoretical and practical aspects that are relevant to his purpose. He explains them with great pedagogical qualities and with a good sense of the exact validity of each point. This is true even of the slippery paragraphs 2.6 and 2.7, where he attacks two difficult questions: (i) the discussion between W. Nyemtchynov and L. Kantorovitch on the significance of sector calculations, and (ii) the relation between dual prices, the "law of value" and actual prices in a competitive economy. Such a competent, serious and well-balanced work should have an impact on the economic thinking in Eastern Europe, especially among the young generation. Since he essentially agrees with the author, the reviewer warmly welcomes the publication of this book.

Those among the Western scholars who will be interested in Porwit's theory of long term planning may, however, notice two weak points of his discussion.

In the first place he is much too brief on the difficult choice of the capital stock to be kept in existence at the end of the plan. This is said to be "externally given" in chapter 1; the aggregate model of chapter 3 relies on capital-output coefficients; but there is no serious discussion of the problem. The unaware reader will certainly not appreciate its difficulty and not realize that it seriously matters for any attempt at decentralization in the process of plan making.

In the second place, Porwit does not spell out precisely the exchange of information between the central program and those dealing with the sectors. How, if at all, are the results of the sector calculations to be taken into account in the further complex calculations? Why should the consideration of prices based on incorrect information result in efficiency in sector calculations? Does he view the process as repeating itself several times? If so, how will it proceed? The reviewer believes these nontrivial questions are important if we want to make real progress in the theory of planning.

However, if such theoretical points are raised, it is because the book finds its place in the library of modern economic science. These questions are intended to invite us to go more deeply into the problem tackled by Porwit. In its present form, his monograph is already perfectly suited to help develop the communications between Eastern and Western scholars. Let us hope that many of the same quality are produced in the years to come.

Planning, Profit and Incentives in the USSR: Vol. I. The Liberman Discussion—A New Phase in Soviet Economic Thought. Edited by MYRON E. SHARPE. White Plains, N.Y.: International Arts and Sciences Press, 1966. Pp. xiii, 314. \$10.00.

This volume collects 31 translations of Soviet articles on the Liberman Proposals and other programs for economic reform in the USSR. The articles are arranged chronologically in three sections. The first two present the development of Professor Liberman's approach and nine responses, *pro* and *con*, to the formulation which has become known as "The Liberman Proposal." The third is a more heterogeneous assembly of 17 later pieces, dealing less

specifically with Liberman and more generally with the role of profits and prices in workable approaches to decentralization. Several of the articles in this section deal with a 1964 experiment in the clothing industry (since greatly expanded) under which the firm's product mix is determined not by orders received from above but by "direct contacts" with trade organizations (and thence with the market place).

The collection offers a good cross-section of one broad stratum of the economic controversy of 1962-65. Although it may be imprecise to describe this level as journalistic (14 of the contributions are taken from *Pravda*, *Izvestiia*, and other daily newspapers, and five others come from primarily political periodicals), the contributors very rarely penetrate to the efficiency implications of alternative administrative arrangements. In part, this reflects the effort of some of the reformers, including Liberman, to separate the implementation of central directives from their origination; they would rather not be suspected of favoring the chaos of the market over centralized, planned guidance of the socialist economy. The discussion, however, soon makes clear that this separation was not easily achieved, and that broader questions of allocative decision-making could not be avoided in the discussion of decentralized implementation. The host of Soviet contributors to this deeper issue are represented in this collection only by the late V. S. Nemchinov and by N. Fedorenko, both leading mathematical economists. Here too, however, the selections were intended for mass consumption.

The focus, then, is upon improving the implementation of central directives, primarily through rationalization of the incentive system. Although tending toward repetition, the articles represent an extensive critique of the Stalinist system, which, all participants agree, has outlived its usefulness. The problem, essentially, stems from basing managerial bonuses primarily on the fulfillment of physical output targets and the basing of those targets, often rather mechanically, upon previously achieved levels. The system generates an over-riding preoccupation with short-run quantitative performance and, more damaging, a strong tendency on the part of the firm to conceal its true capacity from their superior organs. Much of the material on this disfunctional behavior will be familiar from the writings of Berliner, Granick, and Nove, but these detailed observations from the horse's mouth provide authoritative, contemporary insight into the treacherous environment of the Soviet plant manager.

If often lacking in theoretical interest, the discussion is pleasantly free of ideology. One observes only a dogmatic subscription to pricing on the basis of socially necessary labor time, although the need for exceptions is granted and, more important, the definition of this fundamental Marxian variable remains a legitimate subject for debate. There is also a polemical defense of the use of the profit criterion against charges, of Western origin, of creeping capitalism.

So much for the general tone and content of the collection. Among the articles of particular interest are the early papers by Liberman, which provide a clue to the development of their author's thinking. The Liberman Proposals of 1962, to which most of the discussion has been addressed, have as their central elements: (a) retention of assigned output targets and of centralized allocation of critical inputs; (b) the transfer of much detailed operational deci-

sion making from the center to the firm; and (c) the introduction of "profitability," the ratio of profit to fixed and working capital (using Soviet definitions of costs, etc.) as the principal measure of managerial performance, source of managerial bonuses, and, therefore, as the principal objective of enterprise activity. This alteration in the role of the output target (combined with curtailment of administrative interference in plant management) would close the gap between the interests of the firm and of the State. Instead of concealing capacity in pursuit of a lighter output target, the firm would extend itself in pursuit of maximum profit. Profitability, then, is the key to decentralization: it assures rational exercise of the authority relinquished by the center to the firm. The apparent objective of the scheme is more efficient execution of centrally-set tasks, not the substitution of the market for the State Planning Commission in guiding resource allocation.

Liberman's earlier (1955) suggestion had the same objective and also relied upon profit as the basis of an improved incentive system; but here, the rate of profit was defined as a percentage of unit cost of production, the definition then standard in the Soviet Union. The idea was simple: detailed study of Ukrainian machinery plants had shown that the main source of reduction in unit cost was the spreading of overhead as output rose. If, therefore, unit cost as a per cent of price (or, what amounts to the same thing, profit as a per cent of unit cost) were made the main success indicator and determinant of managerial bonuses, the manager would be induced both to eliminate inefficiency in production and to seek higher production targets: profitability could be increased primarily by increasing output; output could be increased only by increased allotments of rationed inputs; such allotments would be granted only if higher output targets were accepted. By replacing the two dominant success indicators (physical output and cost reduction) by one, the incentive to seek lower output targets would be eliminated.

Why did Liberman abandon this approach? Several reasons suggest themselves: (a) not many industries may have been operating in the range of decreasing short-run average total cost; (b) to the extent that Liberman's cost data reflected economies of scale or changing production functions, strong pressure for increased investment would have been generated; and (c) profit rate targets for multi-product firms may not have proven as easy to generate as Liberman argued. This apparent failure notwithstanding, one may imagine Liberman persevering with the notion that in profit lay the "intersection," as later writers were to refer to it, of numerous variables then being separately planned *and* of the interest of the center and the firm.

Gatovskii's article, "The Role of Profit in a Socialist Economy," provides a concise statement of the position of what may be called the conservative reformers: the objective of reform is explicitly restricted to questions of implementation; profit should play a greater role (as success indicator, source of bonuses, and of capital accumulation) but it cannot serve as a guide to investment decisions (except in the choice between goods which are strong or perfect substitutes). In general, "... resources are distributed between branches so as to satisfy the totality of the growing requirements of society, in line, of course, with the available production potentialities."

But how the planners are to discover the latter—"The terms on which alternatives are offered"—Lange, quoting Wicksteed—is left unanswered (and unasked). The price system can play no role in the process since Gatovskii would adjust prices to eliminate disparities in profit rates, thereby also eliminating whatever weak and deceptive signals the latter may have represented. Gatovskii does allude to the possibility of a multiple price system which could provide useful information to the central planners, but this does not appear to be his intention. Like many of his colleagues, he is more concerned with the distributive than the allocative role of the price system. Allocation is a technical problem, to be treated in accordance with central policy.

The opposition denies that profitability can be trusted with the central role in the incentive system. As spread over the contributions of Zverev, Sukharevskii, and several others, a variety of arguments, of unequal merit, are made: (a) if, as intended, major allocations from firm profits are made to workers' bonuses and to decentralized investment, there is danger of inconsistency with central plans for the consumption and investment goods industries; (b) given the failure of Soviet prices to reflect the "importance" of different commodities, profit maximization will misguide what discretion the firm has over its output and input mixes (i.e., one pattern of misallocation will simply replace another); (c) under Liberman's scheme, each firm would be assigned a profitability norm which would become no less a bone of contention between the center and the firm than were the old output targets; and (d) in an economy as large and diverse as the Soviet, no single success indicator can be generally applicable.

In general, the critics rest their case with the identification of potential shortcomings. The rules of the game do not require consideration of the possibility that the proposed reforms represent an improvement over existing procedures. This may represent the "perfectionist bias" to which D. Granick has referred or, perhaps, an overriding distrust of any reduction in central authority over the firm. ("The chaos of the market place" may have more than ideological significance to potentially unemployed central planners.) In any event, the failure to compare outcomes renders this discussion less interesting than it might have been.

The articles by Nemchinov and Fedorenko offer the only cogent thought in the volume on the interaction between planning and implementation. The central point is stressed that decentralization by means of a rational price system facilitates rather than undermines central planning. Nemchinov draws interesting conclusions concerning the introduction of a capital charge, the limitation of central targetting to final rather than total product, and the substitution of State trade in intermediate products for the current centralized distribution system. While Nemchinov's general position will strike familiar notes with Western welfare economists, certain specifics raise doubts. Especially noticeable is the view of the capital charge and profits: profit norms are based on planned charges against fixed assets, the charges varying from branch to branch, and the charges are to be set in accordance with the branches' capital accumulation requirements. The capital charge, therefore, is a financing device (or income source) rather than a rationing device. On the practical level, Nemchinov's program presupposes rationalization of the price

system, an endeavor which seems to enjoy little appreciation and less support where it counts.

Fedorenko also argues for more effective central planning by substitution of "indirect levers" for administrative commands. He emphasizes the potential contributions of mathematical models, computers, and improved information flow to the coordination of economic activity. On the other hand, Fedorenko seems to share the view expressed by Belkin and Berman that not even the mightiest computers can save the centralist model from increasing inefficiency and waste. The major statement for the opposition is by G. Kosiachenko, who argues for the necessity of retaining (and improving) directive planning, increasing the role of profit in the economy, but abandoning all thought of decentralizing through a flexible price mechanism: "... any sort of automatic regulation of the enterprises' activities through price and profit fluctuations is out of the question under the conditions of a socialist economy, for that would mean a transition to spontaneous price formation." In part, his position seems to reflect a lack of appreciation of the possibility of harnessing "indirect levers" to planners' preferences; but he also scores valid points with his references to externalities. And so controversy proceeds: often repetitious and superficial, occasionally illuminated by institutional or theoretical insight; the "best"—which so preoccupies Western theorists—appears rarely, and then, most often implicitly, as the enemy of the better.

A concluding word on the translation. Clearly not being in command of economic terminology, the translators have all too often relied upon cognates and general dictionary definitions. The result is a liberal scattering of individual terms (e.g., "normative cost of processing") and whole sentences ("All material and technical resources are scattered among individual fund-holders . . . and individual detailed commodity positions.") which will tax the imagination of the nonspecialist reader.

BARNEY K. SCHWALBERG

Brandeis University

Langfristige Wirtschaftspolitik in Westeuropa. By KARLHEINZ KLEPS. Beitrage zur Wirtschaftspolitik, Vol. 5. Freiburg im Breisgau: Rombach, 1966. Pp. 524.

This book combines a survey of theories of economic planning with a report on past and present plans in the Common Market countries and the United Kingdom, Sweden, and Norway. French *planification* and the "social market economy" in Western Germany are analyzed in greater detail than the other systems. The last part of the book presents the special problems of economic planning for the European Common Market as a whole.

Kleps points out that there is a close relationship between basic concepts of economic theory prevailing at different periods and the economic policy measures taken by the industrialized countries of Western Europe and the United States. He calls the type of economic policy pursued by most European countries between the last decades of the 19th century and the great depression "Punktueeller Interventionismus" or phase I of government economic policy. A

more thorough discussion of this phase which was based on marginal utility theory and on Marshall's "Principles of Economics" would have helped young economists to get a better understanding of pre-depression theories of government economics. The next phase, called "Autonome Konjunktur und Beschaeftigungspolitik," or phase II, was stimulated by the problems of the great depression. This phase of economic policy and the economic concepts on which it was based are much better understood by contemporary economists than phase I. The book under review deals primarily with the policy which aims at promoting global growth, the so-called phase III. The author mentions the U.S. National Planning Association as the initiator of this policy which began to exert worldwide influence after 1946. Kleps does not concentrate on a comparison of growth rates, a topic more fully covered by Angus Maddison's *Economic Growth in the West*, but he describes the economic situation in which plans for each country were conceived and the special problems of several countries, e.g., regional problems in the Netherlands, the foreign trade situation in Norway, and the monetary and balance-of-payment situation in the United Kingdom. One of the strong points of the study lies in the presentation of many different approaches to planning. But this advantage is diminished by an overemphasis on the description of the instruments of planning. Kleps' book is weak in analyzing the regional problems of France and Italy that played a decisive role in the formulation of French and Italian policy. These problems are discussed more thoroughly in Barzanti's *The Underdeveloped Areas Within the Common Market*.

The author's economic evaluation of planning in general will satisfy those economists who are afraid of the trend towards *dirigisme* in all Common Market countries. Kleps does not agree with the views of conservative economists, e.g., J. Rueff, von Mises, the late W. Roepke and others, who are opposed to all economic policy measures except those designed to restore or sustain free competition. He envisages, though, the danger of increasing government intervention in all types of planning. While recognizing the merits of "Guidelines" or so-called *Indicative* planning as compared to centralized planning in a command economy, he points out that neither French *planification* nor the German "Social Market Economy" was able to cope with problems of stabilization. In contrast to those advocates of the French system who characterize *planification* as market research which supports rather than replaces the market mechanism, Kleps would fully agree with a statement by C. P. Kindleberger: "Information removes uncertainty but collusion removes it more thoroughly, either collusion with government or with other firms" (*National Economic Planning*, Universities-National Bureau Ser. No. 19, Princeton, 1967). In the last section of his book Kleps reviews several problems which face the Common Market Planning Board, especially questions of energy economics, transportation, and agriculture. The difficulty of finding a desirable average growth rate is aggravated by the fact that one country may aim at growth in agriculture while others have a faster growth of industry as their major goal. Even if the Planning Board were to accept E. F. Denison's conclusion ("Sources of Postwar Growth in Nine Western Countries," this *Review*, Proc., May 1967, 56, 325-32) that accelerated economic growth during the last fifteen years was

based to a large measure on the decrease of the labor force in agriculture in favor of increased employment in industry, governments would—for political reasons—still pursue a policy of subsidization of agriculture.

After discussing shortcomings of the "social market economy" in West Germany, especially the lack of coordination in energy policies and the insufficient allocations for education and health, Kleps suggests that one step towards greater economic stability could be found in a better coordination of financial policies of all public households (federal, states, and cities). He recommends that budgets should be formulated for several years. He finds that single-year budgets induce savings at the wrong places and are a cause of instability rather than instruments of sound fiscal policy. It seems that a number of the author's suggestions have been incorporated in the recent German "Economic Stabilization Law." Kleps and several other economists have voiced their dissatisfaction with monetary policies during 1966 which they hold responsible for the present "recession." It seems to this reviewer that a phase IV of economic policy may show a greater awareness of problems of stability in preference to policies to promote "growth at any price."

Business Fluctuations

Indicators of Business Expansions and Contractions. By GEOFFREY H. MOORE AND JULIUS SHISKIN. NBER Occasional Papers No. 103. New York: National Bureau of Economic Research, Columbia University Press, distrib., 1967. Pp. 127. \$6.00.

An Appraisal of Short-Term Economic Forecasts. By VICTOR ZARNOWITZ. NBER Occasional Papers No. 104. New York: National Bureau of Economic Research, Columbia University Press, distrib., 1967. Pp. xii, 144. \$5.00.

These books are the first in a series of National Bureau publications which will deal with topics in the area of forecasting. The study by Moore and Shiskin aims to improve the statistical tools available to forecasters. It (1) updates the list of NBER cyclical indicators and classifies them by timing and economic process, (2) develops an explicit scoring system for selecting indicators, and (3) compares the new list of indicators with previous lists.

The complete list of indicators does not differ drastically from the 1960 list, with five series dropped and thirteen others added; but the short list of particularly significant series has been substantially altered. In using indicators for analysis, forecasters have always implicitly assumed that the economy's structure is sufficiently stable so that the indicators will present an accurate representation of the future in addition to providing historical information. It would, therefore, have been interesting to have had a more detailed *analysis* of the reasons why series, which previously had been considered useful, were eliminated from the lists.

The scoring system is based on the significance, adequacy, conformity, timing, smoothness, and currency of the data. Each criterion is defined with weights assigned according to a number of characteristics. The arbitrary nature of the weights is recognized, and independent observers might have assigned different importance to each item.

However, it is important to determine whether the scoring system measures each series' usefulness for current analysis. First, only *historical* data are examined for their timing and conformity relative to NBER reference cycles. The way these data would have appeared on a contemporaneous basis or the number of false reported movements are never examined. Second, the relative accuracy of the early data and the extent of the errors are neglected. For instance, on one criterion, statistical adequacy, the scoring system favors series which report weekly movements and which indicate the size of subsequent revisions. The retail sales series reports both; the nonagricultural employment series, neither. Partially for these reasons, the statistical adequacy is .77 for retail sales and only .61 for the employment series. Other research has, however, indicated that the average error in the first available retail sales figures is 100 per cent of the mean monthly change, while the nonagriculture employment series is much more accurate. While the overall score did favor the employment series, surely, the criterion, statistical adequacy, in an *ideal* scoring system, would have included *accuracy* as one characteristic.

The scoring system, thus, is not entirely related to the uses for which the indicators are intended. Nevertheless, another set of indicators has been provided for current analysis. Hopefully, the analytical quality of these series will be demonstrated.

Zarnowitz's study evaluates eight sets of *ex ante* forecasts for the period 1957-63. All the predictions were generated by judgmental techniques; most are annual forecasts, but some provide estimates for quarterly intervals, and the predictions of one group were prepared quarterly. Zarnowitz has developed a large number of measures of the errors between the forecasts and the actual data. The discrepancies between the actual and predicted levels as well as between the actual and forecast changes of GNP, its major components, and industrial production were calculated. Zarnowitz correctly recognized that the difference between the predicted and actual changes is more meaningful than the discrepancies between the levels. This point might have been emphasized and less attention might then have been devoted to the level predictions, for forecasters should regard their task as predicting changes and not the data revisions which occur between the beginning and end of a forecast period.

The forecasts of the change in GNP displayed mean absolute errors which were more than 40 per cent of the mean absolute change. However, the GNP forecasts were still better than the predictions of some components, especially in the investment area, thus indicating the presence of offsetting errors. The types of discrepancies, underestimates, overestimates, and turning-point errors were all examined both for the annual forecast and the shorter span and intra-period forecasts. The root mean square errors of the forecasts were compared with similar measures generated by the "forecasts" of three naive models.

It is impossible to summarize all the results, but generally the GNP forecasts

outperformed the naive standards, while some of the sectoral forecasts were substantially poorer. Forecasters generally underestimated changes, and failed to recognize many turns, with both results in accord with previous findings. There was also no systematic uniformity between the size of the errors and the length of the span over which the forecasts were prepared.

This book should not be viewed merely as a historical record of the performance of particular forecasters. Rather the study should be considered as providing some valuable information for determining how forecasting techniques can be improved. First, the results of these judgmental forecasts can be compared with the projections of econometric models. This would enable us to determine which approach is better. Second, although Zarnowitz de-emphasizes this point, there is substantial variation between the records of the various forecasters, even though all used judgmental procedures. If it were possible to replicate the forecasting techniques of the *best* forecasters, it might be possible to improve forecasting procedures in general. Zarnowitz indicates that (1) the use of anticipation data improves the forecasts and (2) expert knowledge of particular sectors improves the projections of activity in these areas. Neither result is surprising, but both have implications for the development of forecasting procedures and the establishment of groups which make predictions. These findings plus Zarnowitz's competent handling of the statistical material make this a study which all economists who are interested in forecasting should read.

H. O. STEKLER

Board of Governors of the Federal Reserve System

The American Economy to 1975—an Interindustry Forecast. By CLOPPER ALMON, JR. New York: Harper & Row, 1966. Pp. xi, 153. \$9.50.

Professor Almon has documented an important milestone in the methodology of long-range economic forecasting. His book describes the first full-scale demonstration of how long-run employment and interindustry demand projections can be integrated with input-output analysis to produce mutually consistent forecasts of the American economy.

The main contribution of this work is "to integrate these parts into a unified, comprehensive, usable forecast of the whole economy" (p. ix). The final forecasts (not published) consist of the constant dollar sales of each of ninety industries to each of 144 markets for each year from 1963 to 1975, including intermediate demands, capital equipment investment, construction and ultimate use. These forecasts are summarized in a Master Table (pp. 153-70) which shows the fraction of the sales of each industry which will go to the various markets in 1975 and the growth rates of the various markets. Two additional rows on the Master Table show the distribution and growth rates of employment.

This comprehensive set of invisible industry sales forecasts is developed in two parts. In the first part, judgmental forecasts of government expenditures to 1980 and judgmental forecasts of exports and competitive imports to 1975 are produced. These forecasts assume no increase in defense and space spending beyond 1964 levels, with defense procurement actually declining

about 1 per cent per year, and exports and imports continuing a rapid but balanced expansion.

The second part involves a series of computerized iterations performed on the inputs to single-equation "structural forecasts" of each industry in order to determine a level of disposable income and consumption that is both consistent with the deduced investment, construction spending and inventory accumulation of each industry, given its sales, and at the same time produces a level of total product matching an independent projection of full-employment output. One cannot but admire such a grand conception and marvel at its successful completion.

Nevertheless, any potential user of these results must tread carefully if he is to avoid the pitfalls of credulity created by such a computer-maintained consistency and the quicksand of choosing to ignore the implications of Almon's clearly stated assumptions.

Consider, for example, the determinants of the level of the independently projected full-employment output to which all final industry projections are matched. These levels are calculated for each forecast year as a product of projected labor force productivity times a fully employed labor force. However, the industry labor productivity projections are all simple exponential extrapolations of historical trends from 1947 to 1963. "All the trends in automation, education, and shifting job structure in each industry are simply assumed to continue into the future. In particular, we have not investigated the effect of capital investment by an industry on its rate of change of productivity" (p. 128). Furthermore, full employment of the labor force (unemployment of about 4 per cent in 1970 and 1975) is to be obtained, it is assumed, by proper government policy.

The labor force projections, in turn, are developed by multiplying the projected age-eligible population by their projected labor-force participation rates. The population projection used in both the forecasts of labor force and consumption spending is "a moderately high series" (p. 120) selected from among several provided by the U.S. Census Bureau. The labor-force participation forecasts are BLS trends based on the assumption that future changes in participation rates will proceed at about 50 per cent of the rate of change from 1948 to 1964.

There is, of course, nothing particularly "consistent" about these assumptions (except, perhaps their optimism). The consistency of which Almon speaks concerns only the industry interactions *after* these technological and labor-force assumptions have determined the overall level of production and employment, given the judgmental forecasts of government expenditures, exports and competitive imports, and specification of the numerous single-equation structural models.

Amid the complexities and multitudinous assumptions of this important long-run forecasting document one searches for a relatively simple conclusion—a critical test of the quality of this particular formulation of the Almon theory of consistent long-run econometric forecasting. One such simple prediction derived from the specific quantitative theory presented in *The American Economy to 1975* is the projected rate of growth of disposable per capita income se-

lected by the iterative computer procedures as satisfying both the input-output consistency requirements and the full-employment final output projections. The specific Almon theory boldly predicts that disposable per capita income "is projected to grow 2.7 per cent per year instead of the 1.7 per cent per year which it grew between 1950 and 1963, or the 0.7 per cent per year it averaged during the 1956-63 period" (p. 47). "In the decade ahead the yearly growth of (disposable per capita) income will run more than double that of the last" (p. 25).

For the quality of the forecast conception, and its lucid, literate and frank presentation, we are deeply indebted to Almon. For the quality of the forecast proper, until time brings forth its own corroboration, we can only form our own private Bayesian judgment of credibility.

The Term Structure of Interest Rates—Expectations and Behavior Patterns
By BURTON GORDON MALKIEL. Princeton: Princeton University Press,
1966. Pp. xxi, 271. \$8.50.

In this volume, Malkiel develops an expectations theory of term structure which includes some elements of the hedging pressure and segmentation theories. In the first five chapters, he reviews the previous work in this field, reformulates the expectations theory so that it focuses on bond prices, and extends the theory to incorporate transactions costs. Malkiel then presents some evidence that the behavior assumptions underlying the expectational theories do not make sufficient allowance for institutional practices. The synthesis he develops is presented in a partial-equilibrium model which takes account of these institutional factors and also allows for some flexibility in supply.

Malkiel begins his analysis with several theorems on bond prices to show that for a given uniform change in yields the absolute change in bond prices increases, but at a diminishing rate. This suggests that prices of long term bonds of different maturities may behave more alike than will prices of short term instruments with different maturities. He next introduces the hypothesis of "a normal range of interest rates" which he uses to determine the first and second derivatives of the yield curve. He simplifies the analysis by assuming a linear utility function so that he works with the mathematical expectation instead of the expected utility. When interest rates are near the upper bound of the normal range, investors will move into long term securities and the yield curve will be negatively sloped. Conversely when interest rates are at the low end of the range, the likelihood of capital losses exceeds that of capital gains and investors go short and the yield curve is positively sloped. In either case, the price changes for most longer term bonds are roughly similar so that whether the slope of the yield curve is positive or negative it will tend to flatten out. The third step in his analysis is to introduce expectations explicit-

ly by assigning a subjective probability to the direction of interest rate changes. For example, at a time when interest rates are near the high side of the range, the market may assume that there is a high probability that interest rates will fall. The introduction of explicit expectations in this model affects the first derivative of the yield curve but does not generally change the second derivative.

This is the basic model. Malkiel shows how it can easily be modified to allow for the fact that short rates may fluctuate more than long rates, to remove the assumption of an invariant normal range of interest rates, and to include a Hicksian liquidity premium.

This expectations theory differs in some respects from the traditional theory. In the neo-classical Fisher-Hicks-Lutz theory, investors choose between short and long term securities on the basis of their expectations of future short term rates for an indefinitely long period. Malkiel assumes that investors think of a normal range of interest rates, plan in terms of a short horizon, and compare alternatives for this short period. In his model investors compare short term forecasts of long term interest rates unlike the investors of the traditional model who compare long term forecasts of short term interest rates. The two models lead to the same results if we assume that expected holding-period yields are equalized for any one holding period. In this case it can be shown that the market is implicitly estimating a set of forward long term rates as well as a whole series of forward short term rates.

In Chapter 4, Malkiel presents results of several empirical tests attempting to predict the differential between long and short rates. The basic idea underlying these tests is that when interest rates are high relative to their normal range, the short rate will tend to be high relative to the long rate. To avoid serial correlation and other biases, the author develops several formulations of the basic regression equation and tests these with three different interest-rate time series. The results all seem to indicate that short rates are more volatile than long rates and that the spread is a function of the gap between the current long rate relative to its normal range. These findings are interesting and suggestive and are consistent with the expectation theory he outlined. Although the author does not define explicitly the substantive content of an expectations theory, he nevertheless asserts that his results constitute independent evidence supporting the expectations theory; but since he does not identify the forecasting requirements on forward rates that distinguish an expectations theory, it is not clear how these tests discriminate among different expectation theories, or between expectation and non-expectation theories.

One of the most interesting chapters in the volume is Chapter 5, where Malkiel analyzes transactions costs and shows that their effects are likely to be felt mostly in the very early maturities. For this reason transactions costs may generate a "humped" yield curve from a curve that would otherwise descend monotonically. He also suggests that transactions costs could account for Kessel's finding that the bias (the amount by which the forward rate overstates future spot rates) varies over the cycle. In Chapter 6 Malkiel presents aggregate, cross-sectional data on institutional holdings and interview data to test the behavior assumptions of the expectations theory and the segmentation the-

ory. He finds that while most bond investors are not indifferent among maturities offering the same holding period yield, they do nevertheless substitute among maturities over a wide range of the yield curve. He also finds evidence that institutional investors have maturity preferences, diverse (non-uniform) expectations and that professional speculative activity may be circumscribed.

Malkiel concludes that neither of the two theories is satisfactory, and therefore attempts to synthesize the expectations and institutional theories in Chapter 7. He modifies the expectations model by introducing diverse expectations, transactions costs and maturity preferences and shows that these factors allow relative changes in supply to affect the term structure. But as expectations become more uniform, the term structure becomes less sensitive to changes in relative supplies. In the Appendix he presents a careful analysis of the circumstances in which a humped yield curve is likely to emerge.

He concludes his study with an analysis of "operation twist." Studies by Okun, Scott, Wood, and Modigliani and Sutch do not leave much scope for changes in relative supplies. But he is not entirely convinced by these studies because the effect of Treasury and Federal actions on the debt was not entirely consistent with the objectives of "operation twist." In addition he indicates that some evidence in favor of "twist" could be derived from his own empirical work and that of Wallace. He concludes that whatever changes in the yield structure did occur very likely resulted from changes in regulation Q and the effect of "twist" on the formation of expectations. This is a disappointing finding in light of all the intellectual effort that has been devoted to term structure theory.

This volume provides a systematic treatment of the subject, covering both the analytical and institutional aspects, and should prove to be especially helpful to students of monetary economics.

Household Capital Formation and Financing 1897-1962. By F. THOMAS JUSTER. National Bureau of Economic Research Series No. 83. New York: Columbia University Press, for National Bureau of Economic Research, 1966. Pp. xiv, 146. \$6.00.

This volume represents another addition to the National Bureau's continuing research program in consumer credit, a field in which it has pioneered for many years. In this monograph Mr. Juster offers a concise quantitative analysis of household capital formation (expenditures on household durable goods and household construction) and of certain global aspects of the means of financing it. Beyond the mainly quantitative approach, the author provides a limited amount of theoretical analysis, including an examination of certain important conceptual problems.

Initially, he elects and defends treating purchases of household durables as investment. He then examines trends in household capital formation and relates them to trends in business capital formation. In contrast to the persistent decline in the ratio of gross business investment to GNP, reflecting essentially

a relative decline in investment in business structures, Juster finds that gross expenditures on major household durables and household construction constitute a rising ratio of GNP. Indeed, whereas in the earlier part of Juster's survey period, the business sector had a strongly dominant share in gross capital formation, toward the end of the survey period the household sector had become slightly more important than the business sector. Moreover, the secular decline in the ratio of gross capital formation to GNP (when the former is confined to the business sector) disappears when the ratio is recomputed to include household capital formation and government civilian construction. If expenditures for research and development and for education are included in the numerator, which Juster considers appropriate for analysis of growth, there is a clearly rising over-all ratio. Juster also takes note of the apparent understatement of both business and household capital formation, mainly in the construction components, because of deficiencies in indices of construction costs. As a result, previous estimates of the ratio of capital formation to GNP in constant dollars may have a considerable downward bias.

In consumer credit the expected basic trends are confirmed: growth in installment credit outstanding has substantially exceeded that in the stock of durable goods and there has been a large rise in the ratio of household debt to household assets. The ratio of household debt to business debt has risen sharply, with recent changes in the absolute amounts of each form of debt reaching near-equality. Juster finds that "a major cause of the expansion in [household] credit use has been a persistent secular relaxation in credit terms" and suggests that "the secular relaxation in credit terms is best interpreted as a secular decline in the effective cost of borrowing."

A cyclical analysis follows. Over time Juster finds declining relative cyclical amplitude in business capital formation. He also finds absolute cyclical amplitude in household capital formation shifting from a fraction of that in the business sector to an amount exceeding it, with non-structures of major importance in both areas. At the same time, absolute cyclical amplitudes in short-term and total credit are found to be similar for both business and household sectors in recent years. Adding timing relationships, Juster finds—as others have before—evidence of a causal link running from consumer credit to consumer outlays to business cycles. Thus he is led to the conclusion that an "obvious implication of these findings is that analysis of business cycle movements should be at least as much concerned with the behavior of households as with the behavior of business firms."

This work presumably is not intended to make its mark in terms of presentation of mainly new or original materials: its *raison d'être*—and a good one indeed—is its presentation of a convenient, up-to-date summary and interpretation of the basic data in the areas covered, plus a restatement and vigorous defense of recent thinking with respect to underlying concepts, to which Juster himself has made a number of contributions. Juster does this well and so reinforces the case for certain changes in conventional thinking, particularly with respect to the concept of capital formation, while making it easier for workers in the field to push on further. His findings and analysis offer a challenge to

business cycle theorists. They will also be useful to makers of economic and financial policy.

Regulation of Interest Rates on Bank Deposits. By ALBERT H. COX, JR. Michigan Business Studies Vol. xvii, No. 4. Ann Arbor: Bureau of Business Research, University of Michigan, 1966. Pp. xii, 207. \$6.00.

Since the advent of high interest rates in recent years, discussions on the constraining effects of legislated ceilings on bank deposit rates have become topical. The present book adds to a greatly needed discourse on the role and effects of the regulations governing the maximum rates allowable on bank deposits.

The author commences by tracing the arguments which supported adoption of the regulations on bank deposit rates and finds the dominant argument to be that excessive competition among banks threatens the solvency of the banking system. This proposition of "destructive competition" raises two questions: (1) does economic analysis suggest that destructive competition is inevitable, and (2) has there been any empirical evidence indicating that destructive competition existed in the past when deposit rates were unregulated.

The inevitability of destructive competition is dismissed by the author as he claims (without the benefit of supporting evidence) that the market structure of the banking sector is an oligopoly-oligopsony structure and hence not one in which destructive competition will prevail. Somewhat more complete is the author's inquiry into the question as to whether rate competition on deposits has ever been a major cause of bankruptcies. His sincere efforts to obtain data which would cast some light on the question are apparent. Unfortunately, the question remains unresolved, primarily because of insufficient data on individual banks during the period prior to the regulation imposing the rate ceilings. Nevertheless, the author's position that intense rate competition was not an important cause of bankruptcies during the period under investigation is not implausible in the light of available data.

Pointing out the close substitutability of bank deposits for deposits of other financial institutions, the author further argues that the consequences of the ceiling on deposit rates have been to restrict the level of commercial bank deposits relative to those of other financial institutions. Happily, the data do support the widely-held belief that the composition of public holdings of various types of securities is responsive to the relative rates of return. With bank deposit rates at the ceiling, increases in rates paid on deposits of other institutions led to declines in bank deposits relative to total deposits. However, the author makes too much of this as he then argues that the final result will be to affect unfavorably the allocation of credit within the financial sector. Before this conclusion is warranted, it must first be established that marginal shifts in deposits among financial institutions will in fact lead to differences in the aggregate composition of assets held by all financial institutions and thereby appreciably affect the ultimate flow of funds to issuers of primary debt.

Discussions of deposit rate regulations raise some disturbing theoretical

questions which, unfortunately, are not brought up in the book. Notwithstanding the author's assertion that the banking sector has an oligopoly-oligopsony market structure, if deposit rates are not regulated what is the equilibrium rate of interest on demand deposits? And perhaps more importantly, what happens to the price level? These are not unrelated questions: a merchant willing to sell his product at a particular price when no interest is paid on demand deposits will surely be willing to take a lower price if he receives a stream of interest payments in addition. Interest-bearing money is simply worth more than non-interest-bearing money and the price level will reflect the higher value of the former. The higher the interest rate paid on demand deposits, the lower the price level will be. While there has as yet been no evidence uncovered which would suggest that such adjustments as outlined above have taken place, analysis suggests that they would take place. The gains from the elimination of the rate ceiling must be balanced against the potential losses due to the deflation that may result.

Moreover, if it is conceded that interest rates on demand deposits will rise above zero when the regulations are removed, there can be little doubt that the redistribution of income from banks to the public (via the interest payments) will decrease the rate of return in the banking industry. Further research is required to determine whether this redistribution ultimately holds good or ill for society.

Underlying the policy questions as to whether interest rates on bank deposits should be regulated is a host of theoretical questions yet unresolved. As usual, the definitive answer must await the results of additional research. The present book adds very little to our understanding of the theoretical issues involved but makes a contribution by providing empirical evidence that should prove valuable in future discussions.

WILLIAM R. RUSSELL

Analytical Methods in Banking. Edited by KALMAN J. COHEN AND FREDERICK S. HAMMER. Homewood, Ill.: Richard D. Irwin, 1966. Pp. xv, 599. \$12.50.

Operations research in banking, by comparison with industry, is still in a preliminary developmental stage. Cohen and Hammer have been in the forefront of many of the pioneering efforts in banking. This book presents a series of articles which the editors presumably feel are the cream of the operations research crop in banking.

After a somewhat rosy-viewed introductory chapter by the editors, the book divides itself into five major sections. The three sections on trust department and bond department operations and "Other Banking Problems" contain a substantial amount of material of relevance primarily to the large diversified metropolitan bank. Although these sections include some reprints of outstanding articles, particularly those by Markowitz, Sharpe, Fisher, and Kessel, it would be stretching it to suppose that medium or small size banks could derive much practical support from research of this nature. Other notable contributions include Crane's simulation model of corporate demand deposits and

Benston's study of economies of scale and marginal costs in banking, the latter being exclusively concerned with small banks.

The bread-and-butter banking problems of bank asset management and lending and credit policy are covered in the first two sections. Here the most ambitious efforts include the well-known Charnes-Chambers linear programming model for bank portfolios, the credit scoring and risk measurement studies of Myers and Forgy, and Paul Smith; and Hester's canonical correlation study of the commercial bank loan offer function. A glaring omission in the articles on bank asset management is Porter's *Yale Essays* study of bank portfolio selection. Another omission is related to the use of statistical marginal cost and marginal revenue estimates for asset and liability management in banking. Benston's study, while certainly one of the best of its kind, is dependent on cost accounting data. A substantial component of costs cannot be allocated by cost accounting methods; hence, Benston's marginal cost estimates are of rather limited validity.

Charnes and Chambers demonstrate clearly that, so far as the formalities are concerned, it is possible to develop a linear program for bank asset management that can accommodate both multiperiod horizons and, if necessary, chance constraints. Unfortunately, the actual constraints used by Charnes and Chambers are extremely artificial, being based on that strange amalgam, the Federal Reserve's "Form For Analyzing Bank Capital." Only a fraction of the real effort required in applying linear programming to an actual bank has been undertaken by Charnes and Chambers. This effort would consist in eliciting from bankers themselves meaningful formulations of the constraints under which they operate. As it stands, Charnes-Chambers is merely an exercise or prospectus. The same artificiality surrounds the IBM-McKinsey bank-management simulation, a description of which is also included in this volume. Here, at least, it is admitted that the IBM game is intended merely as a training device. Hester demonstrates that canonical correlation, a somewhat neglected statistical tool, can help describe aspects of economic behavior, particularly the terms on which loans are granted. The normative relevance of Hester's technique is much less evident. Once again, a sophisticated methodology is expounded, but the hard task of successful practical application remains to be performed.

At times, the book has overtones of a revolutionist's handbook. This is particularly true in those portions devoted to the trust investment function. The Markowitz and Sharpe articles suggest not only that the one-period portfolio selection problem has been solved in principle, but that efficient computational techniques exist for the approximate execution of E-V analyses. The security evaluation model of Ahlers (SEM) creates the impression that a mechanical forecasting method based on exponential smoothing of earnings per share, an estimate of the pay-out ratio, and a measure of the variance in earnings can produce better forecasts of rates of return on securities than the usual techniques used by security analysts to select undervalued securities. Moreover, Ahlers' technique is not really compatible with the insights of the security analyst. Better results are obtained by SEM alone or by orthodox security analysis alone than by any combination of the two. By strong implication, the se-

curity analyst, viewed as a predictor of undervalued securities, is technologically obsolete. If that is not enough, Clarkson's study suggests that the decision-making process of the trust investment officer in buying and selling securities can be very effectively simulated, leaving him free to take very long (permanent?) vacations from his erstwhile duties. The trust department section ends with a crude method for rating the management of investment funds by Jack Treynor, which only serves to remind the reader of the severe judgments against investment fund performance that other studies have presented. In a nut shell, one might conclude that existing trust investment management is ripe for euthanasia by operations research.

This raises a very fundamental and important point with regard to the function of operations research and the prospects for a general operations research revolution in the management of large corporations. The main obstacle is fundamentally one of cost. Under current conditions, operations research is an extremely expensive method of making many types of decisions. The expected payoffs from developing sophisticated analytical techniques must be very substantial before it becomes an effective substitute for ordinary seat-of-the-pants management methods. While the relative cost of operations research is likely to decline as successful applications gain widespread and standardized dissemination, there are few such techniques now available in banking.

The most unequivocally successful operations research applications in banking are of a much less ambitious nature than those related to bank asset management, or trust investment. The volume contains three outstanding examples. Michener and Peterson provide a well-reasoned and effective strategy for deciding on the optimal pursuit duration for collection of defaulted loans; Cohen and Hammer, building on earlier work, provide a technique for determining the optimal coupon schedules for municipal bonds; Byerly demonstrates how Monte Carlo methods can improve scheduling of tellers. In each case the problem is of limited scope, and is well defined and constrained.

One area in which an operations research breakthrough would be worth the cost is corporate cash management and bank lending strategy. The model of corporate demand deposits developed by Crane is definitely a step in the right direction, one in which much more work needs to be done. Crane rightly includes nonprice variables, such as mechanical services and credit services provided to corporations as factors affecting their demand for deposits. However, Crane does not fully develop a hypothesis as to the significance of such items as lines of credit, compensating balances, and the prime rate, and other terms imposed in connection with the corporate customer relationship.

In summary, Cohen and Hammer have provided a very useful service in gathering together a wide variety of material relevant to bank management. Their introductory comments and appraisals of each article are thoughtful and constructive. The most valuable contribution of this volume is at the academic rather than the practical bank operating level. For the first time a text is available to support a course in bank management, having serious intellectual content. On the practical level, while the book is short on examples of demonstrably successful OR applications in banking, one could use the materials collected here as a sales promotion kit to interest workaday bankers in

experimenting more fully and aggressively with quantitative methods of many sorts, not simply those outlined in this volume.

GEORGE R. MORRISON

First National City Bank, N.Y.

Federal Reserve Monetary Policy 1917-1933. By ELMUS R. WICKER. New York: Random House, 1966. Pp. xiv, 221. \$5.95.

An oft-told tale is recounted in Professor Wicker's volume. It is a tale which never loses interest and never fails to intrigue. The main developments of this period are well known. This most recent study fills in many a significant detail of great interest to students of central banking.

Wicker's study is based on various primary sources: The Goldenweiser, Harrison and McAdoo papers, the Hamlin diaries, the Leffingwell letter books, the minutes of the Federal Reserve Board and the minutes and related papers of the Open-Market Investment Committee and the Open-Market Policy Conference. Lester Chandler's biography, based on Governor Strong's papers, provided important information as did the official publications of the Reserve System and the testimony taken before various Congressional Committees. The author restricted himself in the main to a fairly narrow, although important, focus: the attitudes of the Treasury and Federal Reserve officials on various questions as reflected in their writings and their votes on specific issues.

Probably no central banking system in its early years had to function within a more turbulent environment than did the Reserve System. One has only to recall the pre-World War I gold inflow, the then unprecedented problems of war finance, the deflation of 1920-21 which engulfed practically the whole world, the tariff policy of the American government which imposed a heavy burden on foreign debtors, the insistence of the American government that war debts be collected, the demands of the Allied powers for reparations, the machinations of the security affiliates, the epidemic of bank failures in the 'twenties, the overvaluation of the pound and the undervaluation of the franc, the speculative mania of the 'twenties and the overall decline in credit quality, the unwillingness to use fiscal means to combat the Great Depression (tax rates were raised in 1932), the breakdown of the foreign exchange patterns in the early 'thirties and domestic and international liquidity crises. At the end it was President Hoover who proposed a guarantee of bank deposits. If this had been implemented, say, in the middle of 1931, the United States might have been spared the ordeal of plunging into the secondary phases of the depression.

Wicker believes that the growing use of economists "will improve monetary behavior." One hopes that this may be the case. The interpretation of the passing scene is, however, often more an art than a science. And an art it doubtless will remain despite the profusion of data which serve as grist for the economists' mills.

Economists are prone to fall prey to the one-criterion fallacy of central bank policy-price level stabilization, the money supply, full employment, or whatever. In their enthusiasm they are apt to neglect other factors and forces and to become victims of the one-criterion approach in much the same way as

were the rigid gold standard adherents of an earlier period. A central banker needs flexibility of approach, the ability to see the whole forest despite the attractiveness of individual trees.

Above all a central banker must not overlook changes in the quality of credit. One has only to recall the speculative mania in farm lands in World War I, the inventory speculation of 1919, the decline in the quality of bonds and mortgages in the 'twenties, the use by Austrian and German banks of short-term funds to finance long-term projects and the deterioration of acceptance credits, to see the relationship between these and the ensuing developments of the 'thirties. Fortunately, academicians now are placing more emphasis on this extremely important topic.

In recent years it has been customary among economists to adjust their spectacles, to sharpen their pencils and to grade the Reserve System on its performance. If one were to lapse into this pedantic exercise, he would conclude that the Reserve System emerged from World War I with a record which excelled that of the Treasury. It emphasized the need for savings, it opposed the low interest rate policy of the Treasury, it urged that war paper be kept out of commercial bank portfolios. Similarly in World War II, the Reserve System emerged with a better record than the Treasury.

In World War I Federal Reserve credit took the form of loans to member banks instead of open-market operations, which means that in the postwar period the Reserve Banks could bring pressure on member banks to repay their loans and commercial banks in turn could bring pressure on their customers. Some of the excess credit was squeezed out of the banking system. The postwar decline in prices was looked upon as a normal reaction to war and postwar inflation. The policy followed in World War I restored part of the purchasing power of money at the cost of depression, that of World War II has led to a continuous erosion of purchasing power.

In the 'twenties, the Reserve System tried to recreate the pre-1914 world in a totally inappropriate economic environment. Trade barriers, the growing burden of unproductive debt, the restoration of exchange rates at unrealistic levels, the effect of the gold exchange standard as a credit multiplier, the growing arrogance of economic nationalism posed an unrelenting threat. The means adopted in the hope of restoring the one-world concept were financial, the lowering of interest rates in New York to promote the flow of funds to London and to induce the French to take the gold they wished from New York. These policies established interest rates which, President Schacht of the Reichsbank pointed out, could not be maintained. As interest rates rose under the influence of the speculative mania, pressure was placed on some European currencies and the situation was worse than if the United States had, from the outset, geared credit policy to domestic developments. Wicker's emphasis doubtless precluded his own interpretations of these developments which, if they could have been included, would have imparted life to an interesting record.

Similarly the Great Depression is replete with episodes which carry meaning for the present. To be sure, the United States has not repeated the tariff mistakes of that period and is able to rely, as it was not then, on the income

sustaining effects of the built-in stabilizers. However, heavy reliance upon a growing volume of Eurodollars as a means of financing credit needs and equally heavy reliance upon sharp increases in negotiable time certificates of deposit as a means of enlarging bank funds may be laying the basis for future international and domestic liquidity crises.

Have the monetary lessons of that period made an impress? Are we avoiding mistakes in policy, not necessarily the same mistakes but others, which will incur the criticisms of future economists? The decline in credit quality neglected in the 'twenties is being neglected again. Lending terms have been liberalized, loan maturities extended, down payments reduced, protection is thinned, repayments are predicated upon a concatenation of favorable circumstances, bank lending officers come to the fore who have no knowledge of or experience in recessions. Bank credit is being used to finance all types of credit needs. The growth in foreign debt exceeds the ability of many foreign nations to repay. The Administration and the Congress show reluctance, to say the least, to balance the federal budget at high levels of employment. All gold exports are offset by Federal Reserve policy. Other nations are expected to underwrite the balance of payments deficit of the United States. Controls are invoked to obtain temporary surcease. The interest rate curve is twisted and then untwisted. The illiquidity of banks and business firms increases. Consumer indebtedness soars. Consumer prices rise and cost push exerts its virulent influence. So many are the resemblances to the 'twenties that it would appear that not only have we learned no lesson but we seem to be repeating the mistakes of that decade with renewed vigor and determination. Whether performance is better or worse than that of the 'twenties and 'thirties will be left to the judgment of some future historian of the Federal Reserve System who will examine the records with the same diligence as did Professor Wicker.

BENJAMIN HAGGOTT BECKHART

Poughkeepsie, New York

Public Finance; Fiscal Policy

Fiscal Policy for Economic Growth in Latin America. By the Joint Tax Program of the Organization of American States, Inter-American Development Bank, and Economic Commission for Latin America. Baltimore: The Johns Hopkins Press, 1965. Pp. x, 462. \$12.00.

This volume, containing the papers and proceedings of a conference held in Santiago, Chile, in December of 1962, includes papers by V. L. Urquidi, R. Desai, N. Kaldor, A. Harberger and J. H. Adler on the more general aspects of development finance; and by R. Goode, D. Jarach, A. Prest, J. Naharro and H. Wald on the reform of particular taxes. Finally, there is a paper by C. Cosciani on tax coordination in a Latin American common market, and a summary report of the views arrived at by the conference. Each of the main papers is followed by lively discussion, and though geared to the needs of Latin American countries, most of the material is applicable to a much broader setting. In all, the volume is much superior to what usually emerges from confer-

ences of this sort and makes excellent reading for a course in development finance.

The conference was organized in the context of the commitments undertaken by Latin American countries in the Charter of Punta del Este. Including policies to secure a growth rate of 2.5 per cent and a more equitable distribution of income, these commitments (if such they are) present a formidable challenge to tax reform in South America. There is general agreement in the Report that to meet it, a substantially higher ratio of tax revenue to GNP must be reached. Also, there is general agreement that it is well within the countries' economic and administrative capacity to do so. There is somewhat less general agreement on the proper scope and potential of tax policy as a redistributive tool; but the gist of the discussion is that the prevailing distribution of income is intolerably skewed and that much more needs to be done, especially in securing a more adequate tax contribution from property income.

The present system of indirect taxation should be simplified by replacing the multiplicity of specific taxes with a more general tax, be it of the sales or (there being some controversy on this) of the value added tax variety. This general tax should then be supplemented by a set of progressive excises in items of luxury consumption, both home produced and imported. No reference is made to an expenditure tax.

Reform of the individual income tax should aim at a unitary system, going beyond the global complementary tax now used by many South American countries as a supplement to a basic proportional tax with source withholding. The base should be defined broadly including capital gains, with constructive realization at death or transfer. (If this has been politically impossible to apply in developed countries, it seems a bit ironic to recommend it in the LDC setting!) Rates should be realistic and, according to most (but not all) participants, not above 50 per cent. Agricultural income should be included and be subject to income tax as distinct from land taxation. If capital income is to be taxed more heavily than work income, this should be accomplished not via a surcharge under the income tax, but a supplementary flat rate tax on net wealth. While requiring additional administration, the net wealth tax may also be used to strengthen the enforcement of income tax.

Passing over the discussion of transfer and corporation taxes, we proceed to what may well be the most important set of recommendations, relating to land taxation. It is agreed that the contribution of land revenue falls far short of what it should be, and that more effective land taxation is essential not only as a matter of revenue but also as a matter of economic policy. Present land use is highly inefficient in many cases, and this tendency is made worse by under-taxation. The discussion examines various devices to make land taxation more effective. These include better valuation surveys and simplified assessment methods, as well as a self-assessment scheme which entitles the government to purchase at the declared price. Also consideration is given to assessing potential or average rather than actual crops, to using progressive rates, and other devices to improve incentives for more efficient utilization.

In all, the volume shows that the needed directions of tax reform are fairly clear-cut and that there is substantial agreement among economists and tax

experts as to what should be done. Nor are the administrative obstacles of a prohibitive sort. If progress has been slow, the explanation I fear lies in the political obstacles which block a genuine acceptance of the objectives set forth in Punta del Este.

R. A. MUSGRAVE

Harvard University

Fiscal Harmonization in Common Markets: Vol. I: Theory; Vol. II: Practice. Edited by CARL S. SHOUP. New York and London: Columbia University Press, 1967. Pp. xx, 468; xxi, 674. \$30.00 the set.

This thorough and meticulous study was initiated in 1962 and guided by the skilled hand of Professor Shoup. The contributors, who met frequently at Columbia University, attempt to develop a theory of fiscal harmonization and to apply it to particular problems and regions.

D. Dosser in the first chapter blends ingeniously positive and normative principles of the theory of international trade with those of the theory of public finance, while keeping the discussion close to the important current issues. The chapter also serves as a base from which the forays of later chapters spring.

In the second chapter H. Shibata constructs a theory of free trade areas with emphasis on measures to prevent trade deflection. Unlike Dosser, who assumes fixed exchange rates between members of a union, he permits exchange rates to vary.

In Chapter III W. N. McNie explores some of the implications of transport costs for a discussion of the respective merits of the origin and destination principles of indirect taxation.

Chapters IV and V, by Dr. Norbert Anel, deal with the harmonization of public expenditure. Cost-reducing government expenditures are used to develop a theory of expenditure unions. The effects of social security expenditures on the mobility of labor are also examined. Without committing any of the widespread fallacies about the need for harmonization in this field, Anel argues that harmonization forms an important element in the functioning of a common market.

Volume II contains chapters on problems of particular common markets and free trade areas, what they have done and what they plan to do. The European Common Market dominates the discussion, but the Central American Common Market, the Latin American Free Trade Area, East Africa and Soviet Economies are also considered in detail. Dr. Clara Sullivan discusses indirect taxation in three chapters and Dr. Peggy Musgrave direct taxation in two. Dr. G. K. Shaw explores stabilization policies and relates them to tax and public expenditure harmonization. Professor Shibata follows with a chapter on tax harmonization in EFTA. Marion H. Gillim reviews these problems for the Central American Common Market and the Latin American Free Trade Area. J. F. Due and P. Robson discuss the East African Common Market and finally R. Bird ends the volume with an analysis of harmonization in Soviet countries.

It is possible to select only a few points from this large volume of valuable

material. It is curious to say—as Dosser does—that competition (in which the success of one implies the failure of others) is a good synonym for “expansion of individual choice and opportunity” and to equate it to “freedom of firms to produce where they will, for consumers to have a wider range of material (and cultural) enjoyment, for people to live and work where they will.” Competition, as a means, may or may not have these *results*, but so may cooperation and many forms of restriction. Dosser dismisses definitions of integration which are couched in terms of vague aspirations, but the identification of means and ends does not reduce such vagueness. Dosser’s discussion should be contrasted with Bird’s interesting discussion of integration and harmonization in COMECON.

The analysis of public joint-benefit expenditure whets one’s appetite for more, both in Dosser’s and in Andel’s chapter. One would have expected a deeper analysis of the appropriate formula for cost-sharing. Neither the question whether GNP or National Income, nor the problem of the valuation of goods and services (market prices or factor cost? purchasing power parity or national prices converted at equilibrium exchange rates?) is discussed.

R. Bird’s chapter in Volume I on regional policies in a common market raises questions which are now increasingly discussed not only in a regional but also in an international context. Much of existing theory is built on the assumption of either complete immobility or completely free mobility of all factors. But very different conclusions emerge if partial mobility of some factors is assumed. In particular, many of the implications of *laissez-faire* and *laissez-passer* have to be radically modified.

Institute of Development Studies, Sussex

Accelerated Depreciation in the United States, 1954-60. By NORMAN B. TURE. National Bureau of Economic Research Fiscal Study No. 9. New York and London: Columbia University Press, distributor for National Bureau of Economic Research, 1967. Pp. xix, 238. \$7.50.

This book is the first, other than two conference volumes, in the National Bureau’s project on the relation between tax policies and economic growth directed by the author of this study. Its purpose is to shed light on one of the most popular postwar fiscal devices adopted by governments throughout the world—accelerated depreciation. He deals with the changes made by the Internal Revenue Code of 1954 permitting two new methods of depreciation—the double-declining-balance and the sum-of-year-digits—and not on the developments of the 60’s—guide-line lives and the investment credit, although these are to be studied later.

Ture asks the important question: to what extent did these provisions stimulate capital formation? In his search for answers he focuses primarily on the extent to which these provisions have been used by business firms, since non-use would preclude their having any investment stimulus, on the revenue losses resulting from these new methods, and, finally, on relating the order of magnitude of the change in profitability and flow of funds to the demand for additional capital goods.

The major part of his study is concerned with the first question. He bases his analysis of use on Treasury Department data. For unincorporated enterprises, data are available only for 1959. There are some data for all of the years for corporations based on special samples, and a highly detailed study "Life of Depreciable Assets" made for 1959 with broad coverage. He analyzes these data to determine the extent of use of accelerated depreciation by type of business organization, industry, service life of assets, type of facility, and size of firm, with many cross tabulations presented (more than half of the book represents tabular presentations).

The mass of detail defies simple description in a review, but some findings are of especial interest. There was clearly some kind of learning function associated with the accelerated-depreciation provisions. The percentage of corporations using declining-balance rose from 8 per cent in 1954 to 24 per cent in 1960; those using SOYD rose from 5 per cent to 6 per cent. Because some may use both methods, the proportion using straight-line alone in 1960 stands at a startlingly high 70-75 per cent. If we look at assets acquired by corporations from 1953-1959 on hand in 1959, only 45 per cent were under accelerated depreciation. Evidence is more limited for unincorporated enterprises, but they appear to have used accelerated depreciation much less. Despite the fact that the proportion of yearly acquisitions of assets placed under accelerated depreciation was probably rising (although direct information is not available), these percentages are so low as to demand explanation.

Why did so few companies avail themselves of what in most circumstances would increase their present value? The question is whether firms failed to use it for rational or irrational reasons, or sheer ignorance. There are obvious reasons why not all assets acquired would be covered—second-hand facilities and assets with service lives of less than 3 years were ineligible—although this surely could account for but little of the total. Utilities might have had their troubles with regulatory commissions, but 42 per cent of their post-1953 acquisitions were on accelerated depreciation, second only to manufacturing (57 per cent) among major industry groupings. There is enormous variation by size of firm. Use varied from 15 per cent of post-1953 acquisitions for corporations with assets of less than \$1 million, to 17 per cent for those with assets of from \$1 to \$25 million, to 68 per cent for the largest size class. There is still much to be explained, and perhaps the Hall-Stainbach interview studies forthcoming in this series will further illuminate these puzzles.

Ture then proceeds to estimate the corporate depreciation added in 1959 by the accelerated methods—about half of straight-line depreciation on post-1953 additions—in manufacturing and public-utility corporations with assets \$25 million and over. This amount converted into percentage tax reduction, however, tells a different story. The smallest size corporation received 7.5 per cent reduction, while the largest received only 6.1 per cent. Nor is manufacturing the major gainer (5 per cent) in this sense, being superseded by service (17 per cent), agriculture (8 per cent), and utilities (6 per cent).

Finally, Ture uses his estimate of the change in 1959 tax liabilities (\$1.3 billion) as a shift in the supply of funds schedule and Terborgh's estimate of percentage change in yield as a shift in the demand for assets schedule to ar-

rive at an estimate of the effect on corporate outlays in 1959 of not less than \$1.3 billion and as much as \$2.7 billion. I think his conclusion here is incautious. The simple supply-demand analysis can certainly involve double counting (in a perfect capital market), the percentage change in yields may be irrelevant, if ignorant, the mechanical application of various elasticities does not inform us of their legitimacy, and the time response of demand is unclear. It is hard to relate it to the Jorgensen-Hall estimates (AER, June 1967) of the effects of 1954 accelerated depreciation. But by the same token, the questions raised by Ture's study on the limited use of accelerated depreciation requires modification in its effect on the Jorgensen-Hall computation of capital cost. It is not their computation that is relevant, but that of business firms as they learn about these provisions or remain ignorant.

International Economics

Theoretical Issues in International Economics. By M. O. CLEMENT, RICHARD L. PFISTER, AND KENNETH J. ROTHWELL. Boston: Houghton Mifflin, 1967. Pp. xiii, 449. \$6.50; paper, \$5.25.

This is an ambitious book. Its stated purpose is to review a number of contemporary issues of international economic theory "which in particular have received widespread and intensive attention in the last two decades and in which signal contributions have been made" (Preface, p. viii). Each of the chapters is designed as a "survey article," to develop and compare ideas and concepts that have emerged from specific theoretical discussions in the literature. In all, nine topics are treated—every one an old, familiar friend. In Part I, under the heading of Pure Trade Theory, four chapters examine "Trade and Relative Factor Prices" (the effects of trade on factor returns), "Trade and Relative Factor Supplies" (the effects of factor supplies on trade), "The Terms of Trade," and "The Theory of Customs Unions." In Part II, under the heading of International Monetary Theory, five chapters examine "The Adjustment Mechanism in International Payments," "Exchange Rates: Fixed or Flexible?," "Elasticities and Absorption in Devaluation Analysis," "Persistent Disequilibrium: Dollar Shortage and Dollar Glut," and "The Adequacy of International Reserves." Each chapter is accompanied by an extensive bibliography of the literature through mid-1964.

On the whole, I think the volume is a triumph. Professors Clement, Pfister, and Rothwell have digested scores of articles and monographs representing the output of an entire generation of international economists—a gargantuan task in itself. Moreover, in their reviews they have respected both the complexity of contemporary issues and the subtlety of theoretical discussions. And even though they were individually responsible for drafting separate chapters, they were collectively successful in minimizing stylistic differences, substantive inconsistencies, and avoidable redundancies. Consequently, they have produced a volume of extraordinary usefulness—nine autonomous survey articles, all of

high quality and some (especially Chapters 1, 3, 6, and 7) that are absolutely first-rate. Students at the graduate level and teachers will find the book an invaluable reference aid, and it should certainly be read by anyone claiming a professional interest in international economic theory.

To be sure, the volume is not without flaws. The authors may be criticized on a number of grounds—though principally for errors of omission rather than commission. For instance, their list of topics can hardly be described as exhaustive: the number of theoretical issues in international economics is considerably greater than nine, and some of those that are excluded have received at least as much intensive attention in the last two decades as some of those that are included. In particular, one regrets the absence of any survey of the branch of international economic theory that is concerned with commercial policy and welfare. Surely, as a minimum, a chapter would have been warranted reviewing the profession's changing attitude toward the broad question of free trade vs. protection. Likewise, one regrets the very cursory treatment in Chapter 4 of such vital subjects as the general theory of the second best (one paragraph) and customs unions in less developed areas (one sentence). Surely these should have received more consideration than is elsewhere accorded such outmoded issues as, for example, elasticity pessimism, which appears in no less than three different chapters, or the postwar dollar shortage, which occupies much of Chapter 8.

Chapter 2 is seriously deficient in failing to consider adequately the dynamic aspects of international trade theory. This chapter does constitute an impressive restatement of the Heckscher-Ohlin theorem, but it neglects the fundamental fact that the factor-proportions model is basically static in nature. Even when, as in the latter part of the chapter, account is taken of variations in factor supplies and technology, the model is incapable of explaining satisfactorily changing patterns of real-world trade in manufactures. This has been confirmed by several empirical studies. More dynamic approaches to explaining trade are needed, and tentative alternatives have been proposed by a number of economists—among them, Ford, Linder, and Posner—emphasizing economies of scale, technological innovations, and modifications of the entire "productive environment." These theoretical developments are important, yet they are ignored in Chapter 2, which consequently gives a rather misleading impression of what factors are significant in determining industrial trade patterns.

Similarly, Chapter 8 is seriously deficient in failing to take proper notice of financial factors that are significant in determining the United States balance-of-payments position. The chapter purports to survey the various long-term explanations of the dollar's persistent disequilibrium since World War II—of first its shortage and then its glut. From its start, however, the chapter limits itself on grounds of "convenience" (p. 356) to an analysis of the *trade* position of the United States. This is rather like trying to explain the operations of a commercial bank by concentrating exclusively on its function as consumer and seller of goods and services; the narrow focus is convenient but not very meaningful. The United States is much more than a trader in the world community: it is in addition the central bank of issue for the international mone-

tary system. The problem of the American balance of payments cannot be analyzed meaningfully without taking into account, as many economists have done but Chapter 8 does not, the role of the dollar as reserve and vehicle currency and the role of this country as financial intermediary. Little wonder that the chapter is unable to conclude with a "truly useful hypothesis of the dollar problem" (p. 391). Its coverage is simply too inadequate.

Perhaps the weakest chapter, from an analytical point of view, is Chapter 9, which in discussing the problem of international liquidity fails to distinguish clearly between the "demand" for reserves and the "desire" for reserves. As Fritz Machlup pointed out as early as 1962, the two are by no means identical. Demand implies an offer of something in exchange for the object demanded, whereas desire is a psychological concept that implies nothing about a willingness to offer anything in exchange. Yet the chapter speaks, for example, of the "underdeveloped countries' virtually insatiable appetite for international exchange" (p. 429) as if this were the same as their demand for reserves. Nothing could be further from the truth: the LDC's want reserves, but they are unwilling or unable to generate the external surpluses required to earn them. On this issue the chapter is confused. Remarkably, though, in a volume of this scope and ambition, confusions like this are exceedingly rare. The authors are to be commended.

BENJAMIN J. COHEN

Princeton University

Trade, Aid and Development: The Rich and Poor Nations. By JOHN PINCUS. New York and London: McGraw-Hill for the Council on Foreign Relations, 1967. Pp. xv, 400. \$10.00.

This book is a survey of a variety of topics on the trade problems of developing countries and their relationship to the trade policies of developed countries. It includes theoretical issues of trade and development strategy, statistical data on trade and aid, the historical development and role of international economic institutions such as IBRD, GATT, etc., the motivations of aid-givers and aid-receivers as exemplified by the UNCTAD conference, and many policy issues and proposals such as commodity price-fixing agreements and tariff preferences. The most useful aspect of the book, although it is not the major portion of it, is the provision of statistical data. Trade both in primary commodities and in manufactured goods, relative growth rates, the receipt and donation of aid grants, the value of grants versus loans at different assumed rates of discount, and projections of foreign exchange "gaps" and aid "requirements" are provided. The weakness of the book is its inadequate and frequently cavalier treatment of analytical issues on which important questions of economic policy depend. For this latter reason, it is not a good book for students, although parts of it may prove useful for the profession at large.

From time to time, Pincus professes general agnosticism regarding what development policy should be (p. 73, for example) because of the lack of homogeneity among developing countries. Yet, he frequently makes very strong generalized statements on development strategy which are not built up from any well-defined set of assumptions or underlying model that describes the

economic environment in which he is operating. His ideology, which follows that of Myrdal and Prebisch, is represented by the following quotations:

Second, underdeveloped countries are not in practice faced with a choice between free trade and protection. If they want to industrialize they are going to have to protect most industries, with the exception of those for which transport costs, taste differences, or a favorable domestic resource supply situation provide the equivalent of tariff protection. The only relevant issues are which industries to protect, how much protection to give, and at what cost (p. 147).

. . . But no country that faced international competition from industrialized countries have ever become competitive in world markets for manufactures until it developed its own industry behind a protective barrier. The call for free trade in manufactures arises after the country has become competitive (p. 203).

There are two kinds of presumptions built into these statements. One is a question of historical fact that experiences such as late 19th century Japan, which was forced by military power to agree to free trade with Europe and the United States, and Hong Kong since World War II, are somehow no longer relevant. The other problem is analytical and has many aspects. In a short review, it is difficult to establish an economic environment about which meaningful statements can be made. Let us assume we have an economy within which agricultural and mineral wealth is very limited vis-à-vis population pressure. The development of substantial manufacturing activity in a few specialized lines is to the comparative advantage of such countries. Japan, Korea, and India would all fall into this category. Is it possible to protect most industry—actual and potential—simultaneously by the general use of tariff and non-tariff restrictions on imports?

The idea of protection is to pull resources into activities they would otherwise not flow into at the expense of other activities. The advantages that a single six-digit industry would have derived from protection are largely lost when other six-digit industries receive the same "protection" and increase their demands for the economy's scarce investment resources. Moreover, there will be an offsetting change in the relationship of the exchange rate to the internal price level. This results in an upward "real" valuation of the currency which offsets to some degree, although not completely, the effects of a general tariff in limiting foreign competition in manufactured imports. So the real protection being given to each domestic manufacturing industry by widespread tariff and non-tariff restrictions is far less than the apparent protection associated with high nominal tariff rates or price differentials between domestic goods and equivalent imported goods at the official exchange rate. Moreover, this limited "protection" is dispersed widely over a wide variety of industries, each serving the local market on a scale which is frequently too small to absorb modern technology without having to meet tests of cost effectiveness.

However, the policy of widespread nominal protection covering a very large proportion of potential imports does discriminate sharply in one important respect: those domestic manufacturing activities which are comparatively most efficient and which are potential export activities, are heavily penalized. Even

though they are given approximately the same protection on their domestic sales as their less efficient brethren, they are unprotected—frequently drastically so—on their actual or (more importantly) potential exports. Exporters face a very unfavorable conjunction of exchange rates and internal price levels which arise out of the import restrictions. Costs of production in terms of the local currency are too high vis-a-vis export prices translated into domestic prices at the existing exchange rate. Taxing or restricting imports entering the economy is equivalent to taxing exports that leave it. Pincus is apparently unaware of this fact even though much of his book is concerned with the development of industrial exports from LDC's.

One can believe, as does Pincus, that for some countries the greatest opportunities for efficient new investment lie in import substitution in the industrial sector (p. 169). It may well be that agriculture has limited development possibilities in or of itself (p. 158). Does it then follow that because one makes these assessments, perhaps correctly, that governments should heavily tax industrial export and agricultural activities in order to subsidize industrial import substitution? If industrial import substitution is indeed more advantageous, this is the route that would be followed under a neutral fiscal and tax policy where the government carefully ensures that investment funds—either public or private—flow to those uses where the rate of return is highest. It should not be necessary to make the rate of return in industrial import-competing activities look artificially high while simultaneously making rates of return to farmers and industrial exporters look unnaturally low.

A natural consequence of the inappropriate assessment of internal LDC economic policy is to emphasize external constraints thrown up by rich nations against imports from LDC's and to emphasize the heightened importance of aid transfers in this context of foreign exchange scarcity. Pincus summarizes different authors' projections of aid "requirements" based on the "two gap" analysis which separates an *ex ante* savings-investment gap from an *ex ante* foreign exchange gap in viewing aid transfers. He criticizes the two gap formulation by stating, among other things, that: (1) it is of limited usefulness because the two gaps are necessarily equalized *ex post*; (2) the foreign exchange gap implies inflationary pressure whereas the savings-investment gap does not; and (3) "if there is an import surplus without inflation, some domestic producers are losing money and will have to cut back if the surplus persists" (pp. 300-301). Although the first criticism appears true but irrelevant, the second not true in the context of ordinarily accepted two gap models, and the third simply very peculiar, what is particularly upsetting is that the full model to which these comments refer is not spelled out. A systematic listing of assumptions and equations describing the internal logic of the two-gap model and its assumed production technology are all missing, so that the reader is simply exposed to a series of *ad hoc* and rather puzzling comments with no basis for judging their verity. This is rather representative of Pincus' analytical approach in many areas.

Pincus has an extensive discussion on all the advantages and disadvantages of tariff preferences for LDC's in the markets of wealthy countries. He comes out in favor of preferences, although he would make them temporary by hav-

ing general "most favored nation" tariffs fall to the preferred level with the passage of time. His book was completed before the successful completion of the Kennedy Round of the GATT negotiations so that there is now considerably less impact to be obtained from his suggestion. He would modify the "principal supplier" clause in GATT to give LDC's more bargaining power. He favors commodity price-fixing agreements as a means of disguised aid transfers and considers the stabilization of producers' incomes to be of relatively minor economic importance. Generally, he goes along with most proposals for *de facto* aid transfers in one form or another without being much concerned with allocative efficiency.

RONALD I. MCKINNON

Stanford University

Effects of U.K. Direct Investment Overseas. By W. B. REDDAWAY, WITH J. O. N. PERKINS, S. J. POTTER, AND C. T. TAYLOR. Occasional Paper No. 12, Department of Applied Economics, University of Cambridge. New York: Cambridge University Press, 1967. Pp. 196. \$4.75.

After years of speculation in Europe and the United States about the efficiency implications and the balance-of-payments effects of foreign private direct investment, some first-class empirical work on the subject is beginning to appear. This is one such effort, aimed at measuring the effects of foreign private direct investment by British investors upon the British economy. The Cambridge group asked practically all such major investors (1) to account for the transactions undertaken through and with their foreign subsidiaries and affiliates and (2) to offer a best guess on the transactions that *would have occurred* with the United Kingdom if the British investor had not undertaken his overseas investments. Companies incorporating over 70 per cent of the net assets of all United Kingdom foreign direct investment responded to the request.

How to apply the results? In a breathtaking *tour de force*, the Cambridge group made two assumptions: that the aggregate output of goods and services of the United Kingdom, the aggregate level of consumption, and the distribution of income in the United Kingdom are largely determined by government policy; and that the government's policy goals are more or less invariant, whether or not the foreign investment takes place. Accordingly, insofar as foreign investment takes place, the investment's main effect is to divert output from home investment to exports, and not much else.

Given the premises, the initial balance-of-payment impact of the foreign investment consists primarily of: (1) The outward flow of capital; and (2) a certain amount of exports by the United Kingdom, in excess of the U.K. exports which would have taken place if the investor had not been a U.K. resident. In subsequent periods, the effects of the investment become more complex. These include: (3) An inflow of profits to the U.K., net after taxes paid to the foreign host government; (4) an outflow of interest payments from the U.K., representing the marginal cost to the U.K. economy of borrowing reserves or drawing down other overseas assets, in order to secure the capital for that part of the investment which is not provided by way of the export of real

assets through the current account; (5) an inflow of receipts to the U.K. from the export of goods and services in excess of what would have occurred if the investor had not been a U.K. resident; and, finally, (6) a reduction in the outflow of payments from the U.K. due to the saving on imports which were aborted by reason of the decline in home investment that was the consequence of the net outflow of goods associated with the foreign investment.

The Reddaway report does its best to quantify each of these slightly tortuous concepts, using data from the questionnaires purporting to represent the "average" U.K. foreign investment. According to its calculations, the initial favorable effect of a U.K. foreign direct investment of £100 is about £9, while the annual effect thereafter is about £4.

Insofar as the Reddaway report has policy implications, the implications are clear. A country like the United Kingdom could achieve a considerable easing of balance-of-payment strain for a number of years by blocking the continued outflow of direct investment funds. Of course, the wisdom of a cut-back would depend on the opportunity cost; on whether the added home investment and the reduction in the precariousness of the U.K. situation could be used during those years to generate balance-of-payment consequences more favorable than those achieved by the foreign investment.

The virtues of the Cambridge report seem to me to be in the skillful handling of complex facts; the dangers seem to lie in the risk that some unwary government official may actually rely upon its results for policy purposes.

One major difficulty with the Reddaway report is the model of the British economy that underlies the results. It is a most implausible model, in my opinion. In some respects, the model includes some rather startlingly pure manifestations of a competitive economy. Goods and services are priced at their marginal cost; resources are readily shifted, from selling insurance policies for export to making widgets for the home market; there are no supply bottlenecks, and no internal or external economies of scale. At the same time, however, the model assumes a British economy that is presided over by a government whose objectives are given and unchangeable, to be retained through thick and thin whatever the private sector may do. These two groups of characteristics, on first reading, make strange bedfellows. But it is obvious how they have come to be used together. They represent pure forms of the modern economists' aspirations: a society in which all the good fruits of pure competition and all the creative products of a wise and benevolent activist government are somehow blended in a perfect union.

My own image of the British economy is rather different. It is an economy in which the public sector learns by doing, by moving from one uncertain situation to the next and adjusting for past errors as it goes. There are occasional major irreversible decisions which push the economy in new directions. But there is neither a well-articulated plan nor any reasonable expectation of one. As for the private sector, it makes its decisions under conditions of uncertainty, in an industrial structure that is strongly oligopolistic, uncertain of the critical facts relevant to its decisions and unable readily to obtain them. These are characteristics common to many Western economies; for most policy purposes they have to be taken as given. For economies such as these, the Redda-

way model is fairly close to irrelevant. The approach needed is probably one based on sequential analysis, a messy start-stop-ponder-and-choose procedure.

This brings us close to the heart of the matter. It is one thing to devise a hypothetical model of the economy in order to test a series of hypotheses, *ceteris paribus*. It is something else to project the behavior of an economy, as a preliminary step for prescribing policy in order to alter its behavior. Sometimes the two exercises have a good deal in common; sometimes they do not. My guess is that this is one case in which they do not.

But there are some more specific points in the Cambridge study worth exploring. One of these is the assumption that the scarce resource preempted by foreign direct investment is goods and services; and the related assumption that these goods and services, if released, would be available for home investment. My own inclination would be to investigate a model for the United Kingdom economy in which the critical resource-allocating effect of foreign direct investment was to deploy *management* for overseas operations rather than for home enterprise. National savings and investment in the aggregate, according to my preferred version, would be somewhat elastic, being expanded or contracted as necessary to match management's perception of its reach. The effect of this change in assumptions would not be trivial (it could, for example, obviate the need for the critical assumption, made by the Reddaway report, that the United Kingdom has to borrow foreign exchange reserves or liquidate foreign exchange assets to finance its foreign direct investment). The reader may well be tempted to ask just how such a model could be constructed. This is a tough question; but while we are groping for the answer, we ought to resist the overwhelming temptation to assume that the easily measurable magnitudes are the relevant ones.

Another element in the study which I would be inclined to handle differently from the Reddaway report is that of royalties and management fees. The Cambridge team, after some consideration of alternatives, decided to assume that such fees represented the export of a service equal in value and in resource use to the fees received. In reality, management fees are usually assessed by some internal formula of the parent on a basis that has nothing to do with open market prices—if indeed the concept of an “open market price” has any meaning in the context. As for royalties and licensing fees, they ordinarily signal little more than the assignment to a subsidiary of monopoly rights in a foreign patent or trademark; while *bona fide* technical assistance sometimes goes along, that often takes the form of shop manuals, foreigners' visits, and other media of zero marginal cost to the British “exporter.” The Cambridge group's handling of this item, therefore, has an aura of arid unreality.

There is one added difficulty in the Reddaway study that deserves a word or two of comment. This has to do with the elements of vulnerability that are involved in asking investors what might have happened *if they had not made a given investment*. How does an investor make his decision in the first place? According to various studies, he perceives either an opportunity or a threat in some distant market. The signals, threat or promise, are not crystal clear. But

if he invests, he does so with fingers crossed, and with the expectation that in considerable measure he will learn by doing. And so he usually does. The costs of operation differ in lesser or greater degree from the investor's expectation; the market proves amenable or resistant in unexpected ways; the product line proves to need adjusting. But adjustment and adaptation occur as the years pass.

Enter the researcher with the question: What would you have done differently, if you had not invested? The question is asked at a time when the investor has already been exposed to a learning-and-response process in the foreign market which was one of the consequences of the investment itself. With the benefit of that process indelibly imprinted in his mind, will his answer contain bias? Very likely. Can we predict the direction of the bias? Almost certainly.

In the present case, my guess is that he would frame the alternative course of action on the assumption—the erroneous assumption—that his knowledge of the local market and his perception of risk in the local market would be much like that already acquired through the investment route. Hence, he would tend to assume that, in the absence of the investment, he would have sold by way of export any product which his current knowledge suggests is exportable. His estimate would not reflect the characteristic inertia that derives from ignorance and from high perceived risk and which, in my view, is one of the largest blocks to export.

I am tempted to conclude this review with the usual laudatory phrases for a job well done. But Mr. Reddaway hardly needs much comment of that sort from this writer. This is by all odds the best analysis of its kind that has seen the light of day. One only wishes that it could be recognized for what it is—an ingenious exercise whose conclusions are determined by its premises and whose premises may have little relation to the conditions that confront the policymakers.

RAYMOND VERNON

Harvard University

America in the Market Place—Trade, Tariffs and Balance of Payments. By PAUL H. DOUGLAS. New York: Holt, Rinehart and Winston, 1966. Pp. ix, 369. \$7.95.

Senator Douglas provides a highly readable exposition of his views on international trade, tariffs, and the balance of payments. The book is addressed chiefly to the policy-maker and the noneconomist but some of its chapters, like those on the historical development of tariffs and trade, merit the attention of economics students also.

In most questions, Douglas is on the side of the angels. He presents a convincing case for free trade and effectively dismisses the arguments of protectionists. The mercantilists meet with a similar fate and there are trenchant references to present day mercantilists. Nevertheless, in the policy discussion Douglas appears to accept the popular view which considers the other countries' tariff concessions as a gain and our own as a sacrifice. He submits that

we are pledged to get as much as we give and complains that the tariff concessions offered by the Common Market in the Kennedy round of tariff negotiations are not sufficiently generous (p. 146).

In the historical part of the book, Douglas is sharply critical of protectionist tendencies in the United States in the late nineteenth and the early twentieth century and endorses the moves made towards free trade since Cordell Hull's Trade Agreements Act of 1934. But in the discussion of recent tariff negotiations, the United States comes off a little too well. It is claimed that we have had only minor departures from a liberal trade policy and that the specific protective measures used by the the United States "have been relatively slight in comparison with the export bounties and covert forms of discrimination practiced by many other nations" (p. 299). Elsewhere, American generosity and European self-interest are contrasted. Thus, Douglas submits that, in separating the discussion of agricultural goods from that of industrial merchandise in the Kennedy round of negotiations, "once again the generous desire of the Americans to co-operate had been turned by the Europeans to their own advantage" (p. 145).

The views voiced in the discussion of aid to less developed countries are also open to dispute. According to Douglas, "on the whole, the United States emerges from these comparisons as by far the most generous of the industrial nations. It has also distributed its assistance over a much wider spectrum of countries and, having no colonial empire of its own, has made liberal grants and investments in countries over which it has had no political control" (p. 196). This exposition disregards the political and military objectives of U.S. aid and the concentration of a good part of it in Vietnam, Korea, and Taiwan. Also, one can hardly claim that our burden of foreign assistance much exceeds that of any other Western nations. According to the latest OECD compilation, in 1965 U.S. aid to developing countries amounted to 0.64 per cent of national income, while the corresponding ratios were 1.06 in France, 0.84 in Belgium, and 0.59 for the OECD countries as a whole. True, our aid terms are generally more favorable than those of other countries, but much of U.S. food aid is overpriced and tied aid may entail a larger excess cost in this country than elsewhere.

Senator Douglas has considerable interest in international monetary arrangements. He favors a modified version of the Triffin Plan under which new reserves would be distributed to the members of a reorganized IMF in proportion to their quotas. These new collective reserve units would grow at a rate that permits total reserves to increase at about 3 per cent a year. Nevertheless, selective increases would also be permitted.

Increased international reserves would permit countries to "ride out" larger balance-of-payments fluctuations than they have in the past without necessitating variations in exchange rates. Douglas is a staunch opponent of flexible rates. He maintains that Britain narrowly escaped devaluation in 1964 and again in 1965 and that she "was saved directly and indirectly by the United States" (p. 270). Some would interpret the historical evidence in a different fashion and blame the U.S. government for having exerted pressure on Britain not to devalue.

This reader would also disagree with Douglas on the desirability of establishing a trading area consisting of the United States, EFTA, Canada, Australia, New Zealand, and Japan in the event that the Common Market decided against participation. This proposal would create a division in the Atlantic alliance and would tend to increase the dominant position of the United States in political and economic relationships with the allies which is opposed by many Europeans. A continuation of tariff negotiations under the most-favored-nation clause might be a better means for furthering our political and economic objectives.

These comments should not detract from the value of the book which presents an eloquent and reasoned plea for freer trade, for helping less developed countries, and for improving the international monetary mechanism. It should be read by Douglas' former colleagues in Congress, as well as in the Executive Branch, and it should command attention among people interested in our international relations.

The Johns Hopkins University*

Disarmament and World Economic Interdependence. Edited by EMILE BENOIT. New York: Columbia University Press, 1967. Pp. 260. \$8.00.

A precondition for partial disarmament is the recognition of our international interdependence and the convergence of our economic and political systems. Activities that promote the international exchange of people especially scientists and educators, or stimulate trade in goods and services, or that foster economic growth, may contribute to the establishment of peace. The gradual process of international accommodation and depolarization may then lead to partial disarmament and arms controls. Economic problems associated with the transition from defense production to civilian output are manageable. This is the theme of the latest book edited by Emile Benoit, professor of international business at Columbia University and expert on the economic consequences of disarmament. The book contains 17 papers prepared for the Conference on Economic Aspects of World Disarmament and Interdependence held in August, 1965 at Oslo, Norway.

The leading article by Benoit and Harold Lubell of AID provides, for the first time, a comprehensive standardized tabulation of the economic resources devoted to national security by 36 nations. They estimate that these nations account for 97 per cent of the world's military spending of \$133 billion. The statistics are available for 14 of the NATO countries, 8 Communist nations of the Warsaw Pact, and 14 others including China, Israel, and the U.A.R. Data are given in local currencies, then in dollars at official exchange rates and finally at purchasing power parity exchange rates. The defense expenditures for each country are then subdivided into functional categories for military personnel, procurement, research and development, construction, and operations. This enables the authors to analyze separately the economic impact of disarmament on the nations and the extent to which the civilian sectors are burdened. The arms spending is also expressed as a percentage of the govern-

ment budget and of G.D.P. This article should be a significant reference source for economists, sociologists, and political scientists interested in the impact of military spending.

The book is enhanced by several excellent essays on specific countries. Morris Bornstein's article attempts to isolate the economic factors in the Soviet attitude towards arms control. For the U.S.S.R. military spending conflicts with other priorities: investment for growth, improvement in consumption, and foreign economic assistance. Arms control, says Bornstein, could be an attractive answer to their economic problems, and thus the western powers should offer some powerful economic incentives for Soviet cooperation.

Arthur J. Brown of the University of Leeds assesses the complex and uncertain influence of partial disarmament on the balance of payments of the United Kingdom. Olav Bjerkholt uses an interindustry model for Norway to weigh the possible economic result of complete disarmament in his country. Ludek Urban writes as a Communist in his essay stating that socialist countries do not fear the adjustment to arms control. They do not have to worry about maintaining aggregate demand, so their adaptation would be a physical one solved by proper planning.

"Arms Control and the Vulnerability of Communist China's Economy to External Pressures and Inducements" is the title of Alexander Eckstein's monograph. It is a factual statistical study of China's foreign trade and has very little direct relationship to the theme of this book. It would be well to have had it published where the "China watchers" would be more apt to see it.

Like so many other reports on conferences, a few of the articles seem to be included more for diplomatic reasons than for scholarly content. One article would have been suitable for presentation before the chamber of commerce of Southern California to reassure them that they are not part of the military-industrial complex. The author prefers to call the defense companies "problem-solving" companies.

The last 73 pages contain six essays stressing the preconditions of disarmament and are grouped under the broad title of Competition, Cooperation and Convergence in an Interdependent World. Economists from six different countries wrote these articles—some obviously struggling (and in vain) to make their essays fit the theme. The best of these, however, was on "The Convergence of Economic Systems in East and West" written by J. Tinbergen and colleagues.

In times like these it may seem absurd to write about disarmament and to hold international conferences on interdependence, but the world scene changes quickly. The nuclear test-ban treaty was signed less than a year after the Cuban missile crisis. Following the Middle East and Vietnam settlements, perhaps this book will become a reference work for those leaders responsible for easing the adjustment from war to partial disarmament.

ALBERT L. GRAY, JR.

Baldwin-Wallace College

International Economic Institutions. By M. A. G. VAN MEERHAEGHE. New York: John Wiley and Sons, 1966. Pp. xx, 404. \$8.00.

This book aims at a worthy purpose—to combine description of the origins, provisions, and operations of contemporary international economic institutions with an analysis of their effectiveness. Unfortunately, Professor van Meerhaeghe's reach exceeds his grasp in several dimensions.

Part I is an attempted summary and critique of the theory of international trade, international monetary theory, and the theory of international economic policy, condensed into 86 pages. The stated aim of this summary is to "enhance the utility of the next two parts [dealing respectively with world and European organizations], by explaining some terms or concepts in international economics." But as the author (who is professor of economics at the State University of Ghent) points out, he does not pretend to give a complete explanation of the theory of international economic relations. The uses of Part I therefore remain obscure, far too condensed for the beginner, and of no value to the professional. For example, his exposition and critique of Ricardian comparative cost theory, the Heckscher-Ohlin theory, and Samuelson's extension of the factor-price equalization theorem occupy a total of about one thousand words, without the aid of algebra or geometry. The effect is kaleidoscopic (for example, the chapter on international economic policies makes no reference to either foreign private investment or foreign aid, and is, in effect, limited to a cataloguing of various measures affecting balance-of-payments and employment via commercial policy and exchange rate variation); and the reader hopes for more useful material from the rest of the book.

This hope is realized only in part. Part II is largely a description of provisions and operations of the International Monetary Fund and associated international monetary arrangements, the International Bank for Reconstruction and Development and affiliates, the General Agreement on Tariffs and Trade (with a brief reference to the United Nations Conference on Trade and Development), and the international commodity agreements for wheat, sugar, coffee, and tin. Part III gives similar summaries for Benelux, the Organization for Economic Cooperation and Development, the European Coal and Steel Community, the European Economic Community, and the European Free Trade Association.

The book is most useful at the purely descriptive level, covering in orderly fashion the functions of a dozen international economic organizations. Some of this material is unsatisfactory, however. First, there is too much reference to provisions of particular articles or paragraphs of agreements by number, so that unless the reader has a particularly retentive memory he is obliged to leaf back every few pages for the original citation to see what Article 24 of GATT, for example, is about.

Second, and more important, some world and European organizations are passed over with brief mentions (economic functions of the United Nations, and its specialized agencies, UNCTAD, Euratom).

Third, extra-European regional institutions are entirely passed over (Cen-

tral American Common Market and Latin American Free Trade Area receive four lines each, while the regional development banks, Comecon, and the Central African Customs Union are completely ignored).

Fourth, the descriptions are often confusing, partly because of excessive compression and partly, I suspect, because of poor translation. The author's acknowledgement states "In order to achieve translation of this work in the shortest possible time it was necessary to engage the services of a relatively large number of translators. . . . A. Meuleman gave most valuable assistance in achieving uniformity of spelling and terminology, a considerable task in view of the multiplicity of translators."

When it comes to appraisal of the advantages and disadvantages of each institution, the volume is less useful. Professor van Meerhaeghe does not state his value premises, so they must be largely inferred by the reader. He sees little value to OECD and UNCTAD, both institutions being needless in his view. IMF and IBRD receive his approval in general—he discusses the Triffin and Bernstein plans, but views the "so-called lack of international liquidities," as "in the nature of a working hypothesis rather than an imminent danger," requiring no far-reaching changes in the present international monetary system. He sees commodity agreements as potentially moderately useful devices for price stabilization, and says that more agreements and better-managed ones are in order. For promoting the underdeveloped countries' interests in maintaining commodity earnings, he proposes expansion of the IMF compensatory finance facility.

EEC receives his general support, although preferences for EEC associates and the common agriculture policy draw his fire. He also cautions on the basis of Benelux experience against undue haste in integration efforts. EFTA is discussed rather briefly; as the author points out, it owes its origin to the establishment of EEC, and is a medley from both the geographic and economic standpoint.

The effort at appraisal of institutions would have benefited from a concluding chapter, relating the functions of the various organizations to each other, therefore offering a more comprehensive framework for analyzing the value of the various institutions, in terms of the growth of the world economy, or some other specified welfare criteria.

This volume is in no way a substitute for the source material or the monographic literature on the individual institutions (e.g., Curzon's *Multilateral Commercial Diplomacy*, Frank's *European Common Market*, Camps' *Britain and the European Community*, Aubrey's *Atlantic Economic Cooperation*). It offers a moderately useful handbook for the reference shelf. It also points to a need which it does not fulfill—a literate summary and analysis of the functions of all international economic organizations in relation to specified or alternative goals of international economic policy.

JOHN PINCUS

The RAND Corporation
Washington, D.C.

International Economic Problems. By JAMES C. INGRAM. New York: John Wiley & Sons, 1966. Pp. x, 180. \$4.95; paper, \$1.95.

Professor Ingram has written a good introductory, though comprehensive, book of the major problems confronting the world economy. Addressed primarily to elementary students and laymen, the 180-page text provides, first a theoretical background of basic principles of international trade and monetary organization, and then focuses in the last three chapters on three international trade topics which are both timely and important: trade between advanced (A) and underdeveloped (U) countries, the European Economic Community (EEC), and the international monetary system.

The author stresses the importance of a student understanding the comparative advantage theory in order that he may be on "surer" grounds when approaching current and complex issues of trade and development. Some parts of this exposition might seem to be oversimplified, i.e., "we have a clear basis for ranking products in order of factor intensity." But, then, the purpose of the exposition is to provide the student with the bare essentials, and the state of controversy in fields like the terms of trade, infant industry argument, and economies of scale is incorporated. It is pointed out that categorical statements about the secular decline in the terms of trade, or of the "potential" comparative advantage of the infant industries, or of the magnitude of the economies of scale, are hard to make. At the same time, the importance is recognized of the U countries' stand at the United Nations Conference on Trade and Development (UNCTAD): that A countries should open up their economies to U countries' exports and reduce the protection accorded to those of A countries' industries in which U countries have a comparative advantage, i.e., light manufactures. Perhaps because of the relatively recent development of the concept of "effective protection"—that is, protection granted on the value added—economic implications of effective protection (which tend to disfavor U countries' manufactured exports) are not treated as fully as one would wish. Nevertheless, coverage of the U countries' trade problems is, in general, comprehensive and interesting.

In discussing the economic benefits that the EEC has derived from their regional grouping, the author rightly points out the lack of factual evidence to settle conclusively the economies of scale argument. But, on the resource allocation effect, no mention is made of the studies by Verdoorn, Scitovsky, Johnson, and Welmesfelder, all of which have consistently shown the scant degree of the benefit of this effect. Statements like "trade creation appears to have outweighed trade diversion" and "most observers think that the connection is close" (between the formation of the EEC and good fortune) are attributed generally to the rapid increase in income and trade. But the fact that income of these countries grew rapidly even before the Common Market is not spelled out. With respect to the future course of the EEC and its impact on the rest of the world, however, Ingram does emphasize uncertainty, pointing out the undercurrent "inward-looking" attitude and agricultural policy. In this connection, the importance of the Trade Expansion Act (Kennedy round negotiation) is discussed.

Discussion of the instability and dilemma of the existing payment system and its analysis in terms of "expenditure switching" and "expenditure reducing" as means to improve the trade balance of a country should prove exciting to the student. In connection with the analysis of U.S. balance of payments deficits, the improved "competitive position" as reflected by a sharp rise in current accounts of the U.S. economy during 1958-64 *vis-a-vis* Europe is explained in terms of the comparatively slow rise in wages and prices in the United States. But when the author goes one step further and says that this reflects the inherent strength of the American economy, one wonders; the student might get the unwarranted impression that "competitiveness" necessarily reflects the basic comparative advantage of the economy and that these terms can be measured so easily. Furthermore, had Ingram provided figures for the merchandise and service accounts for the preceding years (in addition to the comparison of 1964 with 1958), students would have discovered easily that the 1964 surplus was untypically high. Discussion of selective measures imposed by the United States, i.e. "interest equalization tax" and "buy American," should provide the perceptive student an instance of the inconsistency of the professed claims of free trade and the national interest of countries. The shortcomings of these measures, however, could have been delved into further.

In the next edition of the book, one would like to see one problem in particular discussed, viz., the prospects of regional groupings among the U countries (some steps toward this in Latin America and their limited success so far are very briefly mentioned). Currently, there are several other such views, e.g., the Regional Harmonization of Development Plans proposed by the ECAFE secretariat. Should trade liberalization precede regional cooperation, or should it be just incidental to the basic coordination of national development plans among U countries? Questions like these should make an interesting discussion.

This book should serve as a good supplement to an introductory text. Those belonging to other disciplines such as political science and international relations should find this absorbing single-volume account of contemporary economic problems extremely interesting.

Business Finance; Investment and Security Markets; Insurance

The Capital Expenditure Decision. By G. DAVID QUIRIN. Homewood, Ill.: Richard D. Irwin, 1967. Pp. x, 258. \$7.50.

This slender volume provides a systematic review of the principal aspects of capital expenditure analysis. Quirin's approach is to describe the basic methodology of discounted cash flow approaches to capital budgeting, to review the relevant literature for areas of conflict or unresolved questions in theory, and to attempt formulation of original solutions to these problems.

The result is a fairly balanced text which should provide a novice with a reasonable understanding of the uses and limitations of capital expenditure

theory. At the same time there is sufficient new material, including a number of useful and imaginative illustrations, to attract the attention of those already well versed in the area. As this latter group might imagine, however, Quirin's solutions to heretofore irresolvable problems are generally heuristic, and the theoretical gaps which previously existed still remain with us. Particularly when we drop, as Quirin does in his final two chapters, the convenient assumption that the economic world is one of certainty is it clear that there is yet no definitive solution to the question of appropriate corporate strategy regarding capital structure, or to that of optimal capital budgeting policy.

The first two chapters provide a brief introduction to the importance, in both the private and public sectors, of a rational scheme of resource allocation. Embracing only 23 pages of text, they might easily have been combined. The third chapter provides, in only 30 pages, an examination of the relative merits of seven different methods of evaluating proposed expenditures. Most of the attention centers on discounted cash flow criteria, of which Quirin's preference is for the ratio of discounted gross benefits to discounted gross costs. If a recurring flaw is to be cited, it is the brevity of the discourse on important topics. For example, he terminates (p. 34) the discussion of Gordon's payoff period article,¹ when the relationship between the payback period and the internal rate of return might well have been developed fully.

This chapter suffers from unnecessary quibbling with previous authors. For example (p. 40), he erroneously attributes to Bierman and Smidt² the notion that ranking of projects by net present value is independent of the level of the discount rate, and then goes on to disprove it. Again, in examining the problem of multiple rates of return (pp. 54-5) Quirin provides references to five authors apparently selected solely for their failure to resolve the problem of evaluating multiple rate projects to his satisfaction. Quirin himself simply avoids the question by concluding that a project should be accepted if net present value is positive at the firm's cost of capital, whatever the rate of return might be. In the theoretical world of wealth optimization and unlimited capital, the issue indeed disappears, but it remains with us when capital rationing exists. Later (p. 180), when discussing budgeting with capital rationing, Quirin suggests that a schedule which ranks projects by rate of return must indicate not only when a multiple rate project will be accepted, but also when it must be removed from the accepted list as available capital is allocated to projects offering progressively lower yields. For all the critical comment on earlier writers one expects a more satisfying solution.

An interesting section on narrow vs. wide margins (p. 63) includes the suggestion that benefit and cost streams should be discounted separately, rather than netted in each year, as is the customary practice. The suggestion is particularly relevant in the case of mutually exclusive projects, among which a gross benefit-cost ratio provides greater discrimination as a ranking measure than does the internal rate of return. Quirin then extends the notion to the sit-

¹ Myron J. Gordon, "The Payoff Period and the Rate of Profit," *Journal of Business*, October 1955.

² H. Bierman, Jr. and S. Smidt, *The Capital Budgeting Decision*. New York, 1960.

uation in which a vendor finances equipment purchases for customers. Although we agree that financing and purchasing of fixed assets should generally be considered separately as Quirin suggests, it is not always possible to meet this ideal. In particular, when the most attractive financing proposal is offered by a vendor whose equipment, considered alone, fares only second-best on a benefit-cost ratio scale some combined methodology must be employed.

A second, more detailed, chapter on capital expenditure policy under certainty is followed by two chapters on the cost of capital. It is in the second of these that the principal original material appears. Here Quirin effectively distinguishes the short-run cost of capital from that which obtains in both the intermediate and long run. Concentric isocost ellipses, bounded by attainable levels of debt and equity, are mapped on axes representing total amount of debt and equity. Quirin then develops an expansion path for short-run average capital cost by plotting points of tangency between the curves and parallel lines representing various levels of total capital. In the intermediate run, as financing options are increased, the slopes of the marginal and average cost curves decline. In the long run, after the market adjusts to the effects of new financing, both average and marginal cost curves are horizontal, irrespective of capital structure. Thus Quirin affirms the long-run validity of the Modigliani-Miller thesis, although we may doubt that the required market adjustment will ever be perceptible in a world of imperfect information and continual change.

When considering capital budgeting under risk (Chapter 11), Quirin develops a useful application of the Markowitz portfolio selection model. Proposed projects are sequentially combined with existing operations and with all previously accepted projects to determine whether acceptance of the project in question will add to net present value. This requires prior specification of variances, covariances, and the market's risk preference schedule. Rejected projects which show promise are retested after each new acceptance because of the possibility that a high negative correlation may reduce total variance. Quirin fails to point out that after the last project has been evaluated and a package accepted it is possible that net present value might be further increased by withdrawing a project previously accepted. This would, of course, require that its removal lower total variance and the required capitalization rate sufficiently to offset the decrement to the expected earnings stream.

Quirin's intended audience includes those interested in capital budgeting for both industry and government, and two chapters are devoted specifically to the public sector. These are the weakest chapters in the text, being argumentative and critical rather than analytical. Little new is offered except for the author's personal observations concerning the illogical ways which governments use to allocate their citizens' dollars, and existing theory is accorded only hurried, superficial discussion.

Quirin's text should find wide application in both graduate business programs and management development seminars. It contains relatively few problems, a minimum of present value tables, and little reference to refinements such as accelerated depreciation, continuous compounding, con-

tinuous receipts, and so forth. Its brevity, while sometimes frustrating to one familiar with the subject, makes it a convenient capsule course on an important subject of economic inquiry.

Industrial Organization; Government and Business; Industry Studies

The Demand for Natural Gas in the United States. By PIETRO BALESTRA. Contributions to Economic Analysis No. 46. Amsterdam: North-Holland Publishing Co., 1967. Pp. 153. \$7.00.

This book presents an econometric investigation of natural gas demand in the United States residential and commercial market. The author works up from an overly simple static model to a more elaborate dynamic one. In the latter, which is clearly more appropriate, he divides natural gas demand into new and existing parts. He points out that the high transfer costs of shifting between alternative fuels make price effects almost irrelevant to consumers already locked into existing equipment. These effects carry weight only in the investment decision when a new heating system is purchased or an old one replaced. Judicious use of assumptions leads to a model embodying this phenomenon in which the variables are all observable, and the parameters of this model are estimated.

The data used are by state for 1950-62. Estimation for the static model is for each state separately; estimation for the more satisfactory dynamic model uses first cross-section data for individual years and then pooled cross-section data. Evidence is found for a structural break at about 1956, and Balestra suggests that this is due to the characteristics of gas as an essentially new fuel, penetrating new markets in the early fifties. The final estimates are for 1957-62.

It is in the securing of these final estimates that the book reaches its econometric high point. Very careful attention is given to the problems of pooling cross-section and time series data, and best asymptotically normal (BAN) estimates are secured using a disturbance model which is superior to existing efforts in this area. The usefulness of this procedure is clearly not restricted to studies of the demand for natural gas and it deserves the close attention of general econometricians.¹

Thus the final model used is a good one and the estimating techniques better than that. Nevertheless, the book seems unsatisfactory in several respects.

First, it is rather padded. Far too much time is spent on the estimates and properties of obviously unsatisfactory models; further, elementary material or

¹ Balestra and Marc Nerlove, who cooperated in developing this procedure, have published it separately as P. Balestra and M. Nerlove, "Pooling Cross-Section and Time Series Data in the Estimation of a Dynamic Model: The Demand for Natural Gas," *Econometrica*, July 1966, 34, 585-612.

material readily available elsewhere is sometimes spelled out at unnecessary length.

More important than this, however, is the lack of much discussion as to the economic implications of the results. Considering the importance of the characteristics of natural gas demand for regulatory policy, one would have liked to have seen some treatment of the policy issues. Instead, the final estimates are presented almost as an afterthought to the treatment of estimation procedures.

Such failure to discuss economic issues shows up elsewhere as well. The short-run demand for gas is the demand for the services of an existing stock of capital equipment. Balestra finds it "difficult to conceive of a theoretical situation in which a change in income is accompanied by a short-run change in gas consumption" (p. 23). Yet apparently he has no such difficulty with the short-run effects of price. This discrepancy is left unexplained, and when the long-run dynamic model is developed, the rate of equipment utilization is assumed constant.

Further, there is a closely related question which Balestra leaves undiscussed. In their work on electricity demand, Fisher and Kaysen² found an interesting pattern of short-run effects. In particular, they found that for much of the nation, the pattern of short-run income elasticities over states was closely related to the degree of urbanization. They tentatively explained this in terms of the amount of time spent in the home, thus giving a theoretical basis for the existence of short-run income effects. Balestra notes the results but not the interpretation and finds that urbanization has no important effects on natural gas demand. That may well be true, but it is not clear why there should be a difference in this regard between gas and electricity-using consumers. Balestra does not discuss this.

In fact, Balestra fails to test the urbanization hypothesis in the proper form. He enters degree of urbanization as a separate variable in his cross-section dynamic analysis and finds its effects statistically insignificant. Yet the Fisher-Kaysen hypothesis is exclusively applicable to the short run and to only roughly two-thirds of the states. More important, it is an hypothesis as to income elasticities which is not properly tested by the addition of urbanization as a separate variable. Again, urbanization and short-run income effects may or may not be important, but Balestra too easily dismisses the subject.

Similarly unsupported statements turn up also in some other places. Balestra states (p. 25) that an unweighted average of the prices of various fuels is a better measure of opportunity cost than an average weighted by quantities consumed. This is not obvious to me if the availability and relative prices of alternative fuels vary over observations.

Finally, Balestra assumes (p. 50) that the relative prices of appliances using different fuels can be omitted from the demand regressions. He justifies this in terms of discounting initial cost over a long period and by casual empiricism as to current practices of price setting in the appliance and fuel mar-

² F. M. Fisher in association with C. Kaysen, *A Study in Econometrics: The Demand for Electricity in the United States*, Amsterdam 1962.

kets. The arguments are not wholly convincing and so important a point should not have been passed over in such a fashion.

In short, I should have liked to see a book a good deal shorter in many places and rather expanded in some. The present book seems to me to contribute more to econometric methodology than it does to our knowledge of the gas industry. Nevertheless, the general quality is high and contributions of the latter kind are by no means lacking. Balestra has advanced our quantitative knowledge of demand behavior in the energy industries; one hopes for more such studies.

FRANKLIN M. FISHER

Massachusetts Institute of Technology

Defense Management. Edited by STEPHEN ENKE. Englewood Cliffs, N.J.: Prentice-Hall, 1967. Pp. xiii, 385. \$12.95.

The editor's purpose in assembling the twenty essays that comprise this volume was to describe the use of cost-benefit (or systems) analysis during the last six years in the Department of Defense. It is possible to draw upon production theory to distinguish a cost-benefit problem from an operations research problem in the defense management field in the following (oversimplified) manner. Typically, operations research begins with a given "input mix" and seeks to define the point on the "production function" over it, when the production surface depicts the maximum "product" return attainable from input mixes. Cost-benefit analysis, on the other hand, (1) assumes the production function in relevant input mix ranges has already been defined, usually along one or more isoquants, and (2) permits input mixes to be varied, ordinarily to find a minimum-cost input mix on a given isoquant.

Part I of the book contains five essays concerned with the McNamara-Hitch innovations in defense planning and program budgeting. William A. Niskanen's discussion of the Five Year Force Structure and Financial Program and the program budget is excellent, and nowhere more so than in his expression of some misgivings that the Five Year Program may introduce some anti-innovatory rigidity into Pentagon planning, especially under the extreme centralization of decision making that characterizes the McNamara era. Robert N. Grosse and Arnold Proschan discuss the program budgeting procedure in greater detail but do not go far beyond the exposition of the process. Norman V. Breckner and Joseph W. Noah discuss the costing of systems in very general terms, providing little in the way of realistic illustration, and touching such important problems as time discounting and sensitivity analysis in brief and unsatisfying ways. The following two chapters by Roland N. McKean and Armen A. Alchian survey in repetitious fashion some of the problems and limitations that inhere in the new budgeting and planning procedures. McKean makes two important points: (1) the major importance of the new methods is that they force the planner to consider trade-offs in effectiveness, but (2) any other reasonable system would also call attention to trade-offs, so that choices among such procedures must be based upon the merits of the trade-offs they feature. From this part, however, it is fair to con-

clude that the Novick-Mosher-Smithies-Hitch-McKean program budget analysis of the nineteen fifties has been marvellously effective in practice, although it is no panacea and may contain some potential for rigidity.

Part II contains nine essays which can be grouped under the heading "Cost-Effectiveness Applications" only by some stretching of the meaning of the term. Rather straightforward accounts are given of the earlier, more mundane work at RAND by Richard B. Rainey, Jr., John J. McCall, and Harrison S. Campbell, dealing with force-mobility vs. prepositioning, maintenance of equipment, and spare parts management respectively. While they are competently done, the essays move at a level of summary and nontechnical treatment that is introductory in nature, and the topics are by now a bit overexposed. In a similar, if less cut-and-dried, vein, the essays by R. H. McMahan, Jr. and D. H. Taylor (Central War Alternatives), Herman Kahn and Anthony J. Wiener (New Perspectives on Civil Defense), and Frederick T. Moore (Incentive Contracts) are competent but lackluster, and the Kahn-Wiener piece leaves the definite impression that the authors are rather bored with the whole subject. Jora R. Minasian did the best he could with the rather unimportant problem of land utilization for defense (the Department of Defense holds only about 3.5 per cent of the land held by all Federal agencies) and highlights some rather obvious problems. I found Harry J. Gilman's essay on military manpower utilization a fine example of rather straightforward application of minimum-cost reasoning to defense problems; despite the fact that I would question his too-easy assumption that military draft manpower should be valued at civilian labor market prices, the essay recommends itself as reading in courses where such illustrations of real-world economic reasoning are valuable.

Unquestionably, one of the two highlights of the book is the brilliant essay by James R. Schlesinger on the changing environment of systems analysis. Schlesinger represents the second generation of defense analysts, who must subordinate the simpler analytical problems of deterring spasm nuclear attack to the subtler issues of flexible response and limited nonnuclear war. To a great extent the nature of such environments and scenarios makes the quarter-century old determinate techniques of game theory, programming, and operations research appear dated and overly restrictive upon the imagination. An important strain of the Hitch-McKean witness was that stressing the importance of economic theory as metaphor rather than model; as a guide for steering the expert's intuition along useful paths; as a chisel to shape in frankly inexplicable ways the incommensurable and the intangible into the potentially useful and concrete.

Schlesinger argues, for example, that the basic characteristic of uncertain phenomena is not that they are unforeseen but that they are unforeseeable. An implication of this is the fatuity of hopes for developing rigorous frameworks to cope with uncertainty. Given this assumption, therefore, one may turn his attention to less intellectually satisfying but more fruitful methods of hedging against the unknown future. Schlesinger argues most interestingly and convincingly that one hedge is to postpone decisions until they must be made, and cites as evidence the Kennedy administration's choice of *Polaris* and *Minute-*

man systems as one which froze our deterrent posture unnecessarily into a small-yield missile type. On the basis of information that existed at the time the decision was made, delay was possible and would have permitted a better system to be developed, and therefore the decision made was an inefficient one within the context of these new and less formal techniques.

Part III is another miscellany grouped under the heading "Special Defense Problems," and contains essays on research and development by T. K. Glenan, Jr., on the impacts of defense spending upon the domestic economy (Murray L. Weidenbaum) and upon the balance of payments (Rolf Piekarz), on the planning difficulties of alliances as displayed by NATO (A. W. Marshall), and on military assistance programs (Charles Wolf, Jr.). Once again the level of competence of the work is good if little true novelty is forthcoming, and the essays contain excellent sources of basic data on the several problems as well.

Also in this part is the second highpoint of the volume: an essay by Martin J. Bailey on the potential of decentralizing decision making in defense management, especially through the devices of internal and shadow prices. Bailey recognizes the difficulties of extending these methods to governmental processes lacking the profit criterion, but also feels that in the defense subeconomy under strong presidential leadership the social welfare function can be unambiguously defined. Bailey draws an interesting comparison between the Eisenhower administration's dispersion of such preference-definition among the several services and the Kennedy administration's more Crusoe-like procedure. The essay concludes with a brief illustration of the methods such a plan might adopt in the determination of air- and sea-lift facilities.

One of the disappointing aspects of the work inheres in the introductory nature of most of its presentations: it fails to come to grips with the grander and deeper issues of economic decision making in the defense area. Notably, the need for a major extension of standard welfare economics concepts from the market mechanism's regime to the realm of governmental decision making is peculiarly acute. In the Breckner-Noah, Minasian, and Gilman essays the important question recurs concerning the manner in which one values funds, land, and manpower in defense uses when they have not in fact been bid away from the market by price methods. The authors either take the market's price as the proper valuation without further discussion or discuss alternatives inadequately. And again, the extremely limiting problem of determining criterion variables to implement the effectiveness part of the analysis is not discussed at length in the essays, implicitly lending support to Admiral Rickover's allegation that the accent in cost-effectiveness is indeed on costs.

It was surprising, too, to find that nowhere in the book was the TFX decision drawn upon to illustrate the discussion or to point up the limitations of extensive cost-effectiveness studies when the Secretary of Defense feels intuitively that a low bidder's cost estimates are "less realistic" than a high bidder's. Further, the important impacts the whole affair has had upon head-to-head bargaining and prototype contracting might have argued for some such reference.

Nonetheless, the book is an excellent survey in nontechnical terms of the

McNamara-Hitch revolution in programming and budgeting, cost-effectiveness, and some of the broader economic impacts of the defense budget. In addition it gives some internal evidence of the shift of systems analysis away from the rigorous and determinate model approach to subtler and more imaginative methods of meeting current problems. Its major drawbacks are that it says little that is new, it is (probably inevitably, given the differential in the rates at which defense problems arise and the publishing process moves) a bit dated in its discussion of explicit problems, and it is much over-priced at \$13.

ROBERT E. KUENNE

General Economic Systems Project

The Steel Industry of India. By WILLIAM A. JOHNSON. Cambridge, Mass.: Harvard University Press, 1966. Pp. xv, 340. \$7.50.

This is a useful study of India's experience in expanding her steel industry during the past 10 years. The book's chief merit lies in its careful empirical testing of theoretical criteria (e.g., the social rate of return) to decide whether or not (1) the Indian Government has been wise to give such heavy emphasis to iron and steel, (2) the new mills have been put at sensible locations and have adopted the most appropriate production processes, and (3) these big public projects have achieved reasonable operating efficiency. To the first two queries he answers "yes"; to the latter he answers an ambiguous "no."

The most interesting part of the book is Johnson's measurement of the social returns from the industry's expansion during the second and third Plans. He uses the capital costs of a representative new government mill, the operating costs of the largest private mill (Tata's), and the average c.i.f. price of imported steel to calculate a normative internal rate of return (13 per cent for a .77 mn. ton plant, 21 per cent for a 1.5 mn. ton plant). The values were calculated with shadow prices for foreign exchange (the 1966 devaluation made them market prices) plus a shadow price for coal but not for labor. He notes that these values bias the result downwards, i.e., well-executed projects ought to have been able to do better. In practice, of course, the new government mills (plus the expanded private companies) have done worse—worse in terms of their social returns and far worse in terms of their private returns (the government mills have all experienced heavy losses). Johnson puts most of the blame on the government's control policies for steel, especially its misplaced desire to keep steel prices low to help development and its unwillingness to let public and private producers make high enough profits. Johnson believes that if the government had dared to rely more heavily on prices to curb demand and to discourage over-ordering the saving in demand would have eliminated the need for one of the three new public-sector plants. His feeling that Fourth Plan steel targets are too high is finding short-run support today as Indian steel demand turns slack. Johnson also blames poor management for part of the low returns in the government plants; but his comments on the managerial problems of these plants do not distinguish clearly enough among general problems of government ownership in a democracy, specific problems of organization and control, and the teething problems of new plants anywhere.

On another topic of current relevance in India—the pressure to sacrifice

sound locations to political considerations—Johnson concludes that the four new government plants have all been reasonably located even though each is in a different state. All are in the northeast, where the iron ore and the metallurgical coal are found. However, Johnson has such a hard time coming out loud and clear against a South Indian location (for which there has been considerable pressure) that one doubts such a mill would sacrifice much economics to politics.

The book has nine chapters, eight appendices, 45 tables, a 17-page bibliography, and a good index. The compression of a thorough and well-documented dissertation into a well-organized, well-focused book is not easy, and the author and his editors deserve only middling grades for organization and selectivity. The discussion of iron and steel technology and its relation to the factor proportions problem is disappointing in an area that might have been of great interest. An excess of the subjunctive mood robs many statements of their bite. In the end, not much is said about some of the larger issues of industrial growth at which the author bravely aimed. But a book need not be a paragon of readability and wisdom to be a highly useful contribution. Mr. Johnson has written a book anyone interested in Indian steel definitely should read.

Land Economics; Agricultural Economics; Economic Geography; Housing

Northern California's Water Industry. By JOE S. BAIN, RICHARD E. CAVES, AND JULIUS MARGOLIS. Baltimore: The Johns Hopkins Press, for Resources for the Future, 1966. Pp. xvii, 766. \$15.00.

It is not possible to do justice to this volume in the space of this review. The book consists of 766 pages, much of which is highly technical in nature. The work obviously represents a research undertaking of considerable magnitude. It would have been interesting to know more about the actual research undertaking; only the most fragmentary information is available in the preface regarding the amount of research resources, the personnel involved, and the amount of time devoted to the research on which the book is based.

The book consists of twenty chapters and four appendices. There are four parts to the book—Part I—Structure; Part II—Conduct; Part III—Performance; and Part IV—Summary and Policy Proposals. The fruits of the book are not harvested easily. Not only is the book long and technical, it is also rather poorly organized and written. Nevertheless, the returns from careful study will exceed the cost if one wishes to become informed on the topic under discussion.

The authors use the conventional tools of industry analysis to study the water industry of Northern California. To this reviewer's knowledge, this is the first effort to use this particular set of analytical tools to study water problems. On page 5, the authors state:

An industry study thus tests a set of hypotheses taking the following general form: a given constellation of elements of market structure generate a certain range of patterns of market conduct which, in turn, give rise to certain qualities and defects of market performance. It is not an exercise in unstructured description. Nor does it "test" the axiomatically true—or at least irrefutable—hypothesis that the behavior of human beings can somehow be explained by the environment in which they live. Rather, the industry study tests refutable hypotheses drawn from economic theory.

In this reviewer's opinion, the work is an impressive one. No doubt it will come to be considered something of a landmark in resource economics. It is important to give the basis for the above statement before proceeding so that a rationale can be established for the remainder of this review.

1. The volume is impressive because of what it contains in empirical information about the waters of Northern California and their development, allocation, and use.
2. The volume is impressive because of the always competent and, at times, imaginative use of economic analysis in treating the empirical information bearing on the subject in question.
3. The volume is somewhat less impressive in treating hypotheses resulting from market structure, conduct and performance theory. The reader is never quite sure just what hypotheses are being tested. The main value of the particular theory used would appear to be as a point of departure in organizing the research.
4. The book is not revolutionary with respect to economic evaluation of natural resources. There are many interesting and useful applications developed as particular problems are analyzed. Yet there appears to be no significant contribution to economic evaluation methodology as such.
5. The book is quite impressive in its integrated treatment of economic and political motivation. Some exceedingly interesting material in this connection can be found in Chapter 8 entitled "Conduct of Water Agencies: Organization Motives and Normative Criteria."
6. The policy recommendations are neither surprising nor especially original. Most have been advanced at one time or another by other economists or students of water resource development. However, the policy recommendations are impressive in this particular case because of the documentation.

What, then, are the main conclusions of this ambitious research? The reader is warned that the following treatment is too brief to do justice to the contents of the book. With respect to development, the authors conclude that the practices followed have resulted in excessive development. It appears the California Department of Water Resources has erred more in this respect than have the Federal agencies. The authors conclude that violations of allocative functions have, at times, in the sequence of development assumed significant proportions. With respect to the current situation in California, the following quote is significant:

The Feather River project . . . under present plans will undertake a clearly excessive aggregate interbasin transfer. Not only is the project excessive in aggregate scale; it also includes segments that could be eliminated, which now drag down its overall economic rating. In general, the proposed transfers to the North Bay region, to the Mojave Desert, and to the Palm Springs area for urban use, lack any visible economic justification in toto; the proposed transfer to Kern County for irrigation is, at best, overly large, and any transfer from the Eel to feed these dubious delivery areas is economically unsupportable. It is conceivable that a scaled-down project designed mainly to carry Feather River water to the South Coastal Basin might have economic justification.

The authors trace the cause of the above misallocations to the institutional framework, and develop policy recommendations to correct these evils. Among their recommendations:

1. Two independent commissions, one at the national and one at the state level, with extended powers over the authorization of water projects.
2. Changes in the law to encourage the marketability of water rights.
3. Vesting in the State Water Quality Control Board regulatory powers which would permit them to establish "strict standards for the abatement of all types of pollution" and ". . . a schedule of penalties or taxes which would be payable to the state by various classes of water users for unabated or nonabateable pollution" (p. 668).

The authors are not naive with respect to the political feasibility of their proposals. They say, with respect to the first recommendation above,

This is not the most politically saleable idea ever advanced. But we believe that it has substantial merit, and could be worth a substantial sales effort (p. 664).

One is led to wonder how the authors can analyze the economic and political situation as carefully as they have, and then with apparent comfort offer recommendations such as those listed above. It should be obvious that the implementation of the above recommendations will have to contend with powerful forces. Undoubtedly these forces could be identified from the research under review. Yet the recommendations are simply stated, as though there were some ready client eager to snap them up and put them into practice. As mentioned above, the same type of conclusions and recommendations have been put forth by others for some time, without apparent effect on public decision making. Why? Perhaps Resources for the Future, Inc. should finance an effort to answer this relatively simple question. Otherwise, the financing of such elaborate studies may help educate a small group of professional economists and provide research training for aspiring professional economists without having any visible effect on the allocation of our riches for water resource development.

There are additional features of the book which should be mentioned, both of a plus and minor nature. Appendix A, entitled "A 'Pure' Theory of the Demand-Price Relationship for Irrigation Water," appears to be a distinct con-

tribution to the literature. It should make agricultural economists blush to realize so little has been done in this field, although not all of the relevant literature on the subject has been cited. The book is marred by confusing writing and shallow thought in places. This is surprising when one considers the fact that the economists are obviously competent, and that careful analysis is carried forth in other parts of the book. For example:

Any discrepancy between marginal cost and marginal value tends to signal an excess, or deficiency, in the quantity of resources employed in the activity in question. The *elasticity of demand* indicates the size of the misallocation associated with a given gap between marginal cost and marginal value (p. 162).

What about the elasticity of supply? What about the reallocation of resources associated with a redistribution of income? Again and again the authors refer to price as a determinant of demand. Yet these minor items should not detract the reader from the substantive and rewarding parts of the book.

EMERY N. CASTLE

Oregon State University

The Economics of Outdoor Recreation. By MARION CLAWSON AND JACK L. KNETSCH. Baltimore: The Johns Hopkins Press, 1966. Pp. xx, 328. \$8.50.

This book is about the social and economic aspects of outdoor recreation. It presents some new material and brings together in a convenient form many ideas, analyses, and viewpoints that are widely scattered. Most important, Clawson and Knetsch apply the analytical tools of economists to the problems of outdoor recreation. They fit their material into a broad analytical framework that consists of a supply-demand or market approach. They generally summarize the arguments concerning policy issues rather than advocate specific policies. Clawson and Knetsch direct their book primarily toward park and recreation workers and students in the field of outdoor recreation rather than toward professional economists. But economists concerned with outdoor recreation will find much of interest in the economic analysis and in the discussion of policy issues. The authors acknowledge receiving comments on all or parts of the book from fifty-two individuals who are presumably experts on some of the problems discussed. This is enough to give any reviewer an inferiority feeling.

The book has five parts. Part I includes a discussion of various terms and concepts used throughout the book. Part II is concerned with the demand for outdoor recreation. It is the longest and to me the most interesting part of the book. The authors discuss basic determinants of demand for outdoor recreation, attempt to estimate the demand facing particular sites, and review methods of estimating future demand. Part III is a discussion of various aspects of the supply side of outdoor recreation. It includes quality considerations, statistics concerning existing recreation facilities and their use, and the relation of available recreation resources to the location of population. Part IV brings demand and supply together to discuss various problems and policy issues concerning outdoor recreation. It covers such topics as the valuation of

resources for recreation, the local economic impact of spending for outdoor recreation, the role of public and private agencies, investment criteria, and pricing policies for outdoor recreation facilities. The final part of the book is a look at the future; it includes recommendations for needed research and discussions of major policy issues of the future.

The attempt of Clawson and Knetsch to develop demand curves for outdoor recreation represents a major advance over the employment of *use* as a measure of demand. But their application of demand analysis encounters some difficulties. The first occurs in defining the units for measuring quantity. They define the thing to be measured as the *whole recreation experience* (anticipation, travel to, on-site experience, travel from, and recollection) associated with a visit to a specific recreation area; the unit of measurement is the *visit* by a family or a party. Their demand curve thus shows the relationship between the cost of a visit to a specific recreation area and the number of visits to that area during some time period. Variations in the cost per visit result primarily from the different distances traveled in getting to the recreation site. To estimate this demand curve, the authors use data collected by others in surveys of visitors to particular recreational areas. They convert total visits by residents of various distance zones around a recreation area into attendance rates for the populations of the zones. From this price-attendance rate relationship they move to the demand for specific recreation resources which is the relationship between visits and admission charges at the recreation site.

Their derivation of the demand for specific recreation resources assumes that the observations of visits and costs for the whole recreation experience are points along a single demand curve. Clearly this assumption is not valid—each observation represents only a point on the demand curve for each distance zone. The authors are aware of this inadequacy of the data but feel that their technique gives reasonable though low estimates of “true” demand. I suspect, however, that a probabilistic gravity model similar to the one developed by David L. Huff¹ is more promising, especially for estimating the demand for new recreation areas. The estimation of the parameters of the gravity model would, of course, require surveys of households. We could learn much more about demand curves if public recreation areas would experiment with admission charges.

Several other topics and discussions in the book particularly interested me. I can mention only a few of them. The authors rightly reject the argument that free public parks help redistribute income in favor of the poor. Low income groups cannot travel to distant outdoor recreation facilities so cannot benefit from low park admissions. The discussion of the local impact of outdoor recreation suggests that tourism may not be a panacea for depressed areas. A recreation or tourist business can be a hazardous undertaking, the activity is highly seasonal, and pay scales for most employees of such businesses are among the lowest of major industries.

The attempt to remain neutral on policy issues and to present pro and con arguments leads to discussions that are not as incisive and clear as they could

¹ David L. Huff, *Determination of Intra-Urban Retail Trade Areas*, University of California at Los Angeles, 1962.

be. Sometimes I could not determine whether the authors were presenting their views or someone else's, or whether they accepted certain arguments as valid. I would have been more critical of the arguments for public rather than private provision of outdoor recreation facilities. There is no evidence to show that the political decision-making process has less serious imperfections than a private outdoor recreation market nor that judgments concerning the future are better if publicly made. On another critical note, the last two chapters repeat much material that appears earlier—one short chapter summarizing future policy issues and needed research would have been better.

In summary, this book performs an important function by employing an analytical approach in the discussion of problems of outdoor recreation. Earlier discussions usually lacked such an approach. By bringing together widely scattered materials and presenting them in an integrated and consistent manner, the book also serves a useful function. It should provide both a starting point and a stimulus for further research on this topic.

RICHARD L. PFISTER

Indiana University

Essays in Urban Land Economics—in Honor of Leo Grebler. Los Angeles: University of California Real Estate Research Program, 1966. Pp. 351. \$6.50.

This is a collection of essays in honor of Leo Grebler. It is a good collection. The sixteen essays are divided into five parts covering housing economics; housing finance; urban land economics; the housing industry; and the city. The book is a very interesting mixture of surveys of the economics of problems and policies, and some new material on specific facets of the housing market, with the former group predominating. As with any group of essays written by a number of people, the thread of continuity is not sharp, but divergence is much less than is usually the case, and is not particularly disturbing, as the essays are interesting and useful.

The papers provide a good deal of insight into the fields covered. Factual surveys on housing finance and on FHA-FNMA policies and effects are presented by Robert M. Fisher and Robert C. Weaver respectively. Ernest M. Fisher traces the effects of rent control using New York data. The analysis points out results that could have been (and were) expected on the basis of good economic analysis.

A marked characteristic of the essays is the use of good economic analysis. In exploring such diverse subjects as Chester Rapkin's treatment of price discrimination against Negroes, and land value estimates by Paul F. Wendt and William Goldner, it is clear that economics has much to contribute.

M. Carter McFarland traces the history of residential rehabilitation work, examining the effects of public policy on private decisions to increase rehabilitation efforts, or to continue the downward trend which, as it turns out, may be highly profitable. This is another example of sound economics having some-

thing to say about why problems exist and how we might better be able to attack them.

An essay on place prosperity dealing with some welfare considerations involved in public decisions redistributing economic activity, by Louis Winnick, is a real delight. It points out, in a very sharp but fair manner, the implications of various policies such as various urban renewal schemes and the Appalachia program for locational decisions. The true gains and losses involved in the shifts and their equity considerations, as students of these actions realize, are not all accounted for in the public statements of those responsible for these programs. A mayor of a city often has more reason to rejoice at the opening of a new industrial plant than has a federal administrator, but, as Winnick observes, you can barely tell this at the ceremony. Public officials and public policies have indeed outpaced the economists in this area, but essays such as this will help. To the rapidly growing number of people interested in this whole question, the benefits of this essay alone are greater than the cost of the entire book.

An essay by Fred E. Case deals with some of the characteristics of the enduring city, in which he cites many of the failings of current American cities, and some of the things which he and many would like to see cities become. He is more concerned with these objectives than with the reasons why they have not been achieved in the past. Some of these are supplied by Frank G. Mittlebach in a most interesting essay on the entrepreneurial influences in shaping the American city. Using illustrative examples, he points out many reasons for people making the types of decisions that ultimately shape cities. It is in this essay, more than in any of the others, that the pervasive disassociation of costs from beneficiaries in urban development (which does so much to shape the urban environment) is explored. One is a bit puzzled to find this type of economic consequence so lightly treated in a volume of this nature.

Leland S. Burns traces the threads of economic development theory and the role of housing investments in development in the first essay. After noting that housing often ranks low in dollar payoff as compared to investments—for example, in industrialization—he proceeds to supply a convincing argument that indeed there may be a higher payoff than that accounted for in GNP. Here is the familiar problem that economists are always running into, that many things are indeed valuable even though not measured in the same metric as National Income. Nonmarket economics, or such questions of market failure, are coming more and more to the attention of economists, and rightly so. Burns similarly rejects the extreme position that housing investment ought to be viewed as an end in itself, and takes particular exception, rightly, to estimates so often turned out that so many millions of units of housing are required “to meet unsatisfied needs of developing countries.” He observes that housing is critically short in underdeveloped countries, and in relative shortage everywhere else. The pity is that such statements of requirements, though nonsense, make such good copy and receive the attention they do.

The one difficulty found is that the book is not so much a collection of essays on urban economics as on housing economics. Beyond the possible mis-

nomer here, this may lie at the root of some of our difficulties in urban economics; that we may be preoccupied by housing policies, not always taking into account a broader economic interest. Only a couple of the essays attempt to relate housing matters to the formation of urban regions.

JACK L. KNETSCH

The George Washington University

The Role of Agriculture in Economic Development: A Case Study of Pakistan. By MAHMOOD HASAN KHAN. Wageningen, Netherlands: Centre for Agricultural Publications and Documentation, 1966. Pp. 161.

The analytical framework suggested by Khan for the process of economic development is a modification of the Rostovian model. First, he holds that Rostow's schema makes insufficient allowance for the variety of ways in which differing economies can fulfill the preconditions for take-off. Second, he assumes that the take-off in modern times will practically always be consciously induced by government action. Third, he accepts as essential to the Rostow thesis that the take-off is characterized by a rapid increase in capital formation (it is shown that 10 per cent of income being invested is insufficient where population growth is rapid) and by the establishment of one or more leading sectors. Fourth, he adds two essential conditions for take-off to those outlined by Rostow: (a) Agricultural productivity must show substantial improvement to provide food and raw materials for the expanding economy and (b) underemployment in the agricultural sector must be absorbed so that by the beginning of the stage of self-sustained growth surplus agricultural labor is exhausted.

Khan shows that the transformation of agriculture as manifested in rising productivity is absolutely essential to sustained industrial development. Increasing agricultural productivity enables the farmers to supply the food requirements for the growing urban and industrial population (obviating inflation). It allows the agricultural sector to release the labor force needed for industrial expansion and it expands the rural market for industrial products. Therefore, the method of transforming traditional agriculture is of crucial importance and he summarizes generally accepted methods under three headings: (i) acceptance by farmers of new or improved farm inputs; (ii) adoption of improved farm cultural practices; and (iii) introduction and assimilation of managerial innovations.

The discussion outlined above comprises the first two chapters of the book and gives the theoretical framework upon which the consideration of Pakistan is based. Aside from the modification of the Rostovian model, the value of these chapters is in the careful and concise reorganization of accepted ideas, rather than in new departures.

Three chapters follow on the nature of the Pakistan economy and the progress of its development with emphasis on the agricultural sector. These chapters give an amazingly balanced and concise summary of the traditional agricultural economy, its problems and its progress toward transformation. These

chapters are descriptive and their value lies in their careful summary of the literature with a few additions from unpublished documents.

The final chapter is an assessment of the prospects for the economic development of Pakistan with emphasis on its agricultural aspects. The official Perspective Plan for 1965-1985 calls for a doubling of per capita income and the provision of full employment by 1985. Khan asserts that this objective is impossible under the provisions of the plan for two basic reasons.

1. He estimates that population growth will average about 3.3 per cent per year instead of 2.7 per cent as assumed in the plan. Not only will the faster population growth reduce the projected growth of per capita income, but it will absorb much capital and will greatly increase the number of new jobs which must be created in order to overcome chronic unemployment.

2. The plan projects a growth of 5.6 per cent per year in the agricultural sector, but Khan estimates that this would require a growth of agricultural labor productivity of 4.7 per cent per year as compared to 1.5 per cent achieved recently. The plan does not show how this phenomenal transformation can be achieved and Khan reasons that it is impossible. Therefore, he concludes that substantial progress, but slower than that planned, should be expected.

WILLIS D. WEATHERFORD

Berea College

The Egyptian Agrarian Reform, 1952-1962. By GABRIEL S. SAAB. New York and London: Oxford University Press, 1967. Pp. xvi, 236. \$8.00.

The Agrarian Reform Law was the first major legislative act of the revolutionary Egyptian government under Nasser after King Farouk was overthrown in 1952. Now for the first time a scholarly, objective book in English is available evaluating the results of ten years of reform. Dr. Gabriel Saab was farming in the Nile Delta at the time of the revolution and later served in various departments of the UAR government as well as with the F.A.O. Later he was Director of the Institute of Rural Economics in Beirut. In order to study the Agrarian Reform Laws, Saab visited the major agricultural "mant-iqat" centers for an on-the-spot comparison between plans and implementation. He no longer lives in the UAR and has been free to write this frank, perceptive appraisal of the successes and failures of the monumental effort of reform.

The Egyptian "fellaheen" were ready for revolutionary changes in 1952. Sixty-five per cent of the 6 million feddans (one feddan = 1.038) of cultivated land was owned by six per cent of the landlords. The remaining thirty-five per cent of the land was fragmented into plots that averaged only 2.2 feddans and were owned by 2,769,000 peasants. Rents paid by tenants were extraordinarily high; wages to farm laborers on the large estates were at subsistence levels and sharecroppers were often required to turn over 100 per cent of their cotton crop and 50 per cent of their wheat to the landlords. Yields per feddan were low; water was wasted; drainage was poor; animal power predominated; health was miserable and unrest was widespread.

The major features of the Agrarian Reform Laws are described by the author in specific helpful chapters. (1) Land ownership was limited to 200 feddans per person or 300 feddans per family. In 1961 the maximum was reduced to 100. (2) Some of the land in excess of the limit was sold privately to buyers but at depressed prices. (3) The government expropriated or acquired a total of 955,000 feddans representing 15.5 per cent of the cultivated area (p. 28). The price paid was equal to 70 times the annual land tax—an amount equal to approximately 40 per cent of the market price in 1952. Payment was made in 30 years, 3 per cent non-transferable government bonds which were later repudiated. (4) Some of the land was resold to carefully selected experienced farmers in plots up to 5 feddans. (5) Cooperatives were established in the villages to plan the triennial rotation of crops, to supply seed, fertilizer, and insecticides, to provide agricultural credit and to market the crops. Membership was compulsory for those who received distributed land but voluntary for others. (6) Improvements were made in rural housing, sanitation, health and education. (7) New desert lands were reclaimed in the Sahara, west of the Delta in the Liberation Province and in the oasis areas of the New Valley.

Dr. Saab lists some solid achievements of the first ten years. The land has been redistributed to an additional million Egyptian peasants and the political and economic power of the large landlords has been reduced. There has been a slight improvement in the living conditions of the rural families—perhaps by 10 to 15 per cent in a decade. This has resulted primarily from a reduction in costs, like rent and seed, rather than from increases in income. There has been about a 45 per cent increase in the volume of agricultural output from 1953 to 1962. At least 40,000 feddans in the Liberation Province (El Tahrir), 35,000 feddans in the Egyptian American Rural Improvement Society (EARIS) and 100,000 feddans in the New Valley have been brought under cultivation for the first time.

However, in spite of this vertical and horizontal expansion of agriculture, most Egyptian observers, including this reviewer, are well aware of the inadequacies of the program. Saab points out that the initial enthusiasm of the leaders has disappeared; the bureaucracy is all-prevailing; decision making is painfully slow; land litigation is complex; priorities are uncertain; rising income is used for consumption rather than for vital saving; the agricultural infra-structure is deteriorating; and all the mammoth effort seems to help so few. Egypt has discovered that it is not easy to make a farmer out of an agricultural laborer. Dividing the land is not sufficient. Agrarian reform is far more complex than land reform. Other factors must also accompany social change in the areas of education, health and social organization.

"In conclusion," writes Saab, "the land distribution programme could best be described in 1961 as a major delaying action to win time by redistributing wealth. . . . It has fulfilled most of its initial targets . . . without any grave disruption of agricultural production, and the political power of the feudal landowners has been broken. The state (has) placed formidable obstacles in the way of a self-sustained process of economic, social and culture growth through its reluctance to envisage the emergence of any spontaneous construc-

tive initiative in the redistributed estates. . . . It has thus impressed on the whole land-distribution programme static characteristics gravely endangering its successful long-term evolution" (p. 140).

With this valid conclusion, it is not likely that other nations will copy the Egyptian Agrarian Reform; but no scholar interested in this topic or in the UAR should fail to read Saab's descriptive and factual book. Theoretical economists will miss any references to the actual planning process; to input/output ratios; to zero marginal productivity; to balance of payments difficulties or under-employment. But if one wishes to know how it was done in Egypt this is a very clear description.

Baldwin-Wallace College

Labor Economics

Employment, Race, and Poverty. Edited by ARTHUR M. ROSS AND HERBERT HILL. New York: Harcourt, Brace and World, 1967. Pp. ix, 598. \$3.95.

This is one of four volumes of articles resulting from the Research Program on Unemployment and the American Economy. This program was financed by the Ford Foundation "administered by the Institute of Industrial Relations" on the Berkeley campus, and its co-directors were Arthur M. Ross and R. A. Gordon. Herbert Hill, labor secretary for the NAACP, joined Ross as co-editor of this volume containing twenty separate contributions.

Since so much of the literature dealing with employment patterns of American Negroes is chock-full of the dreary and dismal record of white America, it is pleasing to be able to report that this volume contains evidence that things are changing, at long last, for the better. Co-editor Ross, with the aid of a curious statistical technique that uses absolute differences to measure proportionality, does not wholly concur with this estimate; but the evidence in the volume pushes the reviewer to that conclusion. Without attempting to rate these items in order of importance, the following listing of welcome changes is the basis for a generally optimistic view.

1. Ross notes that "One development in the 1959-1964 period is particularly striking . . . Negroes gained 134,000 skilled trades jobs although the total increase was only 425,000 and 41,000 sales jobs although the total increase was only 62,000. This represents a sharp break from the past" (p. 42).

2. Samuel Krislov, writing on federal government employment, informs us that "Clearly, the Equal Employment Program has seen truly significant changes in the four years of its enforcement. Not only have Negroes garnered 20 per cent of the new positions in the Federal service in this period, but they have significantly altered their pattern of employment" (p. 348).

3. Direct action techniques have scored some successes in previously all white employment situations. For instance, August Meier reports that ". . . the agreement CORE made in the summer of 1964 with the Bank of America in California was a major victory that provided for the hiring of 8,000 Negroes in a twelve month period" (p. 197).

4. Membership exclusion practices by trade unions remain the most recalcitrant single problem area in the fight for fair employment, but even here we find that these vicious practices are now being subjected to a wide array of weapons. Paul Norgren reports that Fair Employment Practices (FEP) Commissions in New York and Philadelphia have been successfully implementing fair employment practices and recently, in the sixties, have finally moved with some success against trade union violators. Most important for the question of union exclusion practices is the change of heart manifest on the NLRB. In an exhaustive and well-done article, lawyer Sanford Rosen explains how the NLRB has come to the position of defining exclusionist activity as an "unfair labor practice" and how this can be useful in moving against such conduct. Moreover, even though Title VII of the 1964 Civil Rights Act contains provisions for eliminating racist membership policies, Rosen makes an impressive case that the NLRB can do the job better.

5. Though George Strauss qualifies his article on management attitudes toward the fair employment question by restricting most of his evidence to the San Francisco area he does report that "Government and Negro action group pressures have pushed many employers past color-blindness to affirmative action" (p. 287). Consistent with this is his statement that "Placement officers from the better colleges report that the demand for Negro graduates far exceeds the supply" (p. 284).

6. And two writers, Norgren and Rowan, make it clear that the fears expressed by all concerned that integration in Southern plants would meet with great resistance have been consistently and grossly exaggerated. Rowan, after reviewing evidence in three plants in Birmingham, notes that "Relations between white and Negro employees have been good in the plants, and transition under the new integrated promotion system has been orderly, with scarcely an incident" (p. 334). Norgren seconds this by saying that "the conclusion seems warranted that racial equality in employment can be promoted through FEP legislation in the South . . ." (p. 566).

In contradistinction to the estimate made above that the winds of change are blowing beneficently, Charles Killingsworth concludes his diagnosis as follows: "The point is that the trends of the past quarter century in Negro migration, birth rates, death rates, occupational shifts and school attendance are now yielding the largest increases in Negro population in the regions and among the groups where Negro disadvantages are greatest" (p. 72). There is supporting evidence elsewhere in this volume, evidence that deals with the intractable ghetto problems, the minimum of returns received so far from our retraining efforts, and the debilitating effects of long-term harsh treatment.

This dichotomy, between improvement on the one hand and the degradation of the ghetto on the other, points up the major failing of research done on Negro employment patterns: the failure to note the growing class cleavage amongst Negroes. It should be understood that the items listed above as contributing to an optimistic view do make things better for that growing body of educated and skilled Negroes, but are simply no help to the school dropout, the unskilled, the functional illiterate.

In the preface to this useful volume of essays, many of them well written, the co-directors of the program explain that the reason for bringing together these essays is "... to furnish better guidelines for policies ..." (p. v). The best place to start is with the recognition that ghetto problems and fair employment problems, while compounded in difficulty and related by the race question, are essentially different.

MALCOLM H. LIGGETT

San Francisco State College

Labor Economics: Wages, Employment and Trade Unionism. By ALLAN M. CARTER AND F. RAY MARSHALL. Homewood, Ill.: Richard D. Irwin, 1967. Pp. xii, 584. \$8.50.

This is a textbook aimed at the introductory labor economics course, presuming a prior knowledge of the principles of economics. The book is divided into three principal sections: (1) Comparative Labor Movements (about 185 pages); (2) Wages, Employment, and Collective Bargaining (about 185 pages); and (3) Public Policy (about 190 pages). The book's most unusual features are an extensive discussion of labor movements in other countries and a somewhat greater emphasis on the economic theory of labor markets than is found in the average text.

In general, the book is competently written, and it probably surpasses the standard of the average level of undergraduate teaching in labor economics. The chapters on labor market theory are followed by appendices with more detailed graphical presentations of production functions, bargaining models, and so on. The exposition is clear, and there is no reason why undergraduates who have passed the usual principles course should have difficulty in understanding the material presented. The material on comparative labor movements helps to place American labor economics in the perspective of labor movements in other countries, and this should be especially valuable for the general student who takes only one course in the field. Also commendable is a two-chapter section devoted to the problems of minority groups in the labor market (Chapters 21 and 22).

Despite the fact that this book can only be described as competently conceived and written, I have an important reservation about its usefulness. That is, while a substantial part of the book is devoted to an exposition of the theory of the labor market, there isn't enough really serious effort devoted to helping students see the relevance of theory to understanding labor market behavior. The relevance of this criticism probably is not shared by a large number of the teachers of labor economics in the United States, and the authors might be unwise in considering the criticism, even if they should think it valid. Nevertheless, my opinion is that textbooks of all kinds and at all levels ought increasingly to reflect the great strides that economists are making in using economic theory to understand economic events. This means that a large part of the empirical material covered should be treated from the point of view of its relevance to economic theory; it also means presenting more empirical materi-

.

al than is usual and selecting the material presented in the light of theoretical considerations.

My criticism extends even to the early chapter on theories of the labor movement. It seems to me pedantic to outline a large number of alternative and sometimes conflicting theories of the labor movement without devoting some space to considering their relevance and usefulness in the light of available evidence. Merely to present the theories becomes too much like Biblical exegesis for my taste. It may lead students to think that economics has little to offer but abstract theorizing.

If the authors had focused on testing economic theory, they would not have been so ready to make the statement that "Labor unions historically have been the major force in reducing the length of the standard work week" (p. 286). While the statement may be true, recent studies of labor supply imply that hours of work have responded to rising income levels. These alternative explanations ought to be contrasted with each other in the text, and an attempt should be made to resolve the conflict.

I question the relevance of presenting an appendix outlining a bargaining model which does not also present data of behavior which the model helps to understand (Chapter 13). While it may be true that the results of collective bargaining need the theory of bilateral monopoly to explain them (Chapter 12), the student is forced to accept this statement on the basis of the authority of the authors.

In Chapter 14, the authors discuss the impact of unions on fringe benefits. Again, while it may be true that unions have had a substantial impact on the composition of the typical wage package, the authors do not present an alternative hypothesis, that employers in a competitive market would have an incentive to offer the kinds of wage packages that their employees desire. If it is true, as the authors state, that the growth of the importance of the federal income tax has had something to do with the increasing demand for fringe benefits, then they ought to consider at least the possibility that fringe benefits would have grown in importance in the absence of unions.

The general issue that bothers me about this text (and it is common to practically all labor economics texts) is that despite the presentation of theory, data, and institutional material, the treatment is compartmentalized to a great extent (perhaps less in this book than in many others), and the hand that writes one section seems to be unaware of the activities of the hand that writes the other. I don't think this is the optimal way to train citizens, who ought to be developing an intellectual framework for dealing with issues on which they would like to form intelligent opinions, or economists, who ought to be gaining an understanding of an orderly and efficient means of drawing information about the world from data.

Nevertheless, given the currently prevailing standards of teaching in this field, the book ranks above average in conception and execution; teachers looking for a textbook to assign their students should give this one serious consideration.

Population; Welfare Programs; Consumer Economics

Studies in the Economics of Income Maintenance. Edited by OTTO ECKSTEIN.
Washington, D.C.: The Brookings Institution, 1967. Pp. xvi, 254. \$6.00.

Economists have been slow to apply sophisticated techniques of analysis to social insurance and welfare problems. Difficulties of definition and quantification of important variables have presented obstacles to such an approach.

In two of the four studies in this book, multiple regression analysis is extensively used. The studies were originally prepared as doctoral dissertations at Harvard under Otto Eckstein, who has supplied a brief introduction to the volume. They analyze particular aspects of Federal Old-Age, Survivors and Disability Insurance (Henry Aaron); of unemployment compensation in Massachusetts (Charles Warden, Jr.); of federally supported State welfare programs (Lora S. Collins); and of unemployment caused by the closing of the Mack Truck Plant in Plainfield, New Jersey, in 1961 (John W. Dorsey). In addition, comparisons are made of social security expenditures in 22 countries (Henry Aaron).

For the most part, the results of these studies are suggestive rather than definitive. Numerous relationships are explored and tentatively assessed, but generally, additional testing of hypotheses is necessary before they can be accepted with confidence.

Among the interesting findings in these studies are the following:

1. A cross-section analysis of 1957 social insurance and welfare expenditures in 22 countries indicates that the length of time a country has had a social insurance system is the most important single determinant of the percentage of its national income devoted to social security expenditures. The older its old-age or health insurance program, the larger is the social security percentage of its national income. Also, very wealthy countries generally spend proportionately less national income on social security.

2. Countries that make heavy use of general revenues to finance social insurance outlays tend to have a smaller proportion of national income devoted to social security than countries relying solely or largely on earmarked taxes, usually on payrolls. This finding may raise doubts about the wisdom of widespread use of general revenue financing for the social insurances in this country.

3. States with low per capita income tend to have a high percentage of their population of various public assistance programs and low average assistance payments to clients. Interstate variation in income level can account for more than half of the interstate variation in the proportion of the population on public assistance.

4. Analysis of 27 industries showed that, between 1947 and 1958, one-third of the unemployment benefits in Massachusetts were caused by cyclical swings, one-third by seasonal variations, about one-eighth by secular declines in employment, and the remainder divided between irregular (frictional) factors and unidentifiable elements. Nine-tenths of the benefits in building construction were attributable to seasonal fluctuations. Presumably experience

rating in unemployment compensation, which rests on individual employer responsibility, is inappropriate for unemployment stemming from cyclical or secular demand factors.

Although State Employment Service personnel thought that separation pay (mean of \$1,338) and \$50-a-week unemployment compensation caused the well-paid Mack workers to refuse jobs much more readily than they would without such financial security, multiple regression analysis did not support that claim. Dorsey's conclusion (p. 233) that "In general, unemployment benefits covered recurrent or ordinary expenditures for most families" seems to be refuted by his statistics (Table 16) showing unemployment benefits amounting to only 81 per cent of recurrent weekly expenditures.

Although many of the statistical results are fairly commonplace and make dull reading (particularly the 75 pages on public assistance expenditures), some results are quite interesting and should stimulate further investigations. Warden's initial reflections on experience rating in unemployment compensation in the light of his industry benefits analysis are one example.

The handling of the incidence of social insurance taxes by two of the authors illustrates the dangers of uncritical acceptance of conventional views. Aaron says (p. 20) that "There is virtual unanimity that payroll taxes levied on the employer are largely shifted, . . ." That is not true of widely varying State tax rates (from zero to 4 per cent) under experience rating in unemployment compensation. Because Warden neglects the incidence of State unemployment taxes, his conclusions about experience rating encouraging a shift of labor costs from habitually unstable industries to stable industries are certainly subject to question. Surprisingly, he does not attempt to reconcile his conclusions about the inappropriateness of experience rating for cyclical and secular-decline unemployment with his notions about the shifting and bearing of the full labor costs under experience rating.

One hopes that other doctoral theses will carry this type of analysis of social insurance and welfare expenditures further and help to clear up some of the mysteries, inconsistencies, and questionable conclusions that plague this subject area.

RICHARD A. LESTER

Princeton University

The Changing Faces of Economic Insecurity. By JOHN G. TURNBULL, with MALCOLM S. COHEN AND MARY PEPPE. Minneapolis: University of Minnesota Press, 1966. Pp. ix, 157. \$5.00

Whether economic insecurity is greater or less than it was fifty years ago, whether the relative importance of the different causes of insecurity have changed and whether society is making more or less adequate provision for alleviating such insecurity as occurs are intriguing questions. By economic insecurity Professor Turnbull means income deficiency which he sees as being primarily due to "income curtailment" or "increased expenses." In fact, under the latter head he deals only with medical expenses, and only briefly with these. Although early in the book he mentions substandard wages as a

factor causing economic insecurity he presents no historical comparisons in this area.

His book concentrates on loss or interruption of income and deals with four of the causes, namely what he terms premature death (meaning thereby "death that leaves financial obligations unmet"), old age ("living too long in economic terms"), unemployment, and illness and accidents (for the latter, occupational only). In chapters devoted to each of these risks he compares the frequency of occurrence in 1960 and 1910, and the effectiveness of what he terms "alleviative programs" aiming to replace through organized measures some fraction of lost income. Of these he deals only with the social insurances because, presumably, of his belief that income maintenance should be based on right rather than need. Even so, the omission of the Veterans' Administration programs seems difficult to justify, while disregard of the public assistance programs involves an underestimate of the effectiveness of public measures in the areas of both income maintenance and medical expenses.

He finds that "there has been a decrease in the frequency of economic insecurity caused by premature death, old age [sic], economic unemployment and illness . . . Old age has increased as an economic insecurity problem . . . One may conclude that the decrease in insecurity from premature death and illness has more than offset the increase in insecurity resulting from old age" (p. 136). One may perhaps agree with his findings about illness, although his estimate of the size of the decrease seems very optimistic and he says little about the rising costs of medical care. But his selection of the age group 14-65 as the age span in which premature death may occur involves a serious underestimate of the importance of this risk as a cause of economic insecurity for it neglects the increasingly important group of aged widows, who thanks to greater longevity and their longer life expectancy relative to men, are coming to form a major component of the economically insecure population. There is even more doubt about the decrease in the frequency of economic insecurity caused by economic unemployment. Turnbull's own analysis of unemployment trends points out that much depends on the years selected as dates for comparison ("if one sets 1960 against 1935 the improvement is apparent: if one compares 1960 with 1906, 1960 does not look so good" pp. 72-73). And while one can agree that society will never again tolerate a level of unemployment such as was experienced in the 1930's, account must be taken of the fact that "the pervasiveness of long-term unemployment appears to have been on the increase since 1945" (p. 71). An evaluation of the significance of unemployment as a cause of insecurity would also call for consideration of the relative prevalence of irregular and partial employment. No evidence is presented for the statement that the increase in insecurity due to old age has been outbalanced by declines in the frequency of the other risks. In fact, if the medical break-throughs to which Turnbull looks forward (e.g. in the area of degenerative diseases) occur, old age will become a still more serious factor making for insecurity.

But even if one grants that economic insecurity because of interruption or loss of income is probably less than it was fifty years ago, owing both to de-

clining frequency of certain causes of non-earning and to the development of a structure of public alleviative programs providing some measure of income replacement, one would have expected that a study of the changing faces of economic insecurity would have given attention to other causes of insecurity which are becoming increasingly important. Prominent among these are what might be termed the sociological factors, notably family breakdown and, on what Turnbull calls the increased expenditure side, size of family. 65 per cent of the four and one-half million people, three-fourths of them children supported by the AFDC program, are there because the father is absent from the home due to divorce, separation, desertion or failure to have married the mother. And the numbers thus supported are far smaller than they should be, owing to the restrictive practices of many states which deny eligibility to families for reasons other than failure to pass a needs test. Similarly, Orshansky's analyses in the *Social Security Bulletin* have shown that of the over 30 million people living below the Social Security Administration poverty line over 5 million are children living in families where the breadwinner had been fully employed during the preceding year, while about half of the 15 million children in the poverty group were members of large families. Had Orshansky's data been available to Turnbull it seems likely that he would have been even more hesitant in hazarding the guess that "the psychological causes of poverty are increasing and the economic (premature death, old age and so on) lessening" (p. 134).

EVELINE M. BURNS

Columbia University

Consumer Choice in the American Economy. By CAROLYN SHAW BELL. New York: Random House, 1967. Pp. xvii, 429. \$7.95.

The title, *Consumer Choice in the American Economy*, states what this book is about: consumer choice, consumption patterns. It also analyzes the market in which the consumer makes choices. Professor Bell's book ends with the same quotation from Adam Smith with which Elizabeth Hoyt's *Consumption in our Society* began in 1938. The composition of our Gross National Product hardly bears out the idea that "Consumption is the sole end and purpose of all production."

Consumer Choice in the American Economy first takes up budget studies, then theories of demand (consumer preferences, utility, and indifference), next considers the consumer market by means of description and models (price competition and non-price competition), lastly it discusses consumer protection.

The book is intended to be a text or supplementary book for a course in consumer economics which might be taught in economics, sociology, or marketing departments or in a school of home economics. The approach of the book is theoretical, analytical, and quantitative. It achieves very well the limited scope which the author has selected.

Among current books on consumption David Hamilton's very good *The Consumer in Our Society* had novelty and freshness when it was published in 1962; Arch W. Troelstrup's popular *Consumer Problems and Personal Fi-*

nance has gone into a third edition. Dr. Aurelia Toyer's paperback, *Get Your Money's Worth*, has readability and practicality. Toyer's book is useful for a union, or a consumer counsel, or an urban antipoverty group. Mrs. Bell's text has amplified and updated the numerous statistics in the consumption field. It is probably the most useful current text for liberal arts college students.

The treatment of diminishing marginal utility and of indifference curves is conventional. It compares favorably, however, with the demand theory analysis in such a book as Samuelson's *Economics*, and is substitutable.

The consumer protection section is concerned with welfare, information, and "Truth in Lending," but it does not show much consciousness of the changing world such as Kenneth Boulding exhibits in *Principles of Economic Policy* (sections on consumer sovereignty, welfare involvement, "income maintenance policy," and need for ethical theory arising out of conflict in value systems).

Mrs. Bell expresses a number of interesting value judgments in her book; for example, she is critical of mass production because it limits variety of choice although she recognizes the low unit cost of much of it. She thinks that the main justification of governmental consumer counsels is to improve information available to consumers. With regard to establishing standards of quality she prefers more enforcement of existing laws rather than imposing quality standards and product specifications. She regards consumers' own experience as the main source of information. Thus, advertising has the function of informing the consumer about variety, new products, and of helping to break his old habit of consumption.

The consumers of the poorer countries are not the concern of this book. Much of the world population spends over 40 per cent of its income on food. In some parts of Brazil over 65 per cent is spent for food. To teach a course in consumption to undergraduates and leave the students without comparison of their own extraordinary ability to command consumer goods and services with that of a large part of the world's population would seem to me to belong to the past.

VIOLA WYCKOFF KOMAREK

New York University

Related Disciplines

The Organization of Inquiry. By GORDON TULLOCK. Durham: Duke University Press, 1966. Pp. vii, 232. \$5.50.

In the words of the author, "The purpose of this book is to answer, or attempt to answer, certain questions about science." Science is intrinsically cumulative and cooperative; one man's work builds on that of others'. Judged by the results, science is organized quite efficiently. Yet "there is no central coordinating organization and . . . there is no more reason to believe in some sort of divine guidance for science than for economic activities." What, then, is the nature of the coordinating mechanism? For the system of science to work, scientists not only must work on problems of interest to other scientists,

but also must report their results honestly. "How does it happen that we can depend upon scientists to refrain from faking research results?" To answer these and related questions the book attempts to "investigate the nature of the scientific community . . . to explain why the individual scientist, who feels quite free and unconstrained, is nonetheless led to investigate problems of interest to others, [and to] exercise the most extreme precautions to insure accuracy."

Tullock's treatment of this broad topic is imaginative and perceptive. He points out that the basis for a coordination and control network rests, first, on the pragmatic interests of applied scientists and those who employ them, and, second, on the real interest in finding truth of at least some members of the basic science community. These two groups potentially can establish standards of relevance and reliability for the work of others. The potential is realized and the network given life through the funds provided by people interested in and willing to pay for practical results, the belief of many practical men and scientists that certain areas of basic research are important, and the desire of scientists, both applied and pure, to get ahead.

Tullock sees the pragmatic test of technical and economic relevance of results, turned into profit opportunities by the patent system, as guiding and controlling research by applied scientists. For the basic science community, Tullock sees the academic advancement system, and the role of publication in respected journals in that system, as the central mechanism. Editors want their journals to be important. If a journal is to be important it must publish articles that are read, favorably received, and not proven false. Both pure and applied scientists read the journals whose articles are in the fields of their interest, and are likely to be significant and reliable. Thus scientists, both pure and applied, interested in a field either because they have been paid to be or because they simply are interested, provide incentives for others to do research whose results they can use.

There is a lot to these ideas and others that Tullock elaborates in his book. Any reader is sure to pick up a number of insights and ideas.

There also is a lot to the book that is irritating. It may be a slight injustice to the author to say that the tone of the book should have been as follows: "I have been doing some thinking and reading about incentives and controls in the organization of scientific research, and here are some of my ideas." I doubt, however, that the implied level of serious research by the author falls grossly short of the mark. Throughout the book sentences and paragraphs take on a tone more suitable in a much more scholarly or more rigorous study. The author further makes the mistake, in the eyes of this reviewer, of pontificating on policy in a superfluous and superficial concluding chapter.

Despite these annoying problems—which really involve style—the book is well worth reading. And it has the virtue of being short.

NOTES

AER MANUSCRIPTS

The following manuscripts, exclusive of comments and replies and in addition to those listed in previous issues, have been accepted for publication in subsequent issues of the *American Economic Review*:

Giorgio Basevi, The Restrictive Effect on the U.S. Tariff Structure and its Welfare Value
Jagdish Bhagwati, More on the Equivalence of Tariffs and Quotas

J. M. Bonin, Consumption, Durable Goods Spending, and Changing OASDHI Seasonality
Bruno Contini, The Value of Time in Bargaining Negotiations: Some Experimental Evidence

J. R. Davis, Chicago Economists, Deficit Budgets, and the Early 1930s

C. J. Goetz, Earmarked Taxes and Majority Rule Budgetary Processes

D. R. Kamerschen, The Influence of Ownership and Control on Profit Rates

D. B. Keessing, A Country's Population and its Industrial Development: Some Evidence from Trade Patterns

Nissan Liviatan and David Levhari, The Concept of the Golden Rule in the Case of More than One Consumption Good

W. Y. Oi and E. M. Clayton, A Peasant's View of a Soviet Collective Farm

J. N. Rosse, A Curiosity in the Theory of Optimal Price Regulation: A Note

Hirofumi Shibata, A Note on the Equivalence of Tariffs and Quotas

Bo Sodersten and Karl Vind, Tariffs and Trade in General Equilibrium

G. E. Thompson, On Varying the Constants in a Linear Programming Model of the Firm

A. W. Throop, The Union-Nonunion Wage Differential and Cost-Push Inflation

Maurice Wilkinson, Factor Shares and the Direction of Technological Change

CANADIAN ECONOMICS ASSOCIATION AND CANADIAN JOURNAL OF ECONOMICS

For many years the Canadian Political Science Association has served as a common learned society for all Canadian social scientists. As the numbers of social scientists have grown, the Association has recently begun to subdivide itself into its components. The first step was taken when sociologists and anthropologists formed the Canadian Sociology and Anthropology Association. In 1966 it was decided to continue this process, by forming separate associations for political scientists and economists. The Canadian Economics Association thus has emerged from the Canadian Political Science Association, and now constitutes the Canadian learned society for economists.

The Canadian Economics Association, officially bilingual, hopes to facilitate scholarly contact among economists through its annual meeting and through conferences. However, its main activity will be publication of a new journal, *The Canadian Journal of Economics*, a bilingual quarterly whose first number will appear in February 1968. The *Journal* will consider materials in all branches of economics, pure and applied, both from Canadian residents and from others. It should serve as a medium for the dissemination of research findings relating to Canada. But it is not planned as a journal of Canadian studies. Its editors expect that its contents will be of interest to economists throughout the world. Manuscripts in English or French should be addressed to the Managing Editor, *Canadian Journal of Economics*, 100 St. George St., Toronto 5, Ontario, Canada.

Individuals may secure membership in the Association by writing to the Assistant Secretary-Treasurer, Canadian Economics Association, 100 St. George St., Toronto 5, Ontario, Canada. The ordinary membership is \$10.00 per year; the *Journal* is received with membership. Institutions may subscribe for \$10.00 per year.

PUBLICATIONS

The *Philippine Journal of Business & Finance*, a monthly, began publication in June 1967. All correspondence and manuscripts should be addressed to the Managing Editor, Suite 201, Manufacturers Building, Plaza Sta. Cruz, Manila, P.O. Box 1324.

A new international quarterly, *Socio-Economic Planning Sciences*, will begin publication in 1968. The new journal will particularly encourage contributions dealing with applications of systems analysis to the planning of public welfare and community services. Further information may be obtained from the Editor-in-Chief, Sumner N. Levine, City University of New York, Graduate Center, 33 West 42 Street, N.Y. 10036.

A new periodical, *The Annals of the Western Regional Science Association*, will begin publication in early 1968. Additional information may be obtained from the Editor, Michael K. Mischaikow, Department of Economics, Western Washington State College, Bellingham, Washington 98225.

The new editor-in-chief of *The Antitrust Bulletin* is Mr. James M. Clabault of Dunnington, Burtolow & Miller, 161 East 42nd Street, New York 10017. Manuscripts should be sent to him.

The U.S. Department of Commerce has published *Industry Profiles*, which provides basic information for each of over 400 four-digit Standard Industrial Classification industries for the period 1958-1965. The publication may be ordered from the U.S. Government Printing Office.

Announcements

A Visiting Lecturer Program in Statistics has been organized for the fifth successive year. The program is sponsored jointly by the principal statistical organizations in the United States, the American Statistical Association, the Biometric Society and the Institute of Mathematical Statistics. The National Science Foundation provides financial support. Leading teachers and research workers in statistics—from universities, industry, and government—have agreed to participate as lecturers. Lecture topics include subjects in experimental and theoretical statistics, as well as in such related areas as probability theory, information theory and stochastic models in the physical, biological, and social sciences. The purpose of the program is to provide information to students and college faculty about the nature and scope of modern statistics, and to provide advice about careers, graduate study, and college curricula in statistics. Inquiries should be addressed to: Visiting Lecturer Program in Statistics, Department of Statistics, Mathematical Sciences Building, Purdue University, Lafayette, Indiana 47907.

A department of demography in the College of Letters and Science was established in July, 1967, at the University of California, Berkeley. The only social science department of its kind in the country, this new unit will greatly expand the university's already extensive resources for training in the field of population studies. The department of demography grows out of an interdepartmental group-degree program established in 1965, which offered the first Ph.D. in demography in the United States. This group-degree program combined faculty from the departments of economics and sociology and from the School of Public Health. The new department retains the interdisciplinary character of the former program through joint appointments. Only M.A. and Ph.D. degrees are now offered but arrangements are underway for the inclusion of an undergraduate major in demography as well.

Inquiries should be addressed to Professor Judith B. Davis, Chairman, Department of Demography, University of California, Berkeley, California 94720.

The Institute for Social Research, University of Natal, is planning to hold a conference on "Focus on Cities—Studies in Contemporary Urban Life," in Durban, South Africa, July 8-12, 1968. For additional information, write to Mr. H. L. Watts, Conference Secretary, University of Natal, Durban, South Africa.

Authors of papers for possible inclusion in the Medical Care Section Program of the November 1968 meeting of the American Public Health Association in Detroit, Michigan, may obtain standard abstract forms from Dr. Donald C. Riedel, Yale University School of Medicine, 60 College Street, New Haven, Connecticut 06510. Two types of papers will be considered: research reports and descriptions of programs or demonstrations. The deadline for submitting abstracts is April 15, 1968. Those whose papers are selected for the program will be notified in early June.

The following unpublished paper, in mimeographed form, is available for interested persons and may be obtained by writing to the author at the address indicated: "A Simple Formal Model of Economic Growth," Gordon Winston, Yale University Pakistan Project, c/o Ford Foundation, P.O. Box 7282, Karachi—3, Pakistan.

The Asia Foundation is continuing for the fourteenth year its program of collecting useful books for distribution to institutions in Asia. Needed are books in excellent condition, in all college and adult level disciplines. Titles in the physical sciences should carry publication date of 1955 or later, in the social sciences and humanities, 1950 or later. Literary classics and anthologies of any date are welcome. Small quantities may be mailed by "Special 4th Class Rate—Books" directly to BOOKS FOR ASIAN STUDENTS, 451 Sixth St., San Francisco, California 94103. Book donations to the Asia Foundation are tax deductible.

Deaths

Thomas J. Anderson, Jr., professor of economics, School of Commerce, New York University, June 30, 1967.

S. R. Arnold, February 9, 1967.

Roger W. Babson, Babson Institute of Business Administration, March 1967.

Edward H. Chamberlin, professor emeritus of economics, Harvard University, July 16, 1967.

George R. Davies, professor emeritus of economics, Bureau of Business and Economic Research, University of Iowa, September 1967.

Max E. Fieser, Robert R. Nathan Associates, Afghanistan, May 26, 1967.

John H. Goff, professor emeritus of business administration, Emory University, September 7, 1967.

Franz Gutmann, lecturer emeritus, University of North Carolina, July 6, 1967.

Robert Szereszewski, The Eliezer Kaplan School of Economic and Social Sciences, The Hebrew University, Jerusalem, June 1967.

Charles J. Walsh, professor of economics, Fordham University, September 1967.

Carl Wood, January 13, 1967.

Retirements

Philip M. Brown, department of economics, Bowdoin College, January 1967.

Frank G. Dickinson, professor of economics, Northern Illinois University, June 1967.

William N. Loucks, professor of economics, University of Pennsylvania, June 1967.

Paul M. O'Leary, professor of economics, Cornell University, June 1967.

Simon N. Whitney, professor of economics, Rutgers—The State University, June 1967.

Charles R. Whittlesey, professor of finance and economics, University of Pennsylvania, December 31, 1966.

Visiting Foreign Scholars

Roy Harrod, Christ Church, Oxford: visiting professor of economics, University of Pennsylvania, fall 1967.

David J. Horwell, University of Southampton: visiting lecturer in economics, University of Pennsylvania, 1967-68.

Larry Levine, University of New Brunswick: Canada Council Fellow, Carnegie Institute of Technology.

Robin Marris, King's College, Cambridge: visiting professor of economics, Harvard University, 1967-68.

Michael McPhelin, Ateneo de Manila, Philippines: visiting professor of economics, Cornell University.

F. J. M. Meyer zu Schlochtern, Organization for Economic Cooperation and Development: visiting lecturer in economics, University of Pennsylvania, 1967-68.

Alec Nove, University of Glasgow: visiting professor of economics, University of Pennsylvania, spring 1968.

Max Peyrard, University of Paris: University of Utah, fall 1967.

Alan A. L. Powell, Monash University, Australia: visiting associate professor of economics, Rutgers—The State University, spring 1968.

Kai Shibata, Aoyama Gakuin University, Tokyo: visiting professor of economics, Carnegie Institute of Technology.

Roy W. Sturgess, University of Edinburgh: visiting lecturer in economics, Rutgers—The State University, 1967-68.

L. Roy Webb, University of Melbourne: visiting professor of economics, Cornell University.

John Willet, University of Melbourne: visiting professor of economics, University of Kentucky, spring 1968.

Giovanni N. Zanetti, Victoria University of Wellington, New Zealand: visiting assistant professor of economics, Michigan State University, January 1, 1968.

Promotions

Abbas A. Alnasrawi: associate professor of economics, University of Vermont.

Albert Ando: professor of finance and economics, University of Pennsylvania.

Alan R. Andreasen: associate professor of marketing and business administration, State University of New York at Buffalo.

R. M. Arunachalam: associate professor of economics, Platteville State University.

William L. Baldwin: professor of economics, Dartmouth College.

Robert A. Battis: professor of economics, Trinity College.

Nicholas A. Beadles: professor of economics, University of Georgia.

Mario L. Belotti: professor of economics, University of Santa Clara.

Ralph E. Berry: assistant professor of economics, Harvard University.

Eugene A. Brady: professor of economics, Iowa State University.

Conrad P. Caligaris: associate professor of economics, Northeastern University.

Joseph R. Cammarosano: professor of economics, Fordham University.

M. O. Clement: professor of economics, Dartmouth College.

Ward S. Curran: associate professor of economics, Trinity College.

Peter L. Danner: associate professor of economics, Marquette University.

John R. Darling: assistant professor of marketing, School of Commerce & Business Administration, University of Alabama.

- Bruce F. Davie: associate professor of economics, Georgetown University.
Tom E. Davis: professor of economics, Cornell University.
Lubomir A. D. Dellin: professor of economics, University of Vermont.
A. Deutsch: associate professor, department of economics and political science, McGill University.
Phoebus J. Dhrymes: professor of economics, University of Pennsylvania.
Peter B. Doeringer: assistant professor of economics, Harvard University.
George W. Douglas: assistant professor of economics, University of North Carolina.
Willard B. Doxey: professor of economics, Bribham Young University.
Mark Z. Fabrycy: assistant professor of economics, School of Commerce, New York University.
A. Fenichel: associate professor, department of economics and political science, McGill University.
Alfred J. Field: assistant professor of economics, University of North Carolina.
Charles B. Franklin, Jr.: associate professor of administration, Florida Atlantic University.
David C. Freytag: associate professor of economics, University of Cincinnati.
Gene A. Futrell: associate professor of economics, Iowa State University.
Robert E. Gallman: professor of economics, University of North Carolina.
James A. Gherity: professor of economics, Northern Illinois University.
Carl Gotsch: assistant professor of economics, Harvard University.
Neil E. Harl: professor of economics, Iowa State University.
William G. Harris: assistant professor of economics, Georgetown University.
Irwin L. Herrnstadt: professor of economics, Northeastern University.
Alan W. Heston: associate professor of South Asian economics, South Asia regional studies department, University of Pennsylvania.
Donald J. Hunter: assistant professor of economics, Iowa State University.
William E. Hurley: professor of continuing education, College of Commerce and Administration, Ohio State University.
Henry D. Jacoby: assistant professor of economics, Harvard University.
Hans E. Jensen: professor of economics, College of Business Administration, University of Tennessee.
Alfred E. Kahn: Robert Julius Thorne Professor of Economics, Cornell University.
Arlyn J. Larson: associate professor of economics, Arizona State University.
Howard Leftwich: associate professor of economics, University of Cincinnati.
Axel Leijonhufvud: associate professor of economics, University of California, Los Angeles.
Jane Leuthold: assistant professor of economics, University of Illinois.
David B. Lipsky: assistant professor of industrial relations, State University of New York at Buffalo.
Leo V. Mayer: assistant professor of economics, Iowa State University.
William J. McKinstry: professor of economics, Miami University.
Peter F. M. McLoughlin: professor of economics, University of Santa Clara.
Koichi Mera: assistant professor of economics, Harvard University.
William C. Merrill: associate professor of economics, Iowa State University.
Charles W. Meyer: professor of economics, Iowa State University.
John M. Mitchell: associate professor of business administration, Geneva College.
James B. Montgomery: associate professor of administration, Florida Atlantic University.
James L. Murphy: associate professor of economics, University of North Carolina.
Roger G. Noll: assistant professor of economics, California Institute of Technology.
Jerry H. Padgett: associate professor of economics, University of Georgia.

- Don V. Plantz : professor of economics, Arizona State University.
- John A. Powers : associate professor of economics, University of Cincinnati.
- James A. Prescott : associate professor of economics, Iowa State University.
- Richard N. Rosett : professor of economics, University of Rochester.
- Anthony Scaperlanda : associate professor of economics, Northern Illinois University.
- David L. Schwartz : assistant professor of economics, Albright College.
- Daniel M. Schydrowsky : assistant professor of economics, Harvard University.
- Elbert W. Segelhorst : associate professor of economics, California State College at Long Beach.
- Gene R. Simonson : professor of economics, California State College at Long Beach.
- Fred Slavick : professor, New York State School of Industrial and Labor Relations, Cornell University.
- J. G. Smith : associate professor, department of economics and political science, McGill University.
- James A. Stephenson : associate professor of economics, Iowa State University.
- Mahlon R. Strasheim : assistant professor of economics, Harvard University.
- Robert D. Taylor : assistant professor of accounting, School of Business Administration, University of Massachusetts.
- C. F. Joseph Tom : professor of economics, Lebanon Valley College.
- Ralph Underhill : assistant professor of behavioral sciences, Graduate School of Business, University of Chicago.
- Alice J. Vandermeulen : senior lecturer in economics, University of California, Los Angeles.
- Hylke Van de Wetering : associate professor of economics, Iowa State University.
- Frank E. Wagner : associate professor of economics, University of Missouri at Kansas City.
- Lawrence Weiser : assistant professor of economics, University of Illinois.
- Thadeus J. Whalen : associate professor of economics, University of Santa Clara.
- Theodore L. Whitesel : professor of economics, University of Texas at Arlington.
- G. Donald Wood : assistant professor of economics, Georgetown University.
- Robert G. Wyckham : assistant professor, department of economics and commerce, Simon Fraser University.

Administrative Appointments

- William R. Allen : chairman, department of economics, University of California, Los Angeles.
- Robert T. Averitt : acting chairman, department of economics, Smith College.
- David A. Baerncopf : head, department of accounting and business statistics, School of Business Administration, University of Oregon.
- Wilbur E. Benson : acting dean, College of Business and Public Administration, Florida Atlantic University.
- Herbert M. Bernstein : chairman, economics department, Washington and Jefferson College.
- W. Robert Brazelton : acting chairman, department of economics, University of Missouri at Kansas City.
- Brian G. Brockway : chairman, department of finance, marketing and law, College of Business and Economics, Lehigh University.
- David B. Brooks, Resources for the Future : chief, Division of Economic Analysis, U.S. Bureau of Mines.
- Dwight S. Brothers : associate director, Development Advisory Service, and lecturer, Graduate School of Business Administration, Harvard University.
- Burnham O. Campbell, University of California, Los Angeles : associate professor and chairman, department of economics, University of Hawaii, 1967-68.

Stephen B. Castle: professor and acting chairman, department of marketing, College of Business Administration, University of Akron.

Benjamin Chinitz: chairman, department of economics, Brown University.

A. J. Cordell: assistant manager of economic analysis, General Foods Corporation.

Kenneth J. Curran: acting president, Colorado College.

Albert L. Danielsen: associate professor and chairman 1967-68, department of economics, University of Georgia.

Daniel E. Diamond: assistant dean, School of Commerce, New York University.

Gordon K. Douglass: chairman, department of economics, Pomona College.

Martin T. Farris: chairman, department of economics, Arizona State University.

Bela Gold: chairman, department of economics, Case Western Reserve University.

Burton C. Hallowell, Wesleyan University: president, Tufts University.

David E. Kaun: chairman, board of studies in economics, University of California, Santa Cruz.

R. W. Kautz: head, department of economics and political science, University of Saskatchewan.

John M. Kuhlman: associate dean, Graduate School, University of Missouri.

Clayburn La Force: associate professor and vice chairman, department of economics, University of California, Los Angeles.

John E. LaTourette: chairman, department of economics, State University of New York at Binghamton.

Karl O. Mann: professor of industrial relations and chairman of graduate studies, School of Business Administration, Rider College.

Joseph W. McGuire: dean, College of Commerce and Business Administration, University of Illinois, July 1, 1968.

Carmelo Mesa-Lago: assistant director, Center for Latin American studies, and assistant professor of economics, University of Pittsburgh.

John R. Meyer: president, National Bureau of Economic Research.

William L. Miller: chairman, department of economics, University of Georgia.

John C. Murdock: dean, Graduate School, and director of research administration, University of Missouri.

Jack W. Nickson, Jr.: chairman, department of economics, School of Business Administration, Old Dominion College.

Douglass C. North: chairman, department of economics, University of Washington.

Edmund S. Phelps: chairman, department of economics, University of Pennsylvania, 1967-68.

Nikos G. Photias: associate dean, School of Business Administration, American University.

Myles E. Robinson: director, marketing program, School of Business Administration, American University.

Richard Scheuch: G. Fox and Company Professor of Economics and chairman, department of economics, Trinity College.

Warren C. Scoville: associate dean, graduate division, University of California, Los Angeles.

Martin Segal: chairman, department of economics, Dartmouth College.

Malcolm F. Severance: chairman, department of economics, University of Vermont.

Donald S. Shoup: assistant to the president, National Bureau of Economic Research.

Leonard S. Silk: editorial page editor and chairman, Board of Editors, *Business Week Magazine*.

Wendell R. Smith: dean, School of Business Administration, University of Massachusetts.

Max D. Snider: assistant dean, College of Business and Economics, Lehigh University.

Harold M. Somers, University of California, Los Angeles: co-editor, *Western Economic Journal*.

William W. Stevenson, Tennessee Valley Authority: senior economist, Acres Research and Planning Ltd., Toronto.

Robert Summers: professor of economics and chairman, graduate group of economics, University of Pennsylvania.

Benjamin J. Taylor: assistant director, Bureau of Business and Economic Research, Arizona State University.

Pedro C. M. Teichert, University of Mississippi: professor of economics and chairman of the faculties of economics, management and political science, University of West Florida.

Alice Vandermeulen, University of California, Los Angeles: co-editor, *Western Economic Journal*.

Peter N. Vukasin: dean, Harpur College, State University of New York at Binghamton.

Richard L. Wallace: chairman, department of economics, University of Missouri.

William H. Wallace, Duke University: economist and assistant vice-president, Federal Reserve Bank of Richmond, Virginia.

Willis D. Weatherford, Jr., Carleton College: president, Berea College.

James E. Wert, State University of New York at Buffalo: professor and chairman, department of finance, University of Arizona.

Robert H. Wessel: vice provost for graduate studies, University of Cincinnati.

Harry J. Wheaton: assistant dean, School of Business Administration, American University.

Harvey J. Wheeler: head, department of economics, School of Industrial Management and Textile Science, Clemson University.

Jack S. Wolf: professor of marketing and chairman of department, School of Business Administration, University of Massachusetts.

Vernon K. Zimmerman: acting dean, College of Commerce and Business Administration, University of Illinois.

Laszlo Zsolodos: chairman, department of economics, University of Delaware.

- John J. Casson, Jr.: instructor in economics, Pace College.
- M. V. Chari, State University of New York: lecturer in economics, University of Pennsylvania.
- Robert Cohen, Brooklyn College: appointment in economics, Eastern College.
- Charles L. Cole: associate professor of economics, California State College at Long Beach.
- Hughe D. Coleman: assistant professor, College of Business and Public Administration, Florida Atlantic University.
- A. Wayne Corcoran: associate professor of accounting, School of Business Administration, University of Massachusetts.
- Edward G. Corrigan: instructor in economics, Fordham University.
- Robert L. Crouch: lecturer in economics, University of California, Santa Barbara.
- J. Gerard Curzon: visiting professor of international economics, Graduate School of Business, University of Chicago.
- Addison T. Cutler: professor of economics, University of Cincinnati.
- James W. Dean: instructor in economics, Northeastern University.
- Fawzy G. Demian, University of Washington: instructor, department of economics and commerce, Simon Fraser University.
- Philip M. DeMoss: assistant professor of economics, University of Missouri at Kansas City.
- Enrique E. Dieulefait: visiting lecturer in economics, University of North Carolina.
- James W. Doane: instructor in economics, Northeastern University.

Robert W. Doede, University of Chicago: assistant professor of economics, University of Pennsylvania.

Robert Ebert: instructor in economics, Baldwin-Wallace College.

R. H. Eckhouse: adjunct professor of administration, Florida Atlantic University.

Milton T. Edelman: department of economics, Southern Illinois University.

Noel M. Edelson, RAND Corporation: lecturer in economics, University of Pennsylvania.

Douglas M. Egan, State University of New York at Buffalo: associate professor, Oregon State University.

Paul T. Ellsworth, professor emeritus of economics, University of Wisconsin: department of economics, University of California, Riverside.

Bernard D. Estafen: assistant professor of business administration, School of Business, Indiana University.

Frank Falero, Jr.: assistant professor of economics, Virginia Polytechnic Institute.

Dean G. Farrer, Fullerton Junior College: assistant professor of marketing, California State College, Long Beach.

Walter Feibes, State University of New York at Buffalo: assistant professor, University of Kentucky.

Martin S. Feldstein: assistant professor of economics, Harvard University.

Marianne Ferber: lecturer in economics, University of Illinois.

Douglas Fisher, Queens College, City University of New York: associate professor of economics, Graduate School of Public Affairs, State University of New York, Albany.

H. Nelson Flanders: visiting lecturer in finance, School of Business Administration, University of Massachusetts.

James D. Forbes: assistant professor of marketing, University of British Columbia.

Glen R. Foster: assistant professor of economics, Brigham Young University.

George B. France, University of York: instructor in economics, University of Connecticut.

Myron Frankman: assistant professor, department of economics and political science, McGill University.

William J. Frazer, Federal Reserve Bank of Chicago: visiting associate professor of economics, University of Kentucky.

Walter Galenson: professor, School of Industrial and Labor Relations, Cornell University.

Joseph C. Gallo: assistant professor of economics, University of Cincinnati.

Charles B. Garrison: assistant professor of economics, College of Business Administration, University of Tennessee.

William Gibson: acting assistant professor of economics, University of California, Los Angeles.

Philip M. Ginsberg, IBM Corporation: acting assistant professor of economics, University of Washington.

Thomas L. Glenn, Tulane University: assistant professor of economics, Franklin and Marshall College.

Elmer R. Gooding: assistant professor of economics, Arizona State University.

Robert J. Gordon: assistant professor of economics, Harvard University.

George Gostenhofer: lecturer in economics, Northeastern University.

Paul Graesser: assistant professor of economics, Northern Illinois University.

Harry Graham: assistant professor, Bureau of Labor and Management, University of Iowa.

Leslie E. Grayson, California Texas Oil Corporation: Development Advisory Service, Harvard University; advisor to the Minister of Economic Affairs, Ghana.

Stuart I. Greenbaum, Office of Comptroller of the Currency: associate professor of economics, University of Kentucky.

L. Christopher Griffiths: instructor in economics, Colorado College.

Sanford Gunn: instructor in accounting, School of Business Administration, University of Massachusetts.

John Hambor: assistant professor of economics, University of California, Santa Barbara.

Eila Hanni, Boston College: assistant professor of economics, Colorado College.

G. L. Harris: visiting professor of administration, Florida Atlantic University.

James B. Heisler: instructor in economics, Nebraska Wesleyan University.

B. J. Hersker: assistant professor of administration, Florida Atlantic University.

Harriet M. Hinck: instructor in economics, Rutgers—The State University.

Roger H. Hinderliter: lecturer in economics, Rutgers—The State University.

W. Dickerson Hogue: research associate, International Business Research Institute, and lecturer in international business administration, School of Business, Indiana University.

A. G. Holtman, Wayne State University: associate professor of economics, Florida State University.

Joseph J. Horton, Jr.: financial economist-econometrician, research division, Federal Deposit Insurance Corporation.

Allen S. Hunter: lecturer, department of economics and commerce, Simon Fraser University.

Sidney Ingerman: assistant professor, department of economics and political science, McGill University.

Tomotaka Ishimine: assistant professor of economics, California State College at Long Beach.

Donald F. Jackson, University of Texas: assistant professor of finance, Southern Methodist University.

William Jaffe, professor emeritus of economics, Northwestern University: visiting professor of economics, Harvard University.

Gerald R. Jantscher: research associate, Brookings Institution.

Jon Joyce: assistant professor of economics, Wesleyan University.

Madelyn Kafoglis: associate professor of economics, College of Business Administration, University of Tennessee.

Sigfried Karsten: assistant professor of economics, University of Wyoming.

Shou-Eng Kee, University of Georgia: associate professor, Indiana University.

Rita Keintz: lecturer in economics, Northeastern University.

Mitchell Kellman: instructor in economics, University of Pennsylvania.

Robert F. Kelly, Indiana University: associate professor of marketing, University of British Columbia.

J. D. Khazzoom: assistant professor, department of economics and political science, McGill University.

Kye C. Kim: assistant professor of economics, State University of New York, College at Brockport.

Jacky Knopp, Jr., State University of New York at Buffalo: associate professor, Canisius College.

John E. Koehler, Yale University: economics department, RAND Corporation.

Kenneth K. Kurihara, Rutgers University: distinguished professor of economic theory, Harpur College, State University of New York at Binghamton.

Jerry R. Ladman: assistant professor of economics, Arizona State University.

Arthur Laffer: research associate, Brookings Institution.

Douglas Lamont: associate professor of international business, University of Alabama.

David Larson: lecturer in economics, University of Maryland.

John Ledyard: research associate in economics, Carnegie Institute of Technology.

Joong-Koon Lee: assistant professor of economics, University of Cincinnati.

Harvey Leibenstein, University of California, Berkeley: Andelot Professor of Economics and Population, Harvard University.

Sima Lieberman: assistant professor of economics, University of Utah.

R. S. Livingstone: adjunct professor of administration, Florida Atlantic University.

Yih-Wu Liu: lecturer in economics, Southern Illinois University.

David J. Loschky: associate professor of economics, University of Missouri.

Douglas M. Lounsbury: lecturer in economics, California State College at Long Beach.

M. A. Loutfi: assistant professor, department of economics and political science, McGill University.

Richard J. Lurito: instructor in economics, Georgetown University.

Michael P. Lynch, University of Chicago: lecturer in economics, University of Pennsylvania.

Edwin Mansfield: visiting professor of economics, California Institute of Technology.

James C. T. Mao: professor of finance, University of British Columbia.

Joseph A. Martellaro: professor of economics, Northern Illinois University.

J. Barry Mason: assistant professor of marketing, University of Alabama.

John F. Masten, Southern Illinois University: East Carolina University.

Stanley Masters: assistant professor of economics, Rutgers—The State University.

Richard V. Mattessich: professor of accounting, University of British Columbia.

Laurence J. Mauer: assistant professor of economics, Northern Illinois University.

Warren Mazek, College of Wooster: assistant professor of economics, Florida State University.

Michael D. McCarthy, Southern Methodist University: assistant professor of economics, University of Pennsylvania.

Joseph W. McGuire, University of Kansas: Ford visiting research professor, Graduate School of Industrial Administration, Carnegie-Mellon University.

Joseph P. McKenna, Virginia Polytechnic Institute: professor of economics, University of Missouri at St. Louis.

Lawrence E. McKibbin: faculty lecturer in business administration, and senior researcher, International Business Research Institute, School of Business, Indiana University.

Eugene McLoone: joint appointment, lecturer, department of economics and College of Education, University of Maryland.

James W. Meehan, Jr.: assistant professor of economics, Northeastern University.

Peter V. Mini: assistant professor of economics, Northeastern University.

Michael Moore: lecturer in economics, University of Maryland.

Willard D. Morgan: assistant professor of economics, University of California, Santa Barbara.

Clarence C. Morrison: associate professor of economics, University of Georgia.

Thomas A. Morrison: associate professor of accounting, School of Business Administration, University of Massachusetts.

Collette H. Moser: lecturer in economics, Rutgers—The State University.

Max Moszer, Drexel Institute of Technology: associate professor of economics, Kent State University.

Max Mueller: lecturer in economics, University of Maryland.

Charlotte F. Muller: professor of urban studies, Graduate Center, City University of New York.

Neal B. Murphy, Federal Reserve Bank of Boston: financial economist, division of research and statistics, Federal Deposit Insurance Corporation.

Lester A. Neidell: lecturer in marketing, State University of New York at Buffalo.

Norman T. Ness, Anderson Clayton & Company : professor of economics, Pomona College, spring 1968.

Thomas E. Ness : faculty lecturer in marketing, School of Business, Indiana University.

W. E. Newkirk, Louisiana State University : associate professor of economics, Drake University.

Robert E. G. Nicol : assistant professor of accounting, University of British Columbia.

A. E. Nielsen : visiting professor of economics, Franklin College.

Charles Nisbet : assistant professor of economics, University of California, Los Angeles.

Morris Norman : assistant professor of economics, University of California, Santa Barbara.

A. L. O'Toole : visiting professor of administration, Florida Atlantic University.

Ibrahim M. Oweiss : instructor in economics, Georgetown University.

Walter P. Page : assistant professor of economics, University of Georgia.

Rollo Edward Park : economics department, RAND Corporation.

Sidney Parnes, State University of New York at Buffalo : professor, State University of New York, College at Buffalo.

Anthony H. Pascal, Economic Development Agency, Department of Commerce : economics department, RAND Corporation.

Werner H. Peterke : assistant professor of economics, Lebanon Valley College.

Llad Phillips : assistant professor of economics, University of California, Santa Barbara.

Nelson E. Pion : instructor in accounting, School of Business Administration, University of Massachusetts.

Judy Pitcher : instructor in economics, University of Kentucky.

Richard L. Porter : professor of economics, Oklahoma State University.

Calvin C. Potter : visiting professor of accounting and finance, University of British Columbia.

P. L. Preston : instructor in administration, Florida Atlantic University.

Clark R. Puckett : assistant professor of economics, State University of New York, College at Brockport.

Joaquin P. Pujol : instructor in economics, University of Pennsylvania.

David Qualls : lecturer in economics, University of Maryland.

Michael Rabbitt, University of California, Berkeley : assistant professor of economics, Franklin and Marshall College.

Ram P. Rajbahak : visiting lecturer in economics, Southern Illinois University.

Richard R. Ratcliff : professor of urban land economics, University of British Columbia.

William S. Rawson : assistant professor of economics, College of Business Administration, University of South Carolina.

Robert H. Reilly, Michigan State University : instructor in economics, University of Connecticut.

Lockwood Rianhard, Jr., State University of New York at Buffalo : associate professor, York University, Toronto.

Ronald G. Ridker : economic advisor, Agency for International Development Mission to India, New Delhi.

Fred Ritchie : lecturer in economics, DePauw University.

James E. Roberts : lecturer in economics, Southern Illinois University.

James W. Robinson : associate professor of economics, College of Business Administration, University of South Carolina.

James Rock : assistant professor, University of Utah.

Richard W. Roll : research associate in economics, Carnegie Institute of Technology.

Saul Rothman : instructor in economics, University of Pennsylvania.

John W. Rowe, Jr. : associate professor of economics, University of Oklahoma.

A. P. Ruderman, Pan American Health Organization: professor of health administration, University of Toronto.

Richard L. Ruth, Hobart and William Smith Colleges: assistant professor of economics, Marquette University.

W. T. Ryan: assistant professor of administration, Florida Atlantic University.

David K. Sandberg: instructor in economics, Brigham Young University.

Thomas J. Sargent: research associate in economics, Carnegie Institute of Technology.

Edward J. Schmidt: assistant professor of economics, Randolph-Macon College.

J. Chip Seagler: assistant professor of economics, University of Georgia.

J. C. G. Seidl: visiting professor of administration, Florida Atlantic University.

Joseph J. Seneca: lecturer in economics, Rutgers—The State University.

Merrill K. Sharp: instructor in economics, Brigham Young University.

Stanford Shedd: lecturer in economics, Southern Illinois University.

Heidemarie Sherman: instructor in economics, Whittemore School, University of New Hampshire.

A. Ross Shepherd: associate professor of economics, University of Missouri at Kansas City.

Phillip H. Siegel: department of business administration, Delaware Valley College of Science and Agriculture.

Charles J. Siegman, Swarthmore College: economist, division of international finance, Board of Governors of the Federal Reserve System.

Eugene Silberberg, Harpur College, State University of New York: assistant professor of economics, University of Washington.

Robert Silverzweig: instructor in economics, State University of New York at Buffalo.

James C. Simmons, Israel Institute of Productivity, Tel Aviv: associate professor of economics, Florida State University.

Richard H. Simpson: assistant professor of accounting, School of Business Administration, University of Massachusetts.

Arnold Simson: lecturer in economics, Syracuse University.

Charles T. Smith, State University of New York at Buffalo: assistant professor, Florida State University.

L. George Smith: professor of administration, Wichita State University.

James A. Socknat: visiting assistant professor of economics, Iowa State University.

Alan Sorkin: research associate, Brookings Institution.

Marvin N. Stark: lecturer, department of economics and commerce, Simon Fraser University.

Herbert Stein: senior staff, Brookings Institution.

Andrew Stern: assistant professor of economics, California State College at Long Beach.

Harold W. Stevenson, University of Minnesota: professor of finance, Arizona State University.

Justin D. Stolen: instructor in economics, DePauw University.

Thomas Stone: instructor in economics, University of Pennsylvania.

Myra Strober: lecturer in economics, University of Maryland.

Tsauh-An Su: assistant professor of economics, College of Business Administration, University of South Carolina.

John Swirls: associate professor of operations research, University of British Columbia.

Victor H. Tidwell, Kansas State University: associate professor of accounting, University of Iowa.

Michael K. Taussig: assistant professor of economics, Rutgers—The State University.

Richard A. Taylor: assistant professor of economics, Northern Illinois University.

John Terninko : instructor in business administration, Whittemore School, University of New Hampshire.

Thomas Thompson : acting assistant professor of economics, University of Washington.

William D. Thompson, Southern Illinois University: Central Missouri State College.

John Tilton : research associate, Brookings Institution.

Joseph L. Tryon, National Planning Association: associate professor of economics, Georgetown University.

Gordon Tullock, University of Virginia: professor of economics and political science, Rice University.

Thurai Venkataswami : instructor in economics, Northeastern University.

Meenakshisunder Venkatesan : assistant professor of marketing, School of Business Administration, University of Massachusetts.

E. Kent Vernon : instructor in economics, Brigham Young University.

A. Vicas : assistant professor, department of economics and political science, McGill University.

Annibal V. Villela, Instituto Brasileiro de Economia Fundacao Getulio Vargas: advisor, economics department, World Bank Group.

Fercy deF. Warner III, Michigan State University: instructor in economics, University of Connecticut.

Gerald Weber : research associate, Brookings Institution.

Donald C. Wellington : assistant professor of economics, University of Cincinnati.

L. C. Westbrook : assistant professor of administration, Florida Atlantic University.

Richard M. Westebbe, Ministry of Commerce, Greece: advisor, economics department, World Bank Group.

Gerald A. Weston : associate professor of economics, Arizona State University.

William E. Wetzel, Jr. : assistant professor of business administration, Whittemore School, University of New Hampshire.

Harland W. Whitmore : assistant professor of economics, University of Cincinnati.

Richard Wienecke : instructor in business administration, Geneva College.

Cyrus Wilson : assistant professor of marketing, School of Business, Indiana University.

Whatarangi Winiata : assistant professor of finance, University of British Columbia.

William H. Witherell : senior economic analyst, Standard Oil Company (New Jersey).

B. S. Wojtun : associate professor of economics, Indiana University of Pennsylvania.

Peter J. Woolley : lecturer, department of economics and commerce, Simon Fraser University.

Parker M. Worthing : assistant professor of marketing, School of Business Administration, University of Massachusetts.

Leaves for Special Appointments

Robert L. Allen, University of Oregon: Fulbright lecturer, University of Salamanca, Spain, 1966-67; Economic and Planning Advisor, Corporación de los Andes, and professor of economics, Universidad de los Andes, Mérida, Venezuela, 1967-68.

James H. Blackman, University of North Carolina: program director for economics, National Science Foundation.

George H. Borts, Brown University: research associate, Brookings Institution.

Eugene A. Brady, Iowa State University: Johns Hopkins University, Bologna Center, Italy.

John F. Burton, University of Chicago: staff labor economist, Council of Economic Advisers.

Robert P. Collier, Utah State University: visiting professor, Mildenhall Air Base, England.

John F. Crecine, University of Michigan: economics department, RAND Corporation.

David G. Davies, Duke University: Fulbright research scholar, Australian National University, Canberra.

Frank deLeeuw, Board of Governors of the Federal Reserve System: visiting professor of economics, State University of New York at Buffalo.

George Delehanty, Northwestern University: Rockefeller Foundation, research and teaching in Nairobi, Kenya.

Emile Despres, Stanford University: Rockefeller Visiting Research Professor in International Affairs, Brookings Institution.

James S. Duesenberry, Harvard University: Council of Economic Advisers, 1967-68.

Robert S. Fairbanks, Northern Illinois University: visiting associate professor, Institute of Government and Public Affairs, University of Illinois.

Geza Feketekuty, Princeton University: visiting professor of economics, Cornell University.

Ralph Gray, DePauw University: Governor's Economic Council, Arkansas.

David Green, Graduate School of Business, University of Chicago: visiting staff member, AID-Cornell University project, Pakistan.

Timothy Hallinan, Agency for International Development: economics department, RAND corporation.

Hugh G. Hansen, University of Wyoming: Engineering Research Institute, in Ceylon.

Bruce Herrick, University of California, Los Angeles: visiting professor, University of California-University of Chile Exchange Program, Santiago.

Hendrik S. Houthakker, Harvard University: Council of Economic Advisers.

Ronald Jones, University of Rochester: visiting professor, Cornell University.

Donald W. Katzner, University of Pennsylvania: Penn-Osaka Exchange, Osaka University, Japan.

Robert G. Layer, Southern Illinois University: Rockefeller Foundation, Bangkok, Thailand.

H. Gregg Lewis, University of Chicago: Centro de Investigaciones Económicas, Universidad Católica de Chile, Santiago.

Millard G. Long, Graduate School of Business, University of Chicago: economics project for Harvard University, Pakistan.

James C. Loughlin, Trinity College: Brookings Institution.

Arthur A. Mandel, San Francisco State College: visiting professor of economics, University of Hawaii.

John A. Menz, California State Office of Planning: Institute for Training and Research on Agrarian Reform, FAO, Santiago, Chile.

Walter Miklius, U.S. Department of Agriculture: visiting associate professor of economics, University of Hawaii.

M. I. Nadiri, Northwestern University: National Bureau of Economic Research.

R. E. Olley, University of Saskatchewan: department of economics, Queen's University, Toronto.

John A. Powers, University of Cincinnati: Comptroller of Currency.

J. Graham Smith, McGill University: McGill-overseas assignment, Institute for Development Studies, University of College of Nairobi, Kenya.

Vernon L. Smith, Purdue University: visiting professor of economics, Brown University.

Norman W. Taylor, Franklin and Marshall College: visiting professor of economics, Tunghai University, Taiwan.

Erik Thorbecke, Iowa State University: head, sector and market analysis section, Agency for International Development.

Jinkichi Tsukui, Seikei University: visiting associate professor of economics, University of Hawaii.

Paul L. Van Moeseke, Iowa State University: visiting professor of economics, University of Louvain.

Lewis E. Wagner, Bureau of Business and Economic Research, University of Iowa: Ford Foundation, Middle East.

Arthur Welsh, Bureau of Business and Economic Research, University of Iowa: Joint Council on Economic Education.

Richard B. Wirthlin, Brigham Young University: visiting associate professor of economics, Arizona State University.

Resignations

David G. Brown, University of North Carolina, August 31, 1967.

Gerald C. Fischer, School of Business, Indiana University.

Ralf C. Kuehnelt, State University of New York at Buffalo.

Kenneth McLennan, Rutgers—The State University, June 1967.

B. H. Schatzmann, School of Commerce and Business Administration, University of Alabama.

J. William Uhrig, Iowa State University.

Miscellaneous

Dudley F. Pegrum, emeritus professor of economics, University of California, Los Angeles, recalled to service.

AMERICAN ECONOMIC ASSOCIATION EMPLOYMENT SERVICES

NATIONAL REGISTRY FOR ECONOMISTS

The National Registry for Economists was established in January, 1966, to provide a centralized nationwide clearinghouse for economists on a year-round basis. It is located in the Chicago Professional Placement Office of the Illinois State Employment Service and is staffed by experienced placement personnel, operating under the guidance and direction of Regional and National Bureau of Employment Security Professional Placement officials, and in cooperation with the American Economic Association. It is a free service. There are no registration, referral, or placement fees. Application and order forms used in the Registry are available upon request from the: National Registry for Economists, Professional Placement Center, 208 South La Salle Street, Chicago, Illinois, 60604.

VACANCIES AND APPLICATIONS

The Association is glad to render service to applicants who wish to make known their availability for positions in the field of economics and to administrative officers of colleges and universities and to others who are seeking to fill vacancies.

The officers of the Association take no responsibility for making a selection among the applicants or following up the results. The Secretary's office will merely afford a central point for clearing inquiries; and the *Review* will publish in this section a brief description of vacancies announced and of applications submitted (with necessary editorial changes). Since the Association has no other way of knowing whether or not this section is performing a real service, the Secretary would appreciate receiving notification of appointments made as a result of these announcements. It is optional with those submitting such announcements to publish name and address or to use a key number. Deadlines for the four issues of the *Review* are February 1, May 1, August 1, and November 1.

Communications should be addressed to: The Secretary, American Economic Association, 629 Noyes Street, Evanston, Illinois 60201.

Vacancies

Economists, mathematicians, statisticians, operations analysts: Needed by the Research Analysis Corporation to participate in defense-related studies of resource allocation techniques and applications. Areas of interest include systems analysis of defense forces, weapon systems, and manpower and material resources, and its constituent elements of cost-effectiveness analysis and military cost analysis. A strong capability is maintained in computer-assisted model building. Staff members are assisted in acquiring a working knowledge of computer techniques if they do not already have it. Candidates should have at least a master's degree. For additional information, send résumé to Mr. John G. Burke, Supervisor of Professional Staffing, Research Analysis Corporation, McLean, Virginia 22101.

Teaching opportunities abroad: University positions, instructor to professor level, in the developing nations of Asia, Latin America, and primarily Africa. Two-year contracts. Salary dependent on level and location; transportation provided. Write to: Overseas Educational Service, 522 Fifth Avenue, New York, New York 10036. An equal opportunity employer.

Economic statistician: Under direction of chief, Research and Analysis Division, conducts research and prepares analyses of economic conditions and trends and statistical indicators relevant to the planning and development programs of the state. Requires master's degree in economics or economic statistics and four years of progressively responsible experience in economic research involving collecting, manipulating, and analyzing economic data. Salary range, \$9,840-\$12,552 per year. File applications with: State of Hawaii, Department of Planning and Economic Development, 426 Queen Street, Honolulu, Hawaii 96813.

Economist I: Under direction of chief, Research and Analysis Division, conducts research and prepares analyses and reports on macro- and microeconomic conditions relevant to the planning and development programs of the state. Requires four years of responsible professional experience involving work in economics and a master's degree in economics or business administration. Specialization in regional economics, econometrics, or statistics helpful. Salary range, \$9,840-\$12,552 per year. File applications with: State of Hawaii, Department of Planning and Economic Development, 426 Queen Street, Honolulu, Hawaii 96813.

Economics: Assistant dean, College of Business, Ph.D. or D.B.A. in business or economics required. Three to 5 years of full-time teaching experience in college or university. Administrative experience given special consideration. Limited teaching opportunity. Initial annual salary \$17,000-\$18,000. Effective date July 1, 1967. Contact: Dean Earl A. Roth, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Visiting professorship in China (Taiwan): Requirements are a graduate degree with ability to teach one or more of the following courses: business administration; electronic data processing; marketing, statistics, quantitative methods, economics and related fields. A four-month up to two-year contract can be arranged to suit individual preference. Round trip air expenses paid. Retired professors and businessmen are also welcomed. Write to: Professor Kenneth K. Fan, Utah State University, Logan, Utah 84321.

Economist: Firm of consultants in economics and statistics in Berkeley, California, is seeking an economist to help meet the demands of an expanding practice. This is a fulltime, career position with unusual potential in the largest practice of its kind in the United States. The work involves the application of econometric techniques to a broad variety of appraisal problems, including present value of life-time earning capacity of persons, future expenses of persons, future losses of businesses, and future income of property. The work requires the preparation of appraisals and reports and their presentation in court as an independent expert witness. The minimum requirement is a Ph.D. in economics, preferably labor economics, and a good working knowledge of statistics and the mathematics of finance. Starting salary depends on qualifications and experience. Send full résumé to: Philip Eden, 1303 Walnut Street, Berkeley, California 94709.

Economists: The United Nations needs economists for challenging research and operational posts at Headquarters, New York, in Geneva, Vienna, and in many of the developing countries throughout the world. These posts are in various fields of specialization (development, econometrics, fiscal policy, foreign trade, international finance, industrial management, transportation, agriculture, mining, water resources, urban planning), at all levels of responsibility and of varying duration—permanent or short term. Candidates with an M.A. or Ph.D. and experience in these fields are invited to contact for additional information: Office of International Organization Recruitment, Department of State, Washington, D.C. 20520.

Economists: Opportunity for participation in original and meaningful research in regional economic studies, industry studies, human resource analysis and state and local finance as part of a continuing state-wide planning function. Requirements include training in economics at the M.A., near Ph.D., or Ph.D. level. Positions can be filled at salary ranges of up to \$12,000, depending upon qualifications. Please send résumé to: James J. O'Donnell, Director, Maryland State Planning Department, 301 West Preston Street, Baltimore, Maryland 21201.

Economists: General Electric's Center for Advanced Studies has openings for econo-

mists who are interested in solving problems of government and industry. Preferred training and background will include experience in operations research and a Ph.D. in economics. Offices are in Santa Barbara, California, and Washington, D.C. Write to: Dr. Stephen Enke, P.O. Box QQ, Santa Barbara, California 93102.

Economist: U.S. Army Corps of Engineers in Huntington, West Virginia, requires an economist in the Planning Branch. Positions are from grade level GS-5 (\$5,331-\$6,915) to GS-9 (\$7,696-\$10,045) and are part of the federal civil service program. Basic requirements are degree in economics or business administration, appropriate experience or training, and the ability to write well. The duties to be performed are: conduct and participate in the coordination of economic studies of river basins, apply professional techniques and principles of economics in formulating water resource investments, determine the potential effects of water resource investments upon the regional and national economy, develop data sources, develop and maintain contacts with specialists in the field. Limited travel and opportunity for additional education are available. Applicants for this position should apply to: Chief, Planning Branch, Huntington District, Corps of Engineers, P.O. Box 2127, Huntington, West Virginia 25721.

Economists: With continued growth and a new M.A. program in economics, the Department of Economics, California State College at Fullerton will have openings in September, 1968, for several additional staff members at the junior level, Ph.D. or near Ph.D. Although the particular areas of specialization in economics are open, we are interested in persons with strong fundamental grounding in economic theory. In general, the Department seeks persons with a high degree of technical economic competence, dedicated to teaching, and devoted to continuing professional activity and development. The College, 8 years old and rapidly expanding, is located on the fringe of the Los Angeles metropolitan area. For further details, write (enclosing detailed résumé): Dr. Levern F. Graves, Department of Economics, California State College, 800 North State College Boulevard, Fullerton, California 92631.

Labor economists and statisticians: Attorneys have discovered that expert economists and statisticians can provide valuable assistance in determining the extent of monetary losses suffered because of wrongful injury or death. Qualifications required to engage in this highly rewarding activity include faculty status of associate professor and above, an interest in human capital analysis, and located near a major city. Our economic consulting organization has several prime markets open. Write to: D. Carl Deiter, President, Economic and Statistical Consultants, Inc., Box 17184, Tampa, Florida 33612.

Economist, chairman of department: California State College at Fullerton is seeking a qualified economist to fill the position of chairman of its Department of Economics. The position requires a Ph.D. degree from a major university and evidence of scholarly writing, leadership, and administrative ability. The approximate salary range is \$11,000 to \$17,000, depending upon experience and qualifications. The Department of Economics is in the School of Business Administration and Economics. Major interest is directed toward the bachelor and master of arts programs in economics. In addition, the department offers undergraduate service courses for various majors in the college and provides graduate courses for the master of arts in social science and the master of business administration programs. The undergraduate program of the School of Business Administration and Economics is fully accredited by the American Association of Collegiate Schools of Business. California State College is a rapidly growing, eight-year old institution, located on the fringe of Los Angeles, 25 minutes from Newport Beach, an hour from the mountains, and within easy driving distance of the University of California at Irvine. The position of department chairman under growth conditions such as the college is experiencing, provides ample opportunity for innovation, dynamic leadership, and professional development. Please address inquiries to: Paul T. Kinney, Dean, School of Business Administration and Economics, California State College at Fullerton, Fullerton, California 92631.

Economics: February or September, 1968. Ph.D. preferred; doctoral candidates with master's degree will be considered. Teaching assignment flexible, including range from elementary to advanced undergraduate courses and/or graduate courses. Rank and salary commensurate with qualifications. T.I.A.A., life insurance, major medical, other fringe benefits. Please send résumé to: Dr. Charles L. Kraemer, Chairman,

Department of Economics and Business Administration, Wagner College, Staten Island, New York 10301.

Economists and econometricians- Abt Associates, Inc., a small research firm in Cambridge, Massachusetts, desires to expand its staff of economists and econometricians. The company is young, vital and growing rapidly. The firm offers unlimited opportunities for independent and creative research in a wide range of areas, management of contracts and research studies, and contact with professionals on the staffs of numerous universities. Abt Associates is presently working with many branches of the U.S. government, private companies, foreign governments and international institutions. Present work includes economic development and planning, transportation, economics, economics of education, urban development, the industrialization of rural areas, and the design of information systems for regional development. Staff members are either social scientists or engineers and mathematicians, and many are both. Abt Associates emphasizes an interdisciplinary approach to economic and social questions and seeks creative operational answers to today's urgent problems. Highly qualified, young and dynamic Ph.D. holders or doctoral candidates are required. Salary open and depends on qualifications. Applicants should apply to: Dr. Clark C. Abt, President, Abt Associates, Inc., 55 Wheeler Street, Cambridge, Massachusetts 02138.

Dean: Dean of the College, spring, 1968. Community college in its tenth year needs replacement for retiring dean. Teaching experience at college level required. Administrative experience desired. Doctor's degree strongly preferred. The College has become the focal point of a nationally unique and significant health education complex. Communicate with: Dr. Moses S. Koch, President, Essex Community College, Baltimore, Maryland 21221. Area 3C1, Mu 6-1200.

Accounting: Two assistant or associate professorships in accounting. Rapidly expanding department located in state university in Greater Detroit Metropolitan Area. Ph.D. or D.B.A. with specialization in accounting theory. C.P.A. given special consideration. Salary \$11,000 and up. Summer teaching and consulting available. Contact: Dr. Emerson C. Erb, Jr., Head, Department of Accounting and Finance, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Finance: Assistant or associate professorship in finance and banking. Rapidly expanding department located in state university in Greater Detroit Metropolitan Area. Ph.D. or D.B.A. with specialization in capital structure, capital investment and financial theory of the firm. Salary \$11,000 and up. July, 1968. Summer teaching and consulting available. Contact: Dr. Emerson C. Erb, Jr., Head, Department of Accounting and Finance, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Business education: Instructor with ability to teach courses in office education. Must have master's degree. Man with plans for higher education preferred, but all applications are invited. Rank and salary open. July, 1968. Contact: Dr. Charles H. Duncan, Head, Department of Business Education, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Business economics: Associate professor to teach courses in managerial economics, business conditions, and related areas at the graduate level. Ph.D. or D.B.A. in economics and/or business administration. College teaching experience preferred. Salary \$11,000-\$13,000, depending on qualifications and experience. Additional stipend for teaching summer school. July, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Data processing: Assistant professor to teach undergraduate and graduate courses in data processing. Opportunity to teach at least one course in another area such as business statistics or introduction to business. Ph.D., D.E.A., or M.B.A. plus. Business experience in data processing required. Salary \$10,600-\$12,000, depending on qualifications and experience. Additional stipend for teaching summer school. July, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Insurance: Assistant or associate professor to teach undergraduate and graduate courses in insurance. Ph.D. or D.B.A. in insurance and related fields. College teaching and business experience in insurance desirable. Salary \$11,000-\$13,000, depending on qualifications and experience. Additional stipend for teaching summer school. July, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Introduction to business: Assistant professor to teach introductory course in business at freshman level. Ph.D., D.B.A., or M.B.A. plus in business administration, with college experience teaching introduction to business. Opportunity to teach at least one course in area of specialization at undergraduate or graduate level. Salary \$10,000-\$12,000, depending on qualifications and experience. Additional stipend for summer teaching. July, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Research and statistics: Associate professor to teach graduate courses in business research, qualitative analysis, and statistics, and undergraduate course in statistics. Ph.D. or D.B.A. in business administration with work in research and quantitative areas. Teaching experience at graduate level desirable. Salary \$11,000-\$13,000, depending on qualifications and experience. Additional stipend for teaching summer school. July, 1968. Contact: Dr. W. Oscar Collins, Head, Department of General Business, Eastern Michigan University, College of Business, Ypsilanti, Michigan 48197.

Management: Two assistant or associate professorships, one in industrial relations and one in management systems or production management, in rapidly expanding department. Greater Detroit Metropolitan Area. Salary \$11,000-plus for academic year. Summer teaching available. July, 1968. Contact: Dr. Claude I. Shell, Head, Department of Management, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Marketing: Assistant or associate professor. Teaching position in an expanding marketing department located in state university in the Greater Metropolitan Detroit Area. Ph.D. or D.B.A. in business or economics required. Training in behavioral sciences, international marketing and/or quantitative methods helpful. Undergraduate and graduate programs. Salary \$11,000 and up for academic year. July, 1968. Contact: Dr. Robert J. Williams, Head, Department of Marketing, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Labor economists and/or statisticians: The measurement of the economic damages suffered by those who are wrongly injured or killed is a new area for the application of economic and statistical knowledge and research techniques. This field has been pioneered successfully and Associated Appraiser of Earning Capacity is now providing this service to attorneys on a nationwide basis. Those in it appraise the losses and are required to testify as an expert in court trials and must withstand hostile cross-examination. It is one of the highest-paid forms of work in the profession and it is possible to engage in it as a part-time activity. Requirements: (1) minimum status of associate professor; (2) experience in research in collective bargaining agreements and fringe benefit programs; (3) location in or near a major metropolitan area. Openings now available in some 20 cities. Waiting list open in other areas. Send résumé and list of publications to: Philip Eden, President, Associated Appraisers of Earning Capacity, 1303 Walnut Street, Berkeley, California, 94709.

Labor economists and/or statisticians: A.S.E.A. is a nonprofit professional society of economist-statisticians who appraise (1) life-time economic losses of persons, suffered as a result of wrongful death or injury or violation of legal rights; (2) economic losses of businesses resulting from a wrongful act; and (3) the future income of property and the appraisal of income property by the capitalization of income method. Examinations are open to all persons with the following minimum qualifications: Ph.D. in economics, associate professorship in economics or statistics, experience in labor economics. The examination covers the application of economic and statistical techniques and the mathematics of finance to these areas

of appraisal. Passage of these examinations helps establish qualifications and competence to do this work in general consulting practice as well as in courts of law. For details, please write to: Dr. Norman H. Leonard, Chairman, Board of Examiners, American Society of Econometric Appraisers, 328 North Liberty Street, Delaware, Ohio, 43015.

Economics: Two new positions for 1968-69 in the areas of micro-macro theory and labor-industrial economics. One appointment will be available in June, 1968, for participation in revision of televised introductory course. Appointments will be made at any level. Ph.D. or near Ph.D. required. Minimum salary level AAUP-A. Address applications to: Dr. David A. Martin, Chairman, Economics Department, State University College, Geneseo, New York, 14454.

Senior economists: CONSAD Research Corporation has immediate positions available in Pittsburgh and New York City. The work is long range and involves participation in interdisciplinary systems research and planning, applying modern analytic methods to public and private sector problems. For a personal discussion about these opportunities, please send a complete résumé to: Dr. Wilbur A. Steger, CONSAD Research Corporation, Pittsburgh, Pennsylvania, 15213.

Economics, business administration: Teaching, with excellent research opportunities. International and development economics; public finance; production management; accounting; marketing. Salary and rank dependent on qualifications. Ph.D.'s strongly preferred. Apply with résumé to: Dean Leo M. Loll, University of Alaska, College, Alaska, 99701.

Marketing: Position available in September, 1968, for Ph.D., D.B.A., or candidates for the degree. Seek persons with a high degree of technical competence, dedicated to teaching and devoted to continuing professional activity and development. Position with flexible course assignments at the undergraduate and graduate level. Growing professionally accredited state college. For further details, write, enclosing vita, to: Dr. Frank L. Roberts, Chairman, Department of Marketing, California State College at Fullerton, Fullerton, California, 92631.

Economist (micro and macro), statisticians: A nonprofit economic research organization in Washington, D.C., is seeking several professional economists and statisticians to participate in a study of regional growth and regional planning. Economic studies will focus on labor force requirements and demographic characteristics of regional populations, on problems of industrial structure and location, on issues of public finance and fiscal policy, and on projecting economic activity. Salary is commensurate with education and experience. Write to: Dr. Sidney Sonenblum, National Planning Association, 1606 New Hampshire Avenue, N.W., Washington, D.C., 20009.

Economic statistics, operations analysis, management science and/or management systems: New Department of Management Sciences needs three additional Ph.D.'s February or September, 1968. Rank and salary commensurate with qualifications. TIAA, life, disability, and major medical insurance and other fringe benefits. Please send résumé to: Dr. Sam Barone, Chairman, Department of Management Sciences, St. Louis University, School of Commerce and Finance, 3674 Lindell Boulevard, St. Louis, Missouri, 63108.

Economists: Newberry College will have two permanent positions available in September, 1968. Prefer candidates with the Ph.D. in economics. Rank and salary competitive. Send vita and references to: Professor James R. Rinehart, Department of Economics and Business Administration, Newberry College, Newberry, South Carolina, 29108.

Management: Professor who is Ph.D. in economics or D.B.A. (or candidate for either degree) sought to teach in three-course sequence in the field of management in new master of business administration program: fall, 1968, advanced management theory; spring, 1969, quantitative aspects of management; fall, 1969, the legal environment of business. Other courses will be assigned at the graduate level or in extensive undergraduate majors in accounting, business administration, or economics, in accordance with the candidate's aptitudes and preferences. Nine-

months' salary up to \$15,000 for candidate with doctoral degree and teaching experience. Please send résumé to: W. P. Carton, Acting Chairman, Department of Accounting, Business Administration, and Economics, Loyola College, Baltimore, Maryland, 21210.

Finance: Professor who is Ph.D. in economics or D.B.A. (or candidate for either degree) sought to teach in three-course sequence in the field of finance in new master of business administration program: fall, 1968, financial management; spring, 1969, financial institutions; fall, 1969, investment analysis. Other courses will be assigned at the graduate level or in extensive undergraduate majors in accounting, business administration, or economics, in accordance with the candidate's aptitudes and preferences. Nine-months' salary up to \$15,000 for candidate with doctoral degree and teaching experience. Please send résumé to: W. P. Carton, Acting Chairman, Department of Accounting, Business Administration, and Economics, Loyola College, Baltimore, Maryland, 21210.

Marketing: Professor who is Ph.D. in economics or D.B.A. (or candidate for either degree) sought to teach a three-course sequence in the field of marketing in new master of business administration program: fall, 1968, marketing management; spring, 1969, marketing research; fall, 1969, sales and advertising policies. Other courses will be assigned at the graduate level or in extensive undergraduate majors in accounting, business administration, or economics, in accordance with the candidate's aptitudes and preferences. Nine-months' salary up to \$15,000 for candidate with doctoral degree and teaching experience. Please send résumé to: W. P. Carton, Acting Chairman, Department of Accounting, Business Administration, and Economics, Loyola College, Baltimore, Maryland, 21210.

Accounting methods: Professor who is Ph.D. in economics or D.B.A. (or candidate for either degree) sought to teach in three-course sequence in the field of accounting methods in new master of business administration program: fall, 1968, managerial accounting; spring, 1969, advanced accounting theory; fall, 1969, accounting systems. Other courses will be assigned at the graduate level or in extensive undergraduate majors in accounting, business administration, or economics, in accordance with the candidate's aptitudes and preferences. Nine-months' salary up to \$15,000 for candidate with doctoral degree and teaching experience. Please send résumé to: W. P. Carton, Acting Chairman, Department of Accounting, Business Administration, and Economics, Loyola College, Baltimore, Maryland, 21210.

Accounting and business administration: September, 1968. Professor with M.B.A. and C.P.A. sought to teach principles of accounting, intermediate accounting, corporation finance (in first semester) and money and banking (in second semester). Size of undergraduate department makes it possible, however, to shift teaching assignments to fit individual capabilities. Class sections are small, generally 20 to 30 students. Our salaries are competitive with anything which is available throughout the country. Please send résumé to: W. P. Carton, Acting Chairman, Department of Accounting, Business Administration, and Economics, Loyola College, Baltimore, Maryland, 21210.

Economists: Ph.D. Three positions. One or more of the following specialties: econometrics and quantitative methods, economic history, comparative economic systems, public finance, history of economic thought, and labor economics. State university. Rank of assistant or associate professor; salary range from \$11,000 to \$15,000; generous benefits; nine-hour teaching load. Send inquiries and a complete résumé to: Robert M. Biggs, Department of Economics, College of Arts and Sciences, University of Toledo, Toledo, Ohio, 43606.

Economics: Expanding Economics Department has vacancies for the academic year beginning September, 1968, in the following areas: principles of economics, economic history, labor economics, international trade, statistics, mathematical economics. Salary and rank according to qualifications and experience. Applicants must possess strong interest in research and economic scholarship and be competent in teaching. Applications should be sent to: Dr. G. O. Rothney, Dean of Arts, Lakehead University, Port Arthur, Ontario, Canada.

Economics: The University of Alaska offers funded research opportunities for economics graduate students from other universities. We solicit especially to degree candidates shopping for dissertation topics in regional economic development, resource economics (minerals, fisheries, forestry, etc.), demography, studies of subsistence economies, state and local finance, and the economics of investment in human beings. The University can provide office or laboratory space and exceptional technical support (secretarial, computer, etc.). Work with small but energetic interdisciplinary faculty. Minimum salary for senior research assistant with master's degree or equivalent is \$900 a month. Write to: Victor Fischer, Director, Institute of Social, Economic and Government Research, University of Alaska, College, Alaska, 99701.

Finance, management, marketing: One position available at a four-year midwestern liberal arts college. Ph.D. or D.B.A. or all courses completed for doctorate required. Opportunity to become head of department. Rank and salary open. Emeriti and others with Ph.D.'s approaching retirement may apply. Write to: Father Alcuin Hemmen, President, St. Benedict's College, Atchison, Kansas, 66002.

Finance, management, quantitative methods: Nonsectarian, coeducational, accredited institution located on new suburban campus near Princeton, New Jersey; teaching positions and department chairmanships open in expanding undergraduate and graduate programs; Ph.D. or D.B.A. required; teaching load 9 hours; salary and fringe benefits competitive; appointment effective September, 1968. Apply to: Dr. D. Dertouzos, Acting Dean, School of Business Administration, Rider College, Trenton, New Jersey, 08602.

Economics: Liberal arts, coeducational college has opening for September, 1968. Introductory and advanced undergraduate courses. Ph.D. preferred; master's required. Rank and salary dependent on training and experience. Write to: Dr. Richard M. Park, Dean of the College, Franklin College, Franklin, Indiana, 46131.

Economist: To chair department in an emerging university, 70 miles from Toronto, Ontario. The position offers the challenges and rewards of developing and administering an economics program in a new provincially-supported university with the opportunities of a two-course teaching load. Ph.D. or equivalent teaching and research experience and some administrative experience required. Rank and salary commensurate with qualifications. Full professor, minimum salary \$15,000, preferred. Applications close January 31, 1968. Appointment to take effect July 1, 1968. Please forward curriculum vita and the names of three referees to: Acting Dean of Arts and Science, Brock University, St. Catharines, Ontario, Canada.

Economics and finance: An expanded program in real estate and urban development at large eastern university has vacancies in economics of land use and real estate finance and valuation. Opportunity to participate in graduate programs of interdisciplinary nature. Rank and salary open P339

Economist: September, 1968. Ph.D. preferred or doctoral candidates. Rank and salary dependent on advanced degree, business and/or teaching experience. Principles and advanced courses to be selected from money and banking, public finance, growth and development, labor economics, business and government and international economics. Twelve-hour teaching assignment. Three classes per semester; three or four courses per year. Liberal fringe benefits, including TIAA. Millikin University is coeducational with an enrollment of 1,400. It is affiliated with the United Presbyterian Church (U.S.A.). The school offers undergraduate majors in economics, accounting, marketing, and industrial engineering. Opportunities for teaching at additional compensation are present in both Evening School and Summer Session. Please send résumé and names and addresses of three references to: Dean James R. G. Olson, School of Business and Industrial Management, Millikin University, Decatur, Illinois, 62522.

Economists: Ph.D. or near (instructor to department chairmanships) and salary according to education and experience. Appointments beginning September, 1968, and a few midyear appointments, to teach all areas of economics in liberal arts colleges and universities located mainly in the Midwest and East. P340

Economics: Head of department of economics located in the School of Business Administration at state university in Texas. Ph.D. in economics. Teaching excellence and research experience desired. Six-hour teaching load. Rank open. Please submit vita. P341

Accounting and marketing: Applications are requested for a one-year appointment, effective September 1, 1968, with the possibility of appointment for a second year (1969-70), to replace a Department member on a leave of absence. The teaching load of twelve hours each semester will consist of one section of principles of marketing and three sections of elementary accounting. Applicants with the master's degree and no experience will be considered for appointment at the rank of instructor. Further graduate work and experience may qualify an applicant for appointment at the rank of assistant professor. Write to: Dr. William F. Railing, Chairman, Department of Economics and Business Administration, Gettysburg College, Gettysburg, Pennsylvania, 17325.

Economist: Ph.D. completed by September, 1968. One position as assistant or associate professor available starting fall, 1968, to teach principles, business finance, money and banking, and/or upper division course. Salary up to \$10,000. Write to: Dean Emerson O. Henke, Hankamer School of Business, Baylor University, Waco, Texas, 76706.

Economists: There are vacancies for two young economists, starting September, 1968. One position would involve teaching undergraduate and graduate courses in quantitative analysis, econometrics and statistics. Second position ideally would be held by an economist management/marketing specialist, with strong background in behavioral sciences. Ph.D. degree preferred. Salary up to \$12,500 for nine months; opportunities for summer school teaching and for participating in research projects. Present enrollment at the University is about 4,000 students and is expected to double within the next five years. Write to: Dr. Andre Simmons, Chairman, Department of Economics, Nevada Southern University, Las Vegas, Nevada, 89109.

Economists, statisticians: The state of Hawaii is organizing a central analysis group to carry out a continuing management planning program. Opportunities will exist for economists, statisticians, program planning and budgeting, and related personnel both on continuing and short-term basis. For further details write, enclosing relevant background information, to: Director, Department of Planning and Economic Development, State of Hawaii, Honolulu, Hawaii, 96813.

Economics and department chairman: New department of two faculty with two additional for September, 1968; major offered in liberal arts program with graduate offerings in master's program in social studies. Ph.D. degree required; teaching interests in statistics and quantitative methods preferred. Send résumé to: Dean, Social Sciences Division, Millersville State College, Millersville, Pennsylvania, 17751.

Economics: Southwestern state university invites applications for senior position (professor or associate professor) in areas of macro, natural resources, Latin-American economics. Applicants must have Ph.D. and a strong publication record as well as substantial experience in a Ph.D. program. Candidate for macro position should be able to cover occasionally in public finance. P342

Management: New programs leading to bachelor's and master's degrees in engineering management require professors. Ph.D. with experience preferred, but doctoral candidates and those with master's degrees will be considered. Areas of interest include finance, economics, marketing, production, quantitative methods and human relations. Excellent opportunities for growth exist. Salary range is \$9,500 to \$13,500 for nine months. Write to: B. R. Sarchet, Professor in Charge, Management, University of Missouri at Rolla, Rolla, Missouri, 65401.

Economists: Office of International Operations, Internal Revenue Service, has unique and intellectually challenging career opportunities for economists in Washington, D.C. Nature of work is primarily concerned with applying economic analysis to intercorporate activities between related corporations to ascertain whether they re-

flect competitive arm's length standards. Basic function is to examine and analyze transactions involving goods and services flowing between related corporations to determine whether the intercorporate transfer prices meet the arm's length standard. Conclusions are then drawn as to whether the corporation has clearly reflected its true taxable income. These economic analyses cover the entire spectrum of business activity and will have an important bearing on the development of tax law guidelines and precedents involving intercorporate pricing in the expanding area of international commerce. Positions are available at entrance salaries ranging from \$10,000 to \$15,000. Position and starting salary will depend upon educational background and professional experience. A representative will be available for interviewing applicants at the American Economic Association meeting in the Sheraton-Park Hotel in Washington, D.C., December 26-30. For further details, write to: Director of International Operations, Attention, Chief, Economic Advisory Branch, Internal Revenue Service, Washington, D.C., 20225.

Economists: With continued growth of the Department of Economics, California State Polytechnic College will have at least two positions open in September, 1968, at the assistant professor level. Immediate needs are for instructors interested in teaching the basic principles courses and in the business and government and public policy areas at the undergraduate level. Ph.D. preferred, but not mandatory. Especially interested in young graduate students completing degree requirements or economists with or without degree but with experience in quantitative economic analysis. For further information, write to: George Galbreath, Head, Department of Economics, California State Polytechnic College, Pomona, California, 91766.

Economics: Robert College, a private, coeducational, American-operated college offering Turkish students B.A. and M.A. programs in English has associate and assistant professorships available starting September, 1968, in economics, economic history, statistics and econometrics, business organization and administration, accounting and finance. Challenging career with interesting research possibilities. Salary \$8,000-\$10,000 per annum according to experience and qualifications. Housing allowance, health and accident insurance plans, tax benefits, travel paid. To apply send résumé before December 31, 1967, to: Recruitment Secretary, Robert College, Office of the Trustees, 548 Fifth Avenue, New York, New York, 10036.

Economics, finance: Assistant professor to professor ranks, salary range of \$9,000 to \$15,000, depending on qualifications. Considerable flexibility of assignments is possible in an expanding department offering economics and finance courses. Write to: Paul E. Fenlon, Department of Economics, University of Texas at El Paso, El Paso, Texas, 79999.

Economists: September, 1968 (also January, 1968); Ph.D. preferred. Teaching positions open in the areas of micro economic theory, macro economic theory, public finance, comparative economic systems, business cycles, statistics, and principles. Rank and salary appropriate to education and teaching experience. Write to: Dr. Marvin R. Cain, Chairman, Department of Social Science, University of Missouri at Rolla, Rolla, Missouri, 65401.

Economists: Indiana University of Pennsylvania, the state's newest university and third largest in undergraduate enrollment, has permanent position openings for the fall of 1968 for two economists, one with strength in general theory and international economics and one in general theory and public finance, also preferably business fluctuations. Each must also teach at least one section of principles regularly. Twelve-hour teaching load maximum, controlled class size. Rank of instructor, assistant or associate professor available dependent upon qualifications. Ph.D. or near-Ph.D. in economics required. Teaching excellence emphasized, research encouraged, professional growth prospects most favorable. Salary range for nine months: instructor, \$6,580-\$8,820; assistant professor, \$7,610-\$10,200; associate professor, \$9,260-\$12,400. Summer supplement normally available on prorated salary basis. Excellent fringe benefits. Write to: Dr. Francis G. McGovern, Chairman, Department of Economics, Indiana University of Pennsylvania, Indiana, Pennsylvania, 15701.

Director of graduate studies in business administration: College of Business at Northern Illinois University will employ a person with experience in directing

doctoral studies to assume responsibilities for developing the graduate program in business. M.B.A. and M.S. degrees now offered by graduate business faculty of 43 members. Additional degrees planned. Write to: Dean Robert L. Thistlethwaite, College of Business, Northern Illinois University, De Kalb, Illinois, 60115.

Mathematician: The College of Business at Northern Illinois University will employ a person with advanced academic preparation in mathematics. Qualifications: Ph.D., minimum of one graduate degree in mathematics; experience or academic degree in business or economics. Write to: Dean Robert L. Thistlethwaite, College of Business, Northern Illinois University, De Kalb, Illinois, 60115.

Economists, statisticians: The Bureau of Labor Statistics expects to have openings at all levels, GS-5 (\$5,331 a year) through GS-15 (\$17,550). Work consists of analysis and research, not only in labor statistics such as employment, unemployment, wages, fringe benefits, industrial disputes, etc., but also retail and wholesale prices, productivity, technological change, labor costs, economic growth and input-output relationships. All positions are within the federal Civil Service System. Need especially great for new Ph.D.'s and those with research or consultation experience past the doctorate. Send application to: Mr. William T. McGuigan, Personnel Officer, U.S. Department of Labor, Bureau of Labor Statistics, Room 2415, GAO Building, 441 G Street, N.W., Washington, D.C., 20212.

Transportation economists: Permanent positions in Columbus, Ohio. Salary range \$12,000-\$18,000. Senior level responsibilities include project leadership in areas of demand analysis, management problems, urban transportation planning, analysis of physical distribution requirements, and economics of transportation alternatives. Ph.D. degree preferred with research experience. Junior level of applicants should have technical bachelor's, plus master's degrees, in economics or business. Experience desirable but not necessary. Write to: Donald D. Renwick, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio, 43201.

Industrial economists: Permanent positions in Columbus, Ohio. Salary range \$12,000-\$20,000. Responsibilities include performance of economic studies related to the many problems of concern to industrial top management. Technological forecasting, market analysis, strategy planning, and operating planning and examples. Business abilities, background in science and engineering, and quantitative techniques would be used to interpret findings clearly to management in such current areas as: agriculture, chemicals, construction, electronics, foods, fuels, graphics, health, energy, packaging, paper, manufacturing, metals, minerals, transportation, and water resources. Master's or Ph.D. degree in economics, business or industrial administration, plus technical bachelor's degree in appropriate areas are desirable, with extensive training in quantitative analysis. Project leadership responsibilities to be expected as capability is demonstrated. Write to: Donald D. Renwick, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio, 43201.

Urban economist: Permanent position in Columbus, Ohio. Salary range \$15,000-\$18,000. Responsibilities include performance of research studies emphasizing the interrelationships of economic, political, and physical problems in the urban environment. Current areas include economic development, public health and education, transportation, air and water pollution, noise abatement, and housing. Project leadership responsibilities to be expected as capability is demonstrated. Ph.D. degree is preferred with cross-discipline background including economics, city planning, sociology, and political science. Ideally, five years of experience including project leadership is preferred. More extensive experience could substitute for Ph.D. degree. Write to: Donald D. Renwick, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio, 43201.

Service industry economists: Permanent positions in Columbus, Ohio. Salary range \$12,000-\$18,000. Responsibilities focus on economic research in such service industries as wholesale and retail trade, finance and banking, insurance, real estate, or agencies and associations serving them. Master's or Ph.D. degrees are preferred with some practical experience in one or more of the industries indicated. Training in quantitative analysis is desirable. Project leadership responsibilities to be expected as capability is demonstrated. Write to: Donald D. Renwick, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio, 43201.

International development economists: Permanent positions in Columbus, Ohio, with possible travel in all countries. Salary range \$13,000-\$20,000. Responsibilities focus on international economic research. General knowledge of regional economics, project planning, industrial processes or infrastructure development is desirable. Project leadership responsibilities to be expected as capability is demonstrated. Master's or Ph.D. degrees are preferred. A cross-discipline background is desirable, including economics, sociology, political science, and technical fields, with emphasis on quantitative analysis. A foreign language capability would be helpful and overseas experience is preferred. Write to: Donald D. Renwick, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio, 43201.

Quantitative economist: Permanent position in Washington, D.C., salary range \$20,000-\$24,000. Responsibilities include project leadership in quantitative cost-benefit studies of government programs in a program-budgeting context. This will include development and application of mathematical models to forecast needs, evaluate alternative programs, and allocate resources. Areas of current research include natural resources, transportation, health, military, and poverty. A Ph.D. degree in economics, emphasizing training in quantitative analysis, is desirable. Experience or training in other social sciences is an asset. Write to: Donald D. Renwick, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio, 43201.

Economics: Fall term, 1968. Ph.D. preferred; doctoral candidates with master's degree will be considered. Teaching fields to include managerial economics, finance, theory and management, senior and graduate levels; micro and macro theory at undergraduate and graduate levels and supervision of independent study at all levels. Rank and salary commensurate with background and experience. TIAA, life insurance, major medical, other fringe benefits. Please send résumé to: Dr. Donald W. Hill, Dean of the College, Rollins College, Winter Park, Florida, 32789.

Economics and business: Sizable new university, favorably located in the Vancouver metropolitan area, invites applications at all rank levels. Department has substantial M.A. and Ph.D. programs in economics in operation; graduate program in business administration imminent. Applicants must possess doctorate (near-doctorate for instructor rank). Additional specialists sought in accounting, economic development, economic history, economic theory, educational economics, finance, international business, international economics, production, organization, quantitative methods and regional economics. For some (but not all) of the senior positions administrative capabilities will be an asset. Write to: Dr. Parzival Copes, Head, Department of Economics and Commerce, Simon Fraser University, Burnaby 2, British Columbia, Canada.

Economists: Saint Mary's University will have three faculty openings available commencing with the academic year 1968-69. All three positions provide for teaching assignments at the undergraduate level. An honors program is expected to be added soon. Ph.D.'s are preferred; others may apply. One of the appointees will be invited to act as chairman of the Economics Department, having a reduced teaching load. Specialization in any area qualifies for application. Preference will be given to applicants showing a strong background in economic theory. Salary and rank depend on qualifications and experience. Contact: Dean H. G. Beazley, Commerce Faculty, Saint Mary's University, Halifax, Nova Scotia, Canada.

Economists: September, 1968. Two positions in economics. Eight-hour teaching load. The courses would be chosen from such fields as economic principles and theory, money and banking, labor economics, income and employment theory, public finance, economic cycles, mathematical analysis, economic systems. The person filling the first position would get first choice of courses. Appointment at the instructor level for a person without the doctorate, and at the assistant professor level for one with the Ph.D. Salary depends upon experience, qualifications and rank. Although an integral part of the University of Minnesota, the University of Minnesota, Morris, is a small, relatively new liberal arts college. It is located 150 miles west of the Minneapolis Campus in a rural area and has a student enrollment of 1,000. Write to: O. T. Driggs, Cochairman, Division of the Social Sciences, University of Minnesota, Morris, Morris, Minnesota, 56267.

Economist: For fall, 1968. Assistant professor. Ph.D. necessary; some teaching experience highly desirable. Normal teaching load nine hours. To teach undergraduate courses primarily in macroeconomics, public finance, and money and banking at a

senior college branch of the University of Michigan located in a suburb of Detroit thirty miles from Ann Arbor. Salary dependent on qualifications and experience. Please send résumé to: Dr. A. J. Obelsky, Department of Economics, University of Michigan Dearborn Campus, Dearborn, Michigan, 48128.

Economists: The Department of Economics, University of Calgary, will have openings for additional staff members at the assistant, associate and professional ranks for the academic year 1968-69. Requirements are a Ph.D., dedication to teaching and a strong interest in research. Salaries range from \$9,000 (minimum for assistant) to \$16,600 (minimum for full professor). Areas of specialization are open but qualifications in urban development would be an advantage. Send detailed résumé to: Dr. F. R. Anton, Head, Department of Economics, University of Calgary, Calgary, Alberta, Canada.

Economists: Rapidly growing state university (18,000 students) with 18-man Economics Department has three new permanent positions to staff with energetic individuals interested in both research and teaching. Positions can be filled at any rank and in a number of specialty fields; e.g., labor, industrial organization, and macro. All positions require Ph.D. in economics. Senior positions require a record of published research as well as interest in working with M.A. and Ph.D. oriented graduate students. Nine-month salary range \$10,000 to over \$18,000. Summer employment, when available, pays an additional two month's salary. Send résumé and references to: Jack W. Skeels, Department of Economics, Northern Illinois University, De Kalb, Illinois, 60115.

Economists: September, 1968. Appointments effective July 1, 1968. Ph.D. required. Two vacancies in the areas of micro- and macroeconomic theory, public finance, money and banking and international trade. One vacancy personnel administration and administrative theory. Atkinson College offers degree programs in the evenings. Rank and salary appropriate to qualifications and experience. Write to: Dr. G. E. Eaton, Chairman of Economics, Atkinson College, York University, 4700 Keele Street, Downsview, Toronto, Ontario, Canada.

Economists: The expanding contract research program of the Dikewood Corporation has created openings at various professional levels for researchers with a graduate degree. Knowledge of computer programming is desirable. Opportunities exist in mathematical economics, medical economics, cost-benefit analysis, regional and international development, transportation research, cost analysis, operations research, program-planning-budget analysis to work individually or as project leader. Most study projects involve multidisciplinary efforts and thus provide the chance to broaden one's perspective and experience in other academic fields. Studies are performed for military aero space, commercial, and governmental, nondefense customers. Dikewood Corporation is an organization of consulting scientists formed ten years ago in order to provide services in the fields of systems analysis, applied research, computer sciences, stock market investment advisory service, and mutual fund management. Please contact: Robert M. Carlisle, Dikewood Corporation, University Research Park, 1009 Bradbury Drive, S.E., Albuquerque, New Mexico, 87106.

Economists, junior and senior levels: Major New York City financial institution needs economists at junior and senior level. Emphasis will be in areas of (1) macroeconomic analysis and forecasting, (2) financial and money market analysis, and (3) industry and regional projections. Econometric models will be used in all areas. Original research encouraged. Training in statistics and econometrics necessary. Junior level: minimum M.A. or equivalent; senior level: Ph.D. or equivalent. Salary commensurate with training and experience plus excellent fringe benefits. Write to: Mr. Kenneth E. MacRae Personnel Officer, Bank of New York, 20 Broad Street, New York, New York.

Economist: September, 1968. Ph.D. preferred. Doctoral candidates and those with master's degree will be considered. Rank and salary depend on qualifications; liberal fringe benefits. Three classes per semester; three or four courses per year. Twelve-hour teaching assignment. Principles of economics, money and banking, public finance, economic development, and basic course in econometrics or mathematical economics. Marietta College is coeducational with an enrollment of 1,800.

The Department of Economics and Business Administration has the largest departmental enrollment and is expanding. The College is situated in a scenic town of 20,000 on the Ohio River. College representatives will be at the A.E.A.'s December meetings in Washington, D.C., to meet candidates. Please send résumé and names and addresses of three references to: Chairman, Department of Economics and Business Administration, Marietta College, Marietta, Ohio 45750.

Economists: Micro or macro. Two openings for September, 1968. Ph.D. or dissertation stage. Salary for associate \$9,875-\$12,389; assistant \$8,124-\$10,560. Appointment level depends on experience and qualifications. Assistant must have had four years of teaching experience and associate must have had six years of teaching experience. Teach principles and advanced course at college of about 4,000 enrollment where emphasis is on good teaching. College expanding toward liberal arts and business administration programs. State college on eastern seaboard convenient to Philadelphia and New York City. P343

**RONALD J.
WONNACOTT and
PAUL WONNACOTT**

FREE TRADE BETWEEN THE UNITED STATES AND CANADA

The Potential Economic Effects

The first major attempt to estimate what would happen in Canada if all trade restrictions between that country and the U. S. were removed. The authors' findings indicate that Canadian industries would benefit substantially provided they reorganize for the large North American market. *Harvard Economic Studies*, 129. \$9.00

**GUSTAV F.
PAPANEK**

PAKISTAN'S DEVELOPMENT

Social Goals and Private Incentives

This book, the first thorough analysis of Pakistan's remarkable economic development in the 1950's and '60's, shows how that nation successfully blended private initiative and government intervention in its economy, and sheds light on economic problems facing other developing nations. *Center for International Affairs*. \$8.95

**ARTHUR M.
JOHNSON**

PETROLEUM PIPELINES AND PUBLIC POLICY, 1906-1959

Tracing the evolution of the pipeline sector of the oil industry from the year federal regulation was imposed down to recent times, Mr. Johnson analyzes the impact of public policy on this sector and evaluates the charges of anti-competitive behavior brought against pipeline management over the years. *Harvard Studies in Business History*, 24. \$15.00.

**NICHOLAS
GEORGESCU-
ROEGEN**

ANALYTICAL ECONOMICS

Issues and Problems

"Careful, perceptive, and eloquent.... The author's ability to bring forth revealing thoughts from past literature in many fields while always taking a fresh critical look at the central issue under consideration is a rare gift."—*American Economic Review*. Second printing. \$12.95.
